Surgical Anatomy. The cervical part of the internal carotid is very rarely wounded. Mr. Cripps, in an interesting paper in the *Medico-Chirurgical Transactions*, compares the rareness of a wound of the internal carotid with one of the external carotid or its branches. It is, however, sometimes injured by a *stab or gunshot wound in the neck*, or even occasionally by a *stab from within the mouth*, as when a person receives a thrust from the end of a parasol or falls down with a tobacco-pipe in his mouth. It used to be believed that the internal carotid was occasionally wounded in the removal of the tonsil. Such an accident cannot happen if the artery is normally placed. The severe and sometimes fatal hemorrhage which has followed this operation in a few instances probably had as its source enlarged branches of the ascending pharyngeal, tonsillar, or ascending palatine arteries. Recently, however, Dr. Gwilym G. Davis, of Philadelphia, demonstrated a specimen in which the internal carotid could have been wounded by incision of the tonsil. The indications for ligature are *wounds*, when the vessel should be exposed by a careful dissection and tied above and below the bleeding point; and *aneurism*, which if non-traumatic may be treated by ligature of the common carotid, but if traumatic in origin by exposing the sac and tying the vessel above and below. The incision for ligature of the cervical portion of the internal carotid should be made along the anterior border of the Sterno-mastoid, from the angle of the jaw to the upper border of the thyroid cartilage. The superficial structures being divided and the Sterno-mastoid defined and drawn outward, the cellular tissue must be carefully separated and the posterior belly of the Digastric muscle and the hypoglossal nerve sought for as guides to the vessel. When the artery is found the external carotid should be drawn inward and the Digastric muscles upward, and the aneurism needle passed from without inward.

Branches.—The branches given off from the internal carotid artery are—

From the Petrous portion . .	Tympanic (internal or deep).
From the Cavernous portion . .	Arteriæ Receptaculi. Anterior Meningeal. Ophthalmic.
From the Cerebral portion . .	Anterior Cerebral. Middle Cerebral. Posterior Communicating. Anterior Choroid.

The cervical portion of the internal carotid gives off no branches.

The **Tympanic** (*ramus caroticotympanicus*) is a small branch from the petrous portion, which enters the cavity of the tympanum through a minute foramen in the carotid canal, and anastomoses with the tympanic branch of the internal maxillary, and with the stylo-mastoid artery.

The **Arteriæ Receptaculi** are numerous small vessels, derived from the internal carotid in the cavernous sinus; they supply the pituitary body, the Gasserian ganglion, and the walls of the cavernous and inferior petrosal sinuses. Some of these branches anastomose with branches of the middle meningeal.

The **Anterior Meningeal** (*a. meningea anterior*) is a small branch which passes over the lesser wing of the sphenoid to supply the dura mater of the anterior fossa; it anastomoses with the meningeal branch from the posterior ethmoidal artery.

The **Ophthalmic Artery** (*a. ophthalmica*) *arises* from the internal carotid, just as that vessel is emerging from the cavernous sinus, on the inner side of the anterior clinoid process, and enters the orbit through the optic foramen, below and

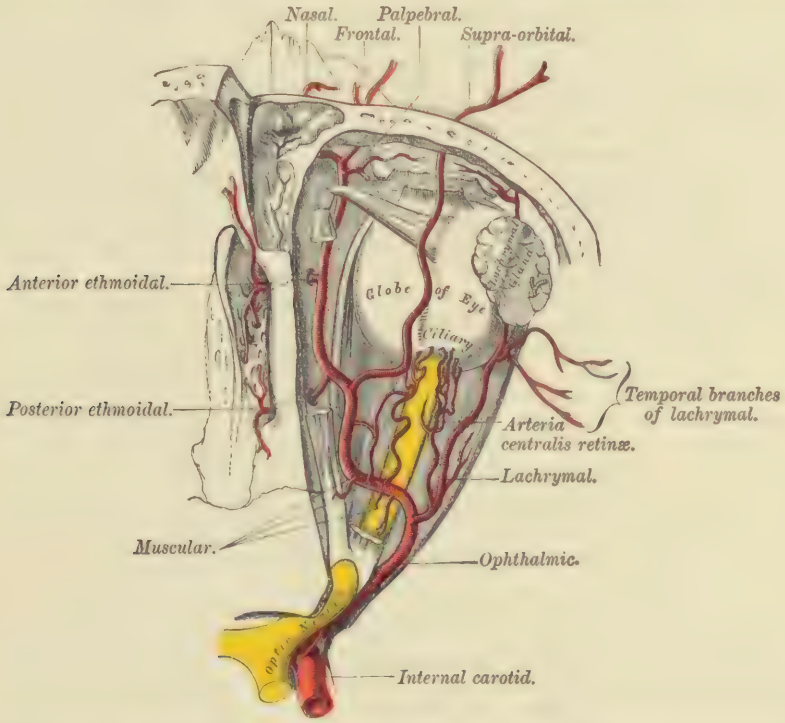

FIG. 400.—The ophthalmic artery and its branches, the roof of the orbit having been removed.

on the outer side of the optic nerve. It then passes over the nerve to the inner wall of the orbit, and thence horizontally forward, beneath the lower border of the Superior oblique muscle, to a point behind the internal angular process of the frontal bone, where it divides into two terminal branches, the **frontal** and **nasal branches.** As the artery crosses the optic nerve it is accompanied by the nasal nerve, and is separated from the frontal nerve by the Rectus superior and Levator palpebræ superioris muscles.

Branches.—The branches of this vessel may be divided into an **orbital group,** which are distributed to the orbit and surrounding parts, and an **ocular group,** which supply the muscles and globe of the eye:

Orbital Group.	*Ocular Group.*
Lachrymal.	Short Ciliary.
Supraorbital.	Long Ciliary.
Posterior Ethmoidal.	Anterior Ciliary.
Anterior Ethmoidal.	Arteria Centralis Retinæ.
Internal Palpebral.	Muscular.
Frontal.	
Nasal.	

The **Lachrymal** (*a. lachrimalis*) is one of the largest branches derived from the ophthalmic, arising close to the optic foramen; not infrequently it is given off from the ophthalmic artery before it enters the orbit. It accompanies the lachrymal nerve along the upper border of the External rectus muscle, and is distributed to the lachrymal gland. Its terminal branches, escaping from the gland, are distributed to the eyelids and conjunctiva: of those supplying the eyelids, two are of considerable size and are named the **external palpebral**; they run inward in the upper and lower lids respectively, and anastomose with the *internal palpebral arteries*, forming an arterial circle in this situation. The lachrymal artery gives off one or two **malar branches**, one of which passes through a foramen in the malar bone, to reach the temporal fossa, and anastomoses with the deep temporal arteries; the other appears on the cheek through the malar foramen, and anastomoses with the transverse facial. A branch, the **recurrent**, is also sent backward through the sphenoidal fissure to the dura mater, which anastomoses with a branch of the middle meningeal artery.

Peculiarities.—The lachrymal artery is sometimes derived from one of the anterior branches of the middle meningeal artery.

The **Supraorbital Artery** (*a. supraorbitalis*) *arises* from the ophthalmic as that vessel is crossing over the optic nerve. Ascending so as to arise above all the muscles of the orbit, it passes forward, with the supraorbital nerve, between the periosteum and Levator palpebræ muscle; and, passing through the supraorbital foramen, divides into a superficial and deep branch, which supply the integument, the muscles, and the pericranium of the forehead, anastomosing with the frontal, the anterior branch of the temporal, and the supraorbital artery of the opposite side. This artery in the orbit supplies the Superior rectus and the Levator palpebræ muscles, and sends a branch inward, across the pulley of the Superior oblique muscle, to supply the parts at the inner canthus. At the supraorbital foramen it frequently transmits a branch to the diploë.

The **Ethmoidal Branches** are two in number—**posterior** (*a. ethmoidalis posterior*) and **anterior** (*a. ethmoidalis anterior*). The former, which is the smaller, passes through the posterior ethmoidal foramen, supplies the posterior ethmoidal cells, and, entering the cranium, gives off a meningeal branch, which supplies the adjacent dura mater, and nasal branches which descend into the nose through apertures in the cribriform plate, anastomosing with branches of the spheno-palatine. The anterior ethmoidal artery accompanies the nasal nerve through the anterior ethmoidal foramen, supplies the anterior ethmoidal cells and frontal sinuses, and, entering the cranium, gives off a meningeal branch, which supplies the adjacent dura mater and nasal branches, which descend into the nose, through the slit by the side of the crista galli, and, running along the groove on the under surface of the nasal bone, supply the skin of the nose.

The **Internal Palpebral Arteries** (*aa. palpebrales mediales*), two in number, **superior** and **inferior**, *arise* from the ophthalmic, opposite the pulley of the Superior oblique muscle; they leave the orbit to encircle the eyelids near their free margin, forming a **superior tarsal arch** (*arcus tarseus superior*) and an **inferior tarsal arch** (*arcus tarseus inferior*), which lie between the Orbicularis muscle and the tarsal plates;

the superior palpebral inosculating at the outer angle of the orbit with the orbital branch of the temporal artery, and with the upper of the two external palpebral branches from the lachrymal artery—the inferior palpebral inosculating, at the outer angle of the orbit, with the lower of the two external palpebral branches

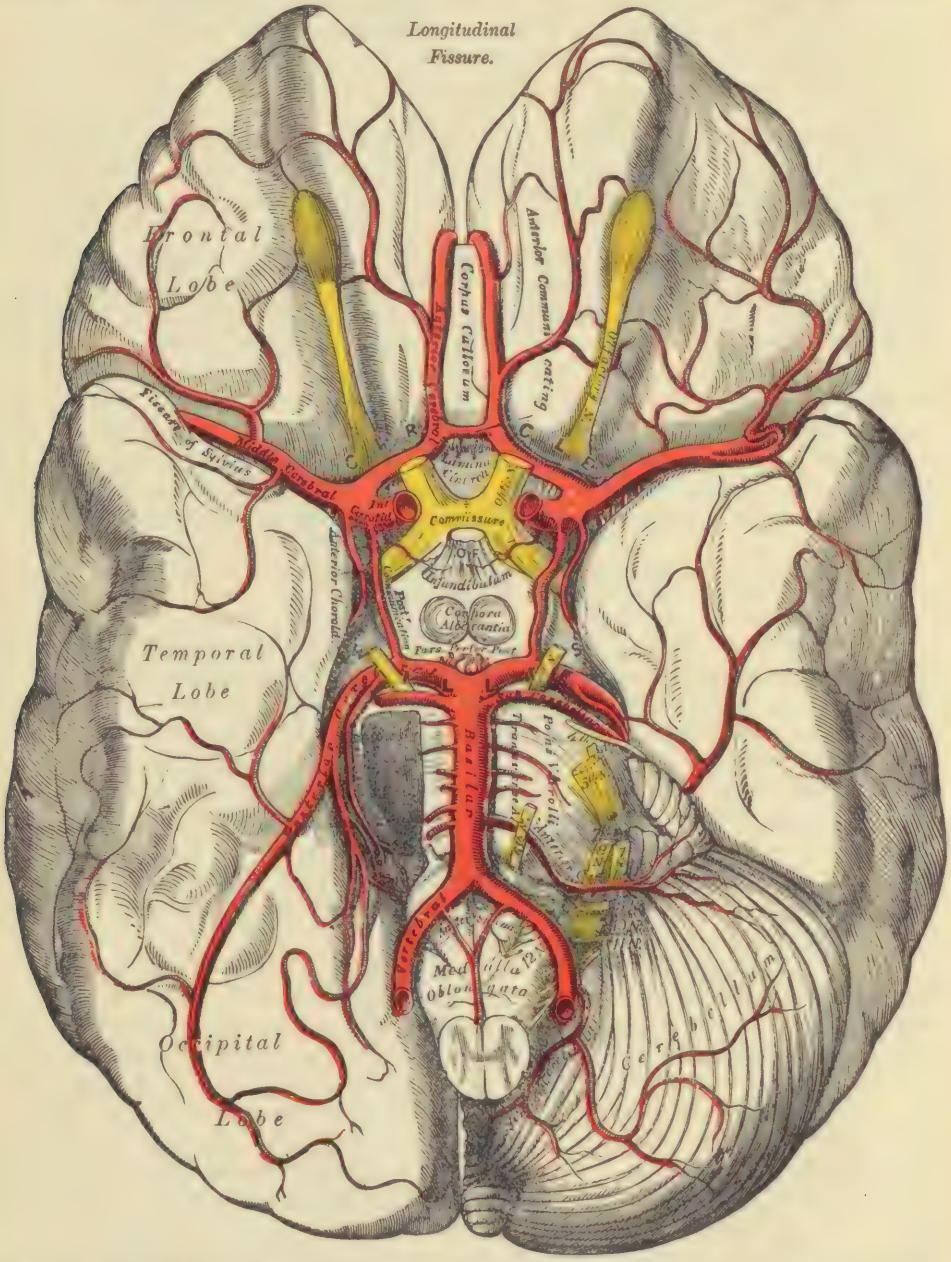

FIG. 401.—The arteries of the base of the brain. The right half of the cerebellum and pons have been removed. N. B.—It will be noticed that the two anterior cerebral arteries have been drawn at a considerable distance from each other: this makes the anterior communicating artery appear very much longer than it really is.

from the lachrymal and with the transverse facial artery, and at the inner side of the lid with a branch from the angular artery. From this last anastomosis a branch passes to the nasal duct, ramifying in its mucous membrane, as far as the inferior meatus.

The **Frontal Artery** (*a. frontalis*), one of the terminal branches of the ophthalmic, passes from the orbit at its inner angle, and, ascending on the forehead, supplies the integument, muscles, and pericranium, anastomosing with the supraorbital artery and with the frontal artery of the opposite side.

The **Nasal Artery** (*a. dorsalis nasi*), the other terminal branch of the ophthalmic, emerges from the orbit above the tendo oculi, and, after giving a branch to the upper part of the lachrymal sac, divides into two branches, one of which crosses the root of the nose, the **transverse nasal**, and anastomoses with the angular artery; the other, the **dorsalis nasi**, runs along the dorsum of the nose, supplies its outer surface, and anastomoses with the artery of the opposite side and with the lateral nasal branch of the facial.

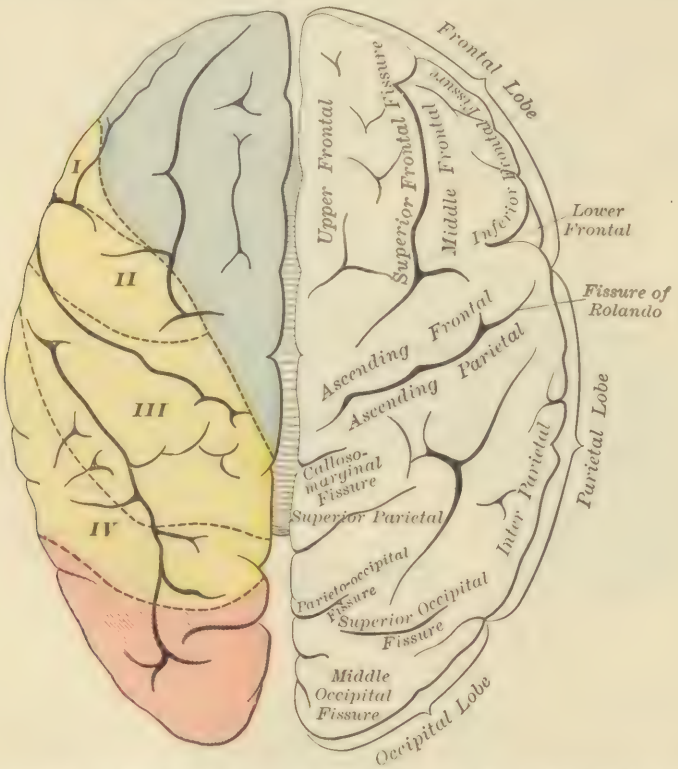

FIG. 402.—Vascular area of the upper surface of the cerebrum. I. The part supplied by the external and inferior frontal artery. II. The part supplied by the ascending frontal. III. The part supplied by the ascending parietal. IV. The part supplied by the parieto-sphenoidal artery. (After Duret.)

The **Ciliary Arteries** (*a. ciliares*) are divisible into three groups, the **short, long,** and **anterior.** The **short ciliary arteries** (*aa. ciliaris posteriores breves*), from six to twelve in number, *arise* from the ophthalmic or some of its branches; they surround the optic nerve as they pass forward to the posterior part of the eyeball, pierce the sclerotic coat around the entrance of the nerve, and supply the choroid coat and ciliary processes. The **long ciliary arteries** (*aa. ciliares posteriores longæ*), two in number, pierce the posterior part of the sclerotic at some little distance from the optic nerve, and run forward, along each side of the eyeball, between the sclerotic and choroid, to the ciliary muscle, where they divide into two branches; these form an arterial circle, the **circulus major**, around the circumference of the iris, from which numerous radiating branches pass forward, in its substance, to its free margin, where they form a second arterial circle, the **circulus minor**, around its pupillary margin. The **anterior ciliary arteries** (*aa. ciliares anteriores*) are

derived from the muscular branches; they pass to the front of the eyeball in company with the tendons of the Recti muscles, form a vascular zone beneath the conjunctiva, and then pierces the sclerotic a short distance from the cornea and terminate in the circulus major of the iris.

The **Arteria Centralis Retinæ** is the first and one of the smallest branches of the ophthalmic artery. It runs for a short distance within the dural sheath of the optic nerve, but about half an inch behind the eyeball it pierces the optic nerve obliquely, and runs forward in the centre of its substance, and enters the globe of the eye through the porus opticus. Its mode of distribution will be described in the account of the anatomy of the eye.

The **Muscular Branches** (*rami musculares*), two in number, **superior** and **inferior**, frequently spring from a common trunk. The **superior**, the smaller, often wanting, supplies the Levator palpebræ, Superior rectus, and Superior oblique. The **inferior**, more constant in its existence, passes forward, between the optic nerve and the Inferior rectus muscle, and is distributed to the External, Internal, and Inferior recti, and Inferior oblique. This vessel gives off most of the anterior ciliary arteries. Additional muscular branches are given off from the lachrymal and supraorbital arteries or from the ophthalmic itself.

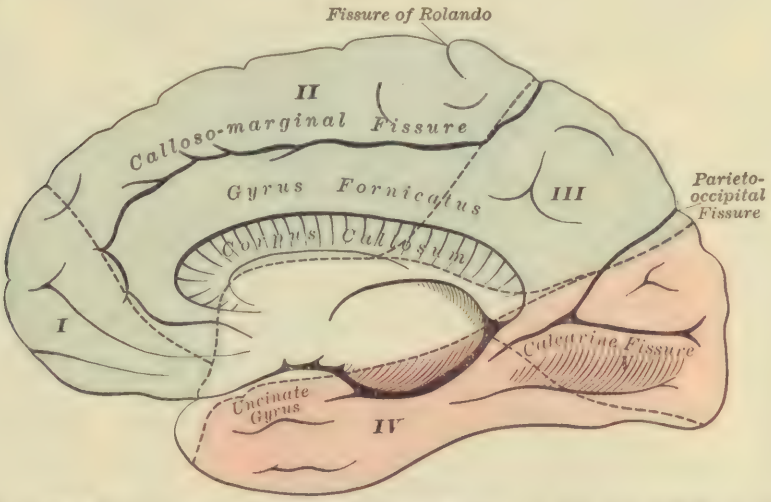

FIG. 403.—Vascular area of the internal surface of the cerebrum. I. The part supplied by the anterior internal frontal. II. The part supplied by the middle internal frontal. III. The part supplied by the posterior internal frontal. IV. The part supplied by the posterior temporal. V. The part supplied by the occipital, both terminal branches of the posterior cerebral. (After Duret.)

The **Anterior Cerebral** (*a. cerebri anterior*) *arises* from the internal carotid at the inner extremity of the fissure of Sylvius. It passes forward and inward across the anterior perforated space, above the optic nerve, to the commencement of the great longitudinal fissure. Here it comes into close relationship with the anterior cerebral artery of the opposite side, and the two vessels are connected together by a short anastomosing trunk, about two lines in length, the **anterior communicating artery**. From this point the two vessels run side by side in the longitudinal fissure, curve round the genu of the corpus callosum, and, turning backward, continue along its upper surface to its posterior part, where they terminate by anastomosing with the posterior cerebral arteries.

Branches.—In their course the anterior cerebral arteries give off the following branches:

Antero-median ganglionic. Anterior internal frontal.
Inferior internal frontal. Middle internal frontal.
Posterior internal frontal.

The **Antero-median Ganglionic** is a group of small arteries which *arise* at the commencement of the anterior cerebral artery; they pierce the anterior perforated space and lamina cinerea, and supply the head of the caudate nucleus.

The **Inferior Internal Frontal Branches** or the **Internal Orbital Arteries,** two or three in number, are distributed to the orbital surface of the frontal lobe, where they supply the olfactory lobe, gyrus rectus, and internal orbital convolution.

The **Anterior Internal Frontal** supplies a part of the marginal convolution, and sends branches over the edge of the hemisphere to the superior and middle frontal convolutions and upper part of the ascending frontal convolution.

The **Middle Internal Frontal** supplies the corpus callosum, the convolution of the corpus callosum, the inner surface of the first frontal convolution, and the upper part of the ascending frontal convolution.

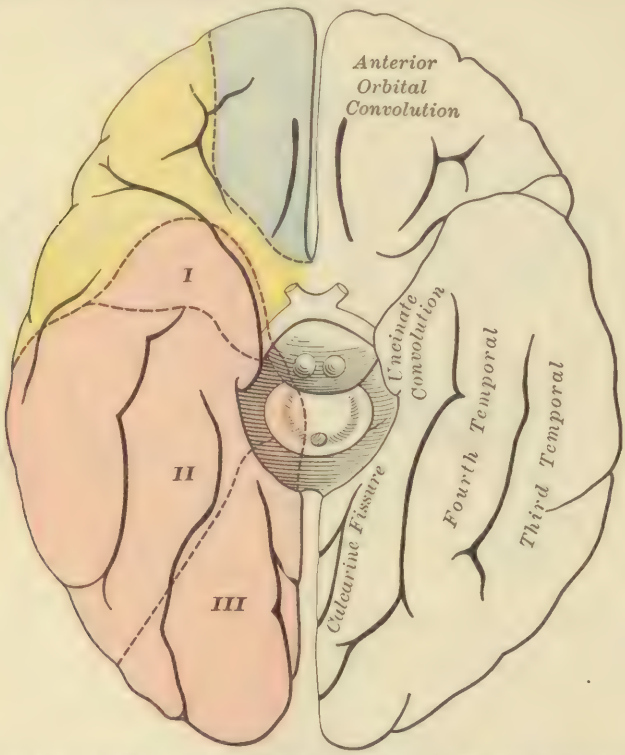

FIG. 404.—Vascular area of the inferior surface of the cerebrum. I. The part supplied by the anterior temporal from the posterior cerebral artery. II. The part supplied by the posterior temporal from the posterior cerebral artery. III. The part supplied by the occipital from the posterior cerebral artery. (After Duret.)

The **Posterior Internal Frontal** supplies the lobus quadratus and adjacent outer surface of the hemisphere.

The **Anterior Communicating Artery** (*a. communicans anterior*) is a short branch, about two lines in length, but of moderate diameter, connecting together the two anterior cerebral arteries across the longitudinal fissure. Sometimes this vessel is wanting, the two arteries joining together to form a single trunk, which afterward divides. Or the vessel may be wholly or partially divided into two; frequently it is longer and smaller than usual. It gives off some of the antero-median ganglionic group of vessels, which are, however, principally derived from the anterior cerebral.

The **Middle Cerebral Artery** (*a. cerebri media*) (Fig. 405), the largest branch of the internal carotid, passes obliquely outward along the fissure of Sylvius, and opposite the island of Reil divides into its terminal branches.

Branches.—The branches of the middle cerebral artery are—

Antero-lateral ganglionic.
Inferior external frontal.
Ascending frontal.
Ascending parietal.
Parieto-temporal.

The **Antero-lateral Ganglionic Branches** are a group of small arteries which *arise* at the commencement of the middle cerebral artery; they pierce the anterior perforated space and supply the greater part of the caudate nucleus, the lenticular nucleus, the internal capsule, and a part of the optic thalamus. One artery of this group (one of the **lenticulo-striate arteries**) is of larger size than the rest, and is of special importance, as being the artery in the brain most frequently ruptured; it has been termed by Charcot the **artery of cerebral hemorrhage.** It passes up between the lenticular nucleus and the external capsule, and ultimately ends in the caudate nucleus.

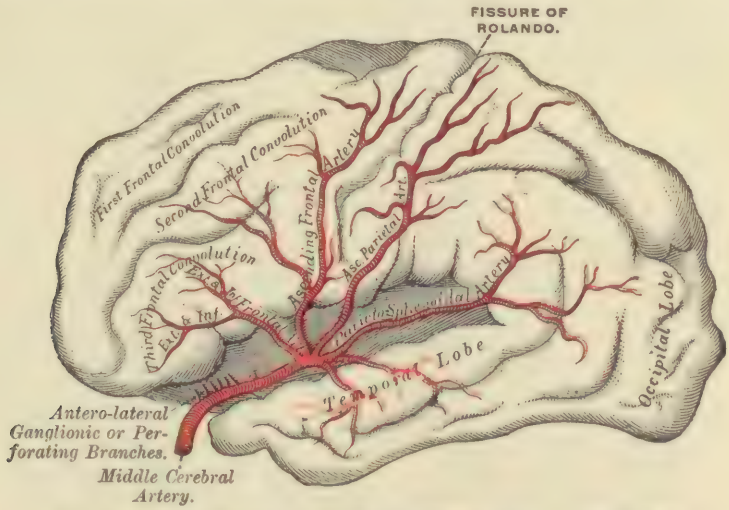

FIG. 405.—The distribution of the middle cerebral artery. (After Charcot.)

The **Inferior External Frontal** supplies the third or inferior frontal convolution, **Broca's convolution,** and the outer part of the orbital surface of the frontal lobe.

The **Ascending Frontal** supplies the ascending frontal convolution.

The **Ascending Parietal** supplies the ascending parietal convolution and the lower part of the superior parietal convolution.

The **Parieto-temporal** or **Parieto-sphenoidal** supplies the supramarginal, the superior, and part of the middle temporal convolutions, and the angular gyrus. It sends branches to the temporal lobe.

The **Posterior Communicating Artery** (*a. communicans posterior*) *arises* from the back part of the internal carotid, runs directly backward, and anastomoses with the posterior cerebral, a branch of the basilar. This artery varies considerably in size, being sometimes small, and occasionally so large that the posterior cerebral may be considered as arising from the internal carotid rather than from the basilar. It is frequently larger on one side than on the other side. From the posterior half of this vessel are given off a number of small branches, the **postero-median ganglionic branches,** which, with similar vessels from the posterior cerebral, pierce the posterior perforated space and supply the internal surfaces of the optic thalami and the walls of the third ventricle.

The **Anterior Choroid** (*a. chorioidea*) is a small but constant branch which arises from the back part of the internal carotid, near the posterior communicating artery. Passing backward and outward between the temporal lobe and the crus

cerebri, it enters the descending horn of the lateral ventricle through the transverse fissure and ends in the choroid plexus. It is distributed to the hippocampus major, corpus fimbriatum, velum interpositum, and choroid plexus.

THE BLOOD-VESSELS OF THE BRAIN.

Recent investigations have tended to show that the mode of distribution of the vessels of the brain has an important bearing upon a considerable number of the anatomical lesions of which this part of the nervous system may be the seat; it therefore becomes important to consider a little more in detail the way in which the cerebral vessels are distributed.

The cerebral arteries are derived from the internal carotid and the vertebral, which at the base of the brain form a remarkable anastomosis known as the **circle**

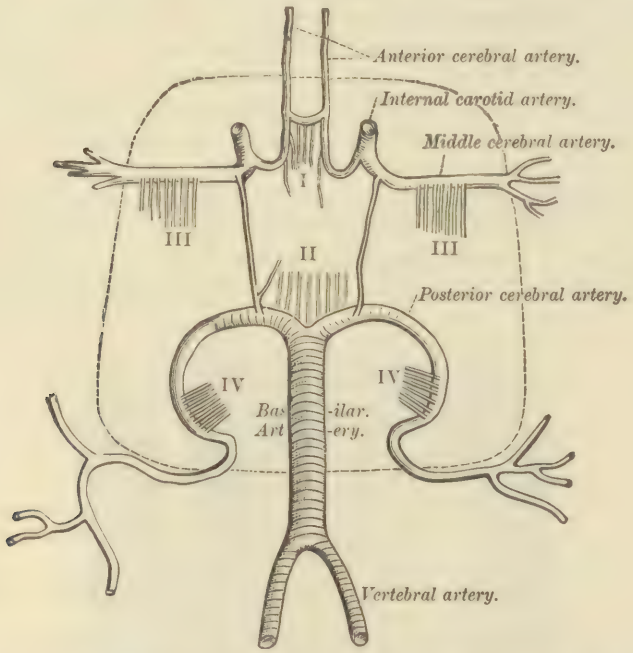

FIG. 406.—Diagram of the arterial circulation at the base of the brain. I. Antero-median group of ganglionic branches. II. Postero-median group. III. Right and left antero-lateral group. IV. Right and left postero-lateral group. The dotted line shows the limit of the ganglionic circle. (After Charcot.)

of Willis (*circulus arteriosus* [*Willisi*]). The tortuosity of the constituent vessels of the anastomosis lessens the impact of the circulation and saves the brain from damage. The outline of the vessels forming the so-called circle is said by Sappey to be hexagonal, and by Testut to be heptagonal. The circle of Willis is formed in front by the anterior cerebral arteries, branches of the internal carotid, which are connected together by the anterior communicating; behind by the two posterior cerebrals, branches of the basilar which are connected on each side to the internal carotid by the posterior communicating (Fig. 401). The parts of the brain included within this arterial circle are the lamina cinerea, the commissure of the optic nerves, the infundibulum, the tuber cinereum, the corpora albicantia, and the posterior perforated space. This arrangement of the vessels of the circle of Willis is not invariable; according to Windle it is maintained in little more than half the recorded cases. In the other cases there are various anomalies.

From the circle of Willis arise the three trunks which together supply each cerebral hemisphere. From its anterior part proceed the two anterior cerebrals, from its antero-lateral part the middle cerebrals, and from its posterior part the posterior cerebrals. Each of these principal arteries gives origin to two very different systems of secondary vessels. One of these systems has been named the **central ganglionic system**, and the vessels belonging to it supply the central ganglia of the brain; the other has been named the **cortical arterial system**, and its vessels ramify in the pia mater and supply the cortex and subjacent medullary matter. These two systems, though they have a common origin, do not communicate at any point of their peripheral distribution, and are entirely independent of each other. Though some of the arteries of the cortical system approach, at their terminations, the regions supplied by the central ganglionic system, no communication between the two sets of vessels takes place, and there is between the parts supplied by the two systems a borderland of diminished nutritive activity, where, it is said, softening is especially liable to occur in the brains of old people.

The Central Ganglionic System.—All the vessels belonging to this system are given off from the circle of Willis or from the vessels immediately after their origin from it, so that if a circle is drawn at a distance of about an inch from the circle of Willis, it will include the origin of all the arteries belonging to this system (Fig. 406). The vessels of this system form six principal groups: (I.) the **antero-median group**, derived from the anterior cerebrals and anterior communicating; (II.) the **postero-median group**, from the posterior cerebrals and posterior communicating; (III.) the right and left **antero-lateral group**, from the middle cerebrals; and (IV.) the right and left **postero-lateral group**, from the posterior cerebrals, after they have wound round the crura cerebri. The vessels belonging to this system are

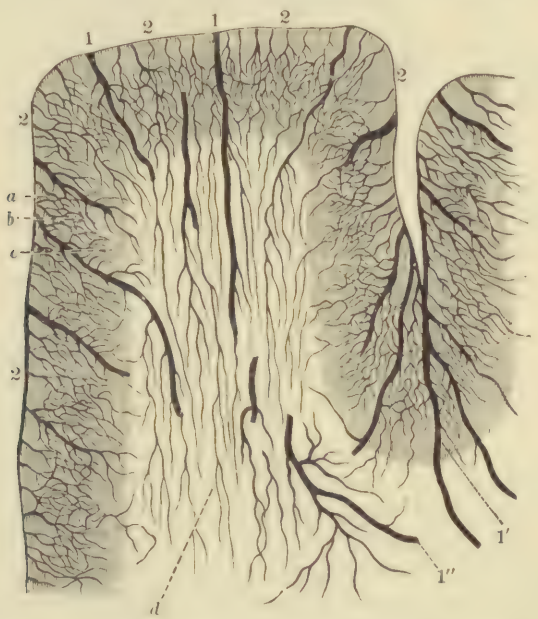

FIG. 407.—Distribution of the cortical arteries. 1. Medullary arteries. 1′. Group of medullary arteries in the sulcus between two adjacent convolutions. 1″. Arteries situated among the short association fibres. 2, 2. Cortical arteries. *a*. Capillary network with fairly wide meshes, situated beneath the pia mater. *b*. Network with more compact, polygonal meshes, situated in the cortex. *c*. Transitional network with wider meshes. *d*. Capillary network in the white matter. (After Charcot.)

larger than those of the cortical system, and are what Cohnheim has termed **terminal arteries**; that is to say, vessels which from their origin to their termination neither supply nor receive any anastomotic branches, so that by one of the small

vessels only a limited area of the central ganglia can be injected; and the injection cannot be driven beyond the area of the part supplied by the particular vessel which is the subject of the experiment.

The Cortical Arterial System.—The vessels forming this system are the terminal branches of the anterior, middle, and posterior cerebral arteries, described above. These vessels divide and ramify in the substance of the pia mater, and give off nutrient arteries which penetrate the cortex perpendicularly. These nutrient vessels are divisible into two classes—the long and short. The **long**—or, as they are sometimes called, the **medullary**—**arteries** pass through the gray matter to penetrate the centrum ovale to the depth of about an inch and a half, without intercommunicating otherwise than by very fine capillaries, and thus constitute so many independent small systems. The **short vessels** are confined to the cortex, where they form with the long vessels a compact network in the middle zone of the gray matter, the outer and inner zones being sparingly supplied with blood (Fig. 407). The vessels of the cortical arterial system are not so strictly terminal as those of the central ganglionic system, but they approach this type very closely, so that injection of one area from the vessel of another area, though it may be possible, is frequently very difficult, and is only effected through vessels of small calibre. As a result of this, obstruction of one of the main branches or its divisions may have the effect of producing softening in a very limited area of the cortex.[1]

ARTERIES OF THE UPPER EXTREMITY.

The artery which supplies the upper extremity continues as a single trunk from its commencement down to the elbow, but different portions of it have received different names according to the region through which it passes. That part of the vessel which extends from its origin to the outer border of the first rib is termed the **subclavian artery**; beyond this point to the lower border of the axilla it is termed the **axillary artery**; and from the lower margin of the axillary space to the bend of the elbow it is termed the **brachial artery**; here the single trunk terminates by dividing into two branches, the radial and ulnar—an arrangement precisely similar to what occurs in the lower limb.

THE SUBCLAVIAN ARTERY (A. SUBCLAVIA) (Fig. 408).

The subclavian artery on the right side *arises* from the innominate artery opposite the right sterno-clavicular articulation; on the left side it arises from the arch of the aorta. It follows, therefore, that these two vessels must, in the first part of their course, differ in their length, their direction, and their relation with neighboring parts.

In order to facilitate the description of these vessels, more especially from a surgical point of view, each subclavian artery has been divided into three parts. The first portion, on the right side, passes upward and outward from the origin of the vessel to the inner border of the Scalenus anticus. On the left side it ascends nearly vertically, to gain the inner border of that muscle. The second part passes outward, behind the Scalenus anticus; and the third part passes from the outer margin of that muscle, beneath the clavicle, to the outer border of the first rib, where it becomes the axillary artery. The first portion of these two vessels differs so much in its course and in its relations with neighboring parts that it will be described separately. The second and third parts are alike on the two sides.

[1] The student who desires further information on this subject is referred to Charcot's Localization of Cerebral and Spinal Diseases, p. 42 *et seq.*, whence the facts above given have been principally derived. Ed. of 15th English edition.

First Part of the Right Subclavian Artery (Figs. 389, 390, 392, 408).

On the right side the subclavian artery *arises* from the arteria innominata, opposite the upper part of the right sterno-clavicular articulation, and passes upward and outward to the inner margin of the Scalenus anticus muscle (Figs. 389, 390, and 408). In this part of its course it ascends a little above the clavicle, the extent to which it does so varying in different cases.

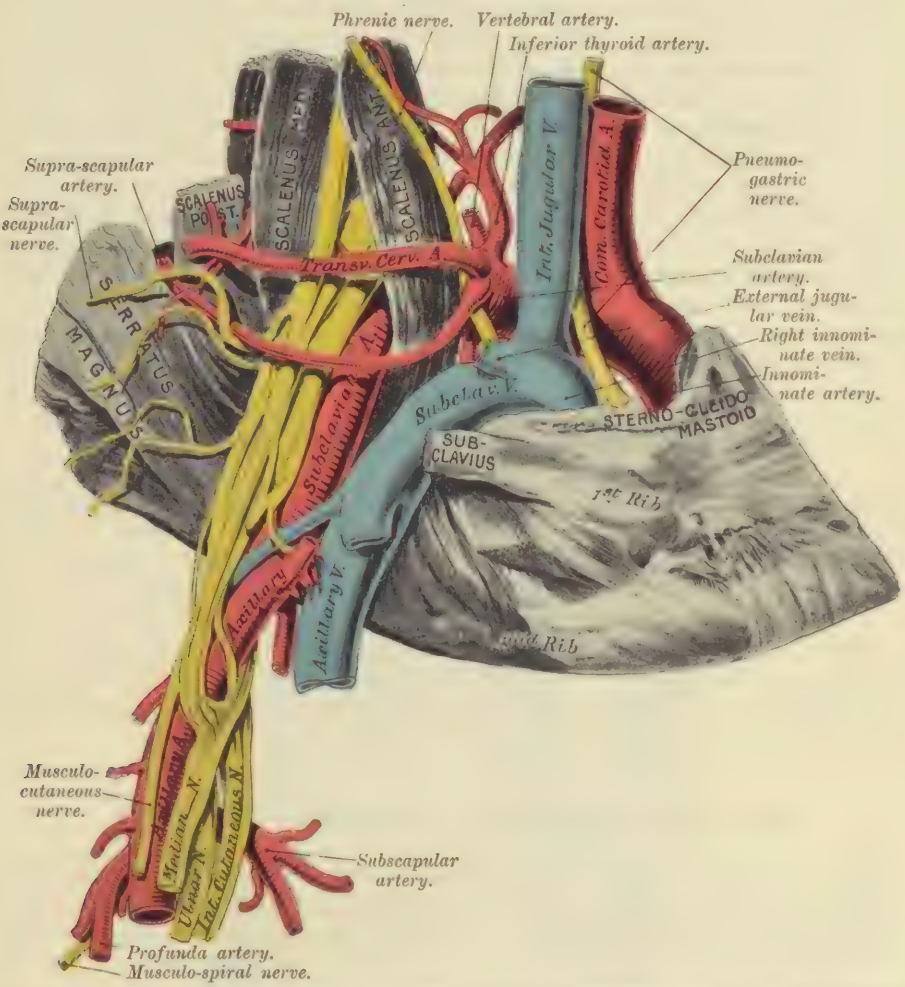

FIG. 408.—The subclavian artery, showing its relations. (From a preparation in the Museum of the Royal College of Surgeons of England.)

Relations.—It is covered, *in front*, by the integument, superficial fascia, Platysma, deep fascia, the clavicular origin of the Sterno-mastoid, the Sterno-hyoid, and Sterno-thyroid muscles, and a second layer of deep fascia. It is crossed by the internal jugular and vertebral veins, and by the pneumogastric nerve and the cardiac branches of the sympathetic nerve. A loop of the sympathetic nerve itself also crosses the artery, forming a ring around the vessels. The anterior jugular vein passes outward in front of the artery but is not in contact with it, being separated from it by the Sterno-hyoid and Sterno-thyroid muscles. Below and behind the artery is the pleura, which separates it from the apex of the lung; *behind* is the cord of the sympathetic nerve; the recurrent laryngeal nerve winds round the lower and back part of the vessel.

Pleura and apex of lung.

First Part of the Left Subclavian Artery (Figs. 388, 389).

The left subclavian artery *arises* from the end of the arch of the aorta, opposite the fourth dorsal vertebra, and ascends nearly vertically to the inner margin of the Scalenus anticus muscle. This part of the vessel is, therefore, longer than the right, is situated deeply in the cavity of the chest, and is directed nearly vertically upward, instead of arching outward like the vessel of the opposite side.

Relations.—It is in relation, *in front*, with the pneumogastric, cardiac, and phrenic nerves, which lie parallel with it, the left carotid artery, left internal jugular and vertebral veins, and the commencement of the left innominate vein and is covered by the Sterno-thyroid, Sterno-hyoid, and Sterno-mastoid muscles; *behind*, it is in relation with the œsophagus, thoracic duct, inferior cervical ganglion of the sympathetic, and Longus colli muscle; higher up, however, the œsophagus and thoracic duct lie to its right side; the latter ultimately arching over the vessel to join the angle of union between the subclavian and internal jugular veins. To its *inner side* are the œsophagus, trachea, and thoracic duct; to its *outer side*, the left pleura and lung.

Second and Third Parts of the Subclavian Artery (Figs. 392, 408).

The **Second Portion of the Subclavian Artery** lies behind the Scalenus anticus muscle; it is very short, and forms the highest part of the arch described by that vessel.

Relations.—It is covered, *in front*, by the skin, superficial fascia, Platysma, deep cervical fascia, the Sterno-mastoid and the Scalenus anticus muscles. On the right side the phrenic nerve is separated from the second part of the artery by the Scalenus anticus muscle, while on the left side the nerve crosses the first part of the artery immediately to the inner edge of the muscle. *Behind*, it is in relation with the pleura and the Scalenus medius muscle. *Above*, with the brachial plexus of nerves. *Below*, with the pleura. The subclavian vein lies below and in front of the artery, separated from it by the Scalenus anticus muscle.

PLAN OF THE RELATIONS OF SECOND PORTION OF SUBCLAVIAN ARTERY.

Pleura.

Behind.
Pleura and Middle Scalenus.

The **Third Portion of the Subclavian Artery** passes downward and outward from the outer margin of the Scalenus anticus muscle to the outer border of the first rib, where it becomes the axillary artery. This portion of the vessel is the most superficial, and is contained in the subclavian triangle (see page 618).

Relations.—It is covered, in *front*, by the skin, the superficial fascia, the Platysma the descending clavicular branches of the cervical plexus, and the deep cervical fascia; by the clavicle, the Subclavius muscle, the suprascapular artery and vein, and the transverse cervical vein; the nerve to the Subclavius muscle passes vertically downward in front of the artery. The external jugular vein crosses the artery at its inner side, and receives the suprascapular and transverse cervical veins, which frequently form a plexus in front of it. The subclavian vein is below and in front of the artery, lying close behind the clavicle. *Behind*, it lies on the Middle scalenus muscle and the lowest cord of the brachial plexus, formed by the union of the last cervical and first dorsal nerves. *Above* it, and to its outer side, is the brachial plexus and Omo-hyoid muscle. *Below*, it rests on the upper surface of the first rib.

Peculiarities.—The subclavian arteries vary in their origin, their course, and the height to which they rise in the neck.

The origin of the right subclavian from the innominate takes place, in some cases, above the sterno-clavicular articulation, and occasionally, but less frequently, in the cavity of the thorax, below that point. Or the artery may arise as a separate trunk from the arch of the aorta. In such cases it may be either the first, second, third, or even the last branch derived from that vessel; in the majority of cases it is the first or last, rarely the second or third. When it is the first branch, it occupies the ordinary position of the innominate artery; when the second or third, it gains its usual position by passing behind the right carotid; and when the last branch, it arises from the left extremity of the arch, at its upper or back part, and passes obliquely toward the right side, usually behind the trachea, œsophagus, and right carotid, sometimes between the œsophagus and trachea to the upper border of the first rib, whence it follows its ordinary course. In very rare instances this vessel arises from the thoracic aorta, as low down as the fourth dorsal vertebra. Occasionally it perforates the Scalenus anticus muscle; more rarely it passes in front of that muscle. Sometimes the subclavian vein passes with the artery behind the Scalenus anticus muscle. The artery may ascend as high as an inch and a half above the clavicle or any intermediate point between this and the upper border of the bone, the right subclavian usually ascending higher than the left.

The left subclavian is occasionally joined at its origin with the left carotid.

Surface Marking.—The course of the subclavian artery in the neck may be mapped out by describing a curve, with its convexity upward at the base of the posterior triangle. The inner end of this curve corresponds to the sterno-clavicular joint, the outer end of the centre of the lower border of the clavicle. The curve is to be drawn with such an amount of convexity that its mid-point reaches half an inch above the upper border of the clavicle. The left subclavian artery is more deeply placed than the right in the first part of its course, and, as a rule, does not reach quite as high a level in the neck. It should be borne in mind that the posterior border of the Sterno-mastoid muscle corresponds to the outer border of the Scalenus anticus muscle, so that the third portion of the artery, that part most accessible for operation, lies immediately external to the posterior border of the Sterno-mastoid muscle.

Surgical Anatomy.—The relations of the subclavian arteries of the two sides having been examined, the student should direct his attention to a consideration of the best position in which compression of the vessel may be effected, or in what situation a ligature may be best applied in cases of aneurism or wound.

Compression of the subclavian artery is required in cases of operations about the shoulder, in the axilla, or at the upper part of the arm; and the student will observe that there is only one situation in which it can be effectually applied—viz., where the artery passes across the upper surface of the first rib. In order to compress the vessel in this situation, the shoulder should be depressed, and the surgeon, grasping the side of the neck, should press with his thumb in the angle formed by the posterior border of the Sterno-mastoid with the upper border of the clavicle, downward, backward, and inward against the rib; if from any cause the shoulder cannot be sufficiently depressed, pressure may be made from before backward, so as to compress the artery against the Scalenus medius muscle and the transverse process of the seventh cervical vertebra. In appropriate cases, a preliminary incision may be made through the cervical fascia, and the finger may be pressed down directly upon the artery.

Ligature of the subclavian artery may be required in cases of wounds or of aneurism in the axilla, or in cases of aneurism on the cardiac side of the point of ligature; and the third part of the artery is that which is most favorable for an operation, on account of its being comparatively superficial and most remote from the origin of the large branches. In those cases where the clavicle is not displaced, this operation may be performed with comparative facility; but where the clavicle is pushed up by a large aneurismal tumor in the axilla the artery is placed at a great depth from the surface, which materially increases the difficulty of the operation. Under these circumstances it becomes a matter of importance to consider the height to which this vessel reaches above the bone. In ordinary cases its arch is about half an inch above the clavicle, occasionally it is as high as an inch and a half, and sometimes so low as to be on a level with the upper border of the clavicle. If the clavicle is displaced, these variations will necessarily make the operation more or less difficult according as the vessel is more or less accessible.

The chief points in the operation of tying the third portion of the subclavian artery are as follows: The patient being placed on a table in the supine position, with the head drawn over to the opposite side and the shoulder depressed as much as possible, the integument should be drawn downward over the clavicle, and an incision made through it, upon that bone, from the anterior border of the Trapezius to the posterior border of the Sterno-mastoid, to which may be added a short vertical incision meeting the inner end of the preceding. The object in drawing the skin downward is to avoid any risk of wounding the external jugular vein, for as it perforates the deep fascia above the clavicle, it cannot be drawn downward with the skin. The soft parts should now be allowed to glide up, and the cervical fascia should be divided upon a director, and if the interval between the Trapezius and Sterno-mastoid muscles be insufficient for the per-

formance of the operation, a portion of one or both may be divided. The external jugular vein will now be seen toward the inner side of the wound: this and the suprascapular and transverse cervical veins, which terminate in it, should be held aside. If the external jugular vein is at all in the way and exposed to injury, it should be tied in two places and divided. The suprascapular artery should be avoided, and the Omo-hyoid muscle held aside if necessary. In the space beneath this muscle careful search must be made for the vessel: a deep layer of fascia and some connective tissue having been divided carefully, the outer margin of the Scalenus anticus muscle must be felt for, and, the finger being guided by it to the first rib, the pulsation of the subclavian artery will be felt as it passes over the rib. The sheath of the vessels having been opened, the aneurism needle may then be passed around the artery from above downward and inward, so as to avoid including any of the branches of the brachial plexus. If the clavicle is so raised by the tumor that the application of the ligature cannot be effected in this situation, the artery may be tied above the first rib, or even behind the Scalenus anticus muscle; the difficulties of the operation in such a case will be materially increased, on account of the greater depth of the artery and the alteration in position of the surrounding parts.

The second part of the subclavian artery, from being that portion which rises highest in the neck, has been considered favorable for the application of the ligature when it is difficult to tie the artery in the third part of its course. There are, however, many objections to the operation in this situation. It is necessary to divide the Scalenus anticus muscle, upon which lies the phrenic nerve, and at the inner side of which is situated the internal jugular vein; and a wound of either of these structures might lead to the most dangerous consequences. Again, the artery is in contact, below, with the pleura, which must also be avoided; and, lastly, the proximity of so many of its large branches arising internal to this point must be a still further objection to the operation. In cases, however, where the sac of an axillary aneurism encroaches on the neck, it may be necessary to divide the outer half or two-thirds of the Scalenus anticus muscle, so as to place the ligature on the vessel at a greater distance from the sac. The operation is performed exactly in the same way as a ligature of the third portion, until the Scalenus anticus is exposed, when it is to be divided on a director (never to a greater extent than its outer two-thirds), and it immediately retracts. The operation is therefore merely an extension of ligature of the third portion of the vessel.

In those cases of aneurism of the axillary or subclavian artery in which the aneurism encroaches upon the outer portion of the Scalenus muscle to such an extent that a ligature cannot be applied in that situation, it may be deemed advisable, as a last resource, to tie the first portion of the subclavian artery. On the left side this operation has been regarded as almost impracticable; the great depth of the artery from the surface, its intimate relation with the pleura, and its close proximity to the thoracic duct and to so many important veins and nerves, present a series of difficulties which it is very difficult to overcome. Nevertheless, Professor Halsted and Schumpert have each tied successfully the first portion of the left subclavian for aneurism. J. K. Rodgers, of New York, also did it successfully. On the right side the operation is practicable, and has been performed. Dr. Nassau, of Philadelphia, successfully ligated the first part of the right subclavian. The main objection to the operation in this situation is the smallness of the interval which usually exists between the commencement of the vessel and the origin of the nearest branch. The operation may be performed in the following manner: The patient being placed on the table in the supine position with the neck extended, an incision should be made along the upper border of the inner part of the clavicle, and a second along the inner border of the Sterno-mastoid, meeting the former at an angle. The attachment of both heads of the Sterno-mastoid must be divided on a director and turned outward; a few small arteries and veins, and occasionally the anterior jugular vein, must be avoided, or, if necessary, ligatured in two places and divided, and the Sterno-hyoid and Sterno-thyroid muscles are to be divided in the same manner as the preceding muscle. After tearing through the deep fascia with the finger-nail, the internal jugular vein will be seen crossing the subclavian artery; this should be pressed aside and the artery secured by passing the needle from below upward, by which the pleura is more effectually avoided. The exact position of the vagus, the recurrent laryngeal, the phrenic and sympathetic nerves should be remembered, and the ligature should be applied near the origin of the vertebral, in order to afford as much room as possible for the formation of a coagulum between the ligature and the orgin of the vessel. It should be remembered that the right subclavian artery is occasionally deeply placed in the first part of its course when it arises from the left side of the aortic arch, and passes in such cases behind the œsophagus or between it and the trachea.

Collateral Circulation.—After ligature of the third part of the subclavian artery the collateral circulation is mainly established by three sets of vessels, thus described in a dissection:

"1. A posterior set, consisting of the suprascapular and posterior scapular branches of the subclavian, anastomosing with the subscapular from the axillary.

"2. An internal set produced by the connection of the internal mammary on the one hand, with the superior and long thoracic arteries, and the branches from the subscapular on the other.

"3. A middle or axillary set, which consisted of a number of small vessels derived from branches of the subclavian, above, and, passing through the axilla, terminated either in the main trunk or some of the branches of the axillary below. This last set presented most conspicuously the peculiar character of the newly formed or, rather, dilated arteries, being excessively tortuous, and forming a complete plexus.

"The chief agent in the restoration of the axillary artery below the tumor was the subscapular artery, which communicated most freely with the internal mammary, suprascapular, and posterior scapular branches of the subclavian, from all of which is received so great an influx of blood as to dilate it to three times its natural size."[1]

When a ligature is applied to the first part of the subclavian aretry, the collateral circulation is carried on by 1, the anastomosis between the superior and inferior thyroid; 2, the anastomosis of the two vertebrals; 3, the anastomosis of the internal mammary with the deep epigastric and the aortic intercostals; 4, the superior intercostal anastomosing with the aortic intercostals; 5, the profunda cervicis anastomosing with the princeps cervicis; 6, the scapular branches of the thyroid axis anastomosing with the branches of the axillary; and 7, the thoracic branches of the axillary anastomosing with the aortic intercostals.

Branches.—The branches given off from the subclavian artery are:

Vertebral.	Internal mammary.
Thyroid axis.	Superior intercostal.

On the left side all four branches generally *arise* from the first portion of the vessel; but on the right side, the superior intercostal usually arises from the second portion of the vessel. On both sides of the body the first three branches arise close together at the inner margin of the Scalenus anticus; in the majority of cases a free interval of from half an inch to an inch exists between the commencement of the artery and the origin of the nearest branch; in a smaller number of cases an interval of more than an inch exists, but it never exceeds an inch and three-quarters. In a very few instances the interval has been found to be less than half an inch. The vertebral artery arises from the upper and posterior part of the subclavian artery, the internal mammary from the lower part of the artery; the thyroid axis from in front and the superior intercostal from behind.

The **Vertebral Artery** (*a. vertebralis*) (Fig. 399) is generally the first and largest branch of the subclavian; it *arises* from the upper and back part of the first portion of the vessel, and, passing upward, enters the foramen in the transverse process of the sixth cervical vertebra,[2] and ascends through the foramina in the transverse processes of all the vertebræ above this. Above the upper border of the axis it inclines outward and upward to the foramen in the transverse process of the atlas, through which it passes; it then winds backward behind its articular process, runs in a deep groove on the upper surface of the posterior arch of this bone (Fig. 16), and, passing beneath the posterior occipito-atlantal ligament (Figs. 199 and 202), pierces the dura mater and arachnoid, and enters the skull through the foramen magnum. It then passes forward and upward, inclining from the lateral aspect to the front of the medulla oblongata. It unites in the middle line with the vessel of the opposite side at the lower border of the pons Varolii to form the **basilar artery** (Fig. 401).

Relations.—At its origin it is situated behind the internal jugular and vertebral veins, and is crossed by the inferior thyroid artery: it lies between the Longus colli and Scalenus anticus muscles, having the thoracic duct in front of it on the left side. It rests on the transverse process of the seventh cervical vertebra and the sympathetic nerve. Within the foramina formed by the transverse processes of the vertebræ it is accompanied by a plexus of nerves from the inferior cervical ganglion of the sympathetic, and is surrounded by a dense plexus of veins which unite to form the vertebral vein at the lower part of the neck. It is situated in

[1] Guy's Hospital Reports, vol. i., 1836: case of axillary aneurism, in which Mr. Aston Key had tied the subclavian artery on the outer edge of the Scalenus muscle twelve years previously.

[2] The vertebral artery sometimes enters the foramen in the transverse process of the fifth vertebra. Dr. Smyth, who tied this artery in the living subject, found it, in one of his dissections, passing into the foramen in the seventh vertebra.—Ed. of 15th English edition.

front of the cervical nerves, as they issue from the intervertebral foramina. While winding round the articular process of the atlas, it is contained in a triangular space, the **suboccipital triangle**, formed by the Rectus capitis posticus major, the Superior oblique and the Inferior oblique muscles; and at this point is covered by the Complexus muscle (Fig. 283). The suboccipital nerve here lies between the artery and the bone. Within the skull, as the artery winds round the medulla oblongata, it is placed between the hypoglossal nerve and the anterior root of the suboccipital nerve, beneath the first digitation of the ligamentum denticulatum, and finally ascends between the basilar process of the occipital bone and the anterior surface of the medulla oblongata.

Branches.—These may be divided into two sets—those given off in the neck and those within the cranium.

Cervical Branches.	*Cranial Branches.*
Lateral Spinal.	Posterior Meningeal.
Muscular.	Anterior Spinal.
	Posterior Spinal.
	Posterior Inferior Cerebellar.
	Bulbar.

The **Lateral Spinal Branches** (*rami spinales*) enter the spinal canal through the intervertebral foramina and divide into two branches. Of these, one passes along the roots of the nerves to supply the spinal cord and its membranes, anastomosing with the other arteries of the spinal cord; the other divides into an ascending and a descending branch, which unite with similar branches from the artery above and below, so that two lateral anastomotic chains are formed on the posterior surface of the bodies of the vertebræ near the attachment of the pedicles. From these anastomotic chains branches are given off to supply the periosteum and the bodies of the vertebræ, and to communicate with similar branches from the opposite side; from these communicating branches small branches are given off which join similar branches above and below, so that a central anastomotic chain is formed on the posterior surface of the bodies of the vertebræ.

Muscular Branches are given off to the deep muscles of the neck, where the vertebral artery curves round the articular process of the atlas. They anastomose with the occipital and with the ascending and deep cervical arteries.

The **Posterior Meningeal** (*ramus meningeus*) is a small branch given off from the vertebral opposite the foramen magnum. It ramifies between the bone and dura mater in the cerebellar fossæ, and supplies the falx cerebelli.

The **Anterior Spinal** (*a. spinalis anterior*) is a small branch which *arises* near the termination of the vertebral, and, descending in front of the medulla oblongata, unites with its fellow on the opposite side at about the level of the foramen magnum. One of these vessels is usually larger than the other, but occasionally they are about equal in size. The single trunk thus formed descends on the front of the spinal cord, and is reinforced by a succession of small branches which enter the spinal canal through the intervertebral foramina; these branches are derived from the vertebral artery and the ascending cervical branch of the inferior thyroid artery in the neck; from the intercostal in the dorsal region; and from the lumbar, ilio-lumbar, and lateral sacral arteries in the lower part of the spine. They unite, by means of ascending and descending branches, to form a single anterior median artery, which extends as far as the lower part of the spinal cord. This vessel is placed in the pia mater along the anterior median fissure; it supplies that membrane and the substance of the cord, and sends off branches at its lower part to be distributed to the cauda equina, and ends on the central fibrous prolongation of the cord.

The **Posterior Spinal** (*a. spinalis posterior*) *arises* from the vertebral at the side of the medulla oblongata: passing backward to the posterior aspect of the spinal cord, it descends on each side, lying behind the posterior roots of the spinal nerves, and is reinforced by a succession of small branches which enter the spinal canal through the intervertebral foramina, and by which it is continued to the lower part of the cord and to the cauda equina. Branches from these vessels form a free anastomosis round the posterior roots of the spinal nerves, and communicate, by means of very tortuous transverse branches, with the vessel of the opposite side. At its commencement it gives off an ascending branch, which terminates on the side of the fourth ventricle.

The **Posterior Inferior Cerebellar Artery** (*a. cerebelli inferior posterior*) (Fig. 401), the largest branch of the vertebral, winds backward round the upper part of the medulla oblongata, passing between the origin of the pneumogastric and spinal accesssory nerves, over the restiform body to the under surface of the cerebellum, where it divides into two branches—an *internal*, which is continued backward to the notch between the two hemispheres of the cerebellum; and an *external*, which supplies the under surface of the cerebellum as far as its outer border, where it anastomoses with the anterior inferior cerebellar and the superior cerebellar branches of the basilar artery. Branches from this artery supply the choroid plexus of the fourth ventricle.

The **Bulbar Arteries** comprise several minute vessels which spring from the vertebral and its branches and are distributed to the medulla oblongata.

Surgical Anatomy.—The vertebral artery has been tied in several instances: 1, for wounds or traumatic aneurism; 2, after ligation of the innominate, either immediately to prevent hemorrhage, or later on to arrest bleeding where it has occurred at the seat of ligation; and 3, in epilepsy. In these latter cases the treatment has been recommended by Dr. Alexander, of Liverpool, in the hope that by diminishing the supply of blood to the posterior part of the brain and the spinal cord a diminution or cessation of the epileptic fits would result. But, on account of the uncertainty as to what cases, if any, derived benefit from the operation, it has now been abandoned as a treatment for epilepsy. The *operation of ligation of the vertebral* is performed by making an incision along the posterior border of the Sterno-mastoid muscle, just above the clavicle. The muscle is pulled to the inner side, and the anterior tubercle of the transverse process of the sixth cervical vertebra is sought for. A deep layer of fascia being now divided, the interval between the Scalenus anticus and the Longus colli muscles just below their attachment to the tubercle is defined, and the artery and vein are found in the interspace. The vein is to be drawn to the outer side, and the aneurism needle is passed from without inward. Drs. Ramskill and Bright have pointed out that severe pain at the back of the head may be symptomatic of disease of the vertebral artery just before it enters the skull. This is explained by the close connection of the artery with the suboccipital nerve in the groove on the posterior arch of the atlas. Disease of the same artery has been also said to affect speech, from pressure on the hypoglossal nerve where it is in relation with the vessel, leading to paralysis of the muscles of the tongue.

The **Basilar Artery** (*a. basilaris*) (Fig. 401), so named from its position at the base of the skull, is a single trunk formed by the junction of the two vertebral arteries; it extends from the posterior to the anterior border of the pons Varolii, lying in the median pontine groove, under cover of the arachnoid. It ends by dividing into the two **posterior cerebral arteries.**

Branches.—Its branches are, on each side, the following:

Transverse.	Anterior Inferior Cerebellar.
Internal Auditory.	Superior Cerebellar.
	Posterior Cerebral.

The **Transverse** or **Pontal Branches** (*rami ad pontem*) supply the substance of the pons Varolii.

The **Internal Auditory** (*a. auditiva interna*) accompanies the auditory nerve into the internal auditory meatus. It supplies the internal ear.

The **Anterior Inferior Cerebellar Artery** (*a. cerebelli inferior anterior*) passes backward across the crus cerebelli, to be distributed to the anterior border of the under surface of the cerebellum, anastomosing with the posterior inferior cerebellar branch of the vertebral.

The **Superior Cerebellar Artery** (*a. cerebelli superior*) on each side *arises* near the termination of the basilar. It passes outward, immediately behind the third nerve, which separates it from the posterior cerebral, winds round the crus cerebri, close to the fourth nerve, and, arriving at the upper surface of the cerebellum, divides into branches which ramify in the pia mater and, reaching the circumference of the cerebellum, anastomose with the branches of the inferior cerebellar arteries. Several branches are given to the pineal gland, the valve of Vieussens, and the velum interpositum.

The **Posterior Cerebral Artery** (*a. cerebri posterior*) (Figs. 401, 403, 404, and 406), on each side, is the terminal branch of the basilar. It is larger than the preceding, from which it is separated near its origin by the third nerve. Passing outward, parallel to the superior cerebellar artery, and receiving the posterior communicating from the internal carotid, it winds round the crus cerebri, and passes to the under surface of the occipital lobes of the cerebrum, and break up into branches for the supply of the temporal and occipital lobes. The **branches** of the posterior cerebral artery are:

Postero-median ganglionic.		Anterior temporal.
Posterior choroid.	Three terminal	Posterior temporal.
Postero-lateral ganglionic.		Occipital.

The **postero-median ganglionic branches** (Fig. 406) are a group of small arteries which arise at the commencement of the posterior cerebral artery; these, with similar branches from the posterior communicating, pierce the posterior perforated space, and supply the internal surfaces of the optic thalamus and the walls of the third ventricle. The **posterior choroid** enters the interior of the brain beneath the splenium of the corpus callosum, and supplies the velum interpositum and the choroid plexus. The **postero-lateral ganglionic branches** are a group of small arteries which arise from the posterior cerebral artery, after it has turned round the crus cerebri; they supply a considerable portion of the optic thalamus. The **terminal branches** are distributed as follows: the **first**, or the **anterior temporal branches**, to the under surface of the anterior portion of the temporal lobe; the **second**, or the **posterior temporal branches**, to the external occipital and the third temporal convolutions; and the **third**, or the **occipital branches**, to the inner and outer surfaces of the occipital lobe.

Circle of Willis (*circulus arteriosus* [*Willisi*]).—The remarkable anastomosis which exists between the branches of the internal carotid and vertebral arteries at the base of the brain constitutes the circle of Willis. It is formed in *front*, by the anterior cerebral arteries, branches of the internal carotid, which are connected together by the anterior communicating; *behind*, by the two posterior cerebrals, branches of the basilar, which are connected on each side with the internal carotid by the posterior communicating arteries (Fig. 401). It is by this anastomosis that the cerebral circulation is equalized, and provision made for effectually carrying it on if one or more of the branches are obliterated. The parts of the brain included within this arterial circle are—the lamina cinerea, the commissure of the optic nerves, the infundibulum, the tuber cinereum, the corpora albicantia, and the posterior perforated space.

The **Thyroid Axis** (*truncus thyreocervicalis*) (Figs. 392 and 410) is a short thick trunk which *arises* from the forepart of the first portion of the subclavian artery, close to the inner border of the Scalenus anticus muscle, and divides, almost immediately after its origin, into three branches—the **inferior thyroid, suprascapular,** and **transversalis colli.**

The **Inferior Thyroid Artery** (*a. thyreoidea inferior*) (Fig. 392) passes upward, in front of the vertebral artery and Longus colli muscle; then turns inward behind the sheath of the common carotid artery and internal jugular vein, and also behind the sympathetic nerve, the middle cervical ganglion resting upon the vessel, and reaching the lower border of the lateral lobe of the thyroid gland it divides into two branches, which supply the posterior and under part of the organ, and anastomose in its substance with the superior thyroid and with the corresponding artery of the opposite side. (See page 602.) The recurrent laryngeal nerve passes upward, generally behind but occasionally in front of the artery. Its **branches** are:

Inferior Laryngeal. Œsophageal.
Tracheal. Ascending Cervical.
Muscular.

The **inferior laryngeal branch** (*a. laryngea inferior*) ascends upon the trachea to the back part of the larynx, in company with the recurrent laryngeal nerve, and supplies the muscles and mucous membrane of this part, anastomosing with the laryngeal branch from the superior thyroid artery and with the inferior laryngeal branch from the opposite side. The **tracheal branches** (*rami tracheales*) are distributed upon the trachea, anastomosing below with the bronchial arteries. The **œsophageal branches** (*rami œsophagei*) are distributed to the œsophagus, and anastomose with the œsophageal branches of the aorta. The **ascending cervical** (*a. cervicalis ascendens*) is a small branch which arises from the inferior thyroid just where that vessel is passing behind the common carotid artery, and runs up on the anterior tubercles of the transverse processes of the cervical vertebræ in the interval between the Scalenus anticus and Rectus capitis anticus major muscles. It gives **muscular branches** (*rami musculares*) to the muscles of the neck, which anastomose with branches of the vertebral, and sends one or two branches (*rami spinales*) into the spinal canal through the intervertebral foramina to be distributed to the spinal cord and its membranes, and to the bodies of the vertebræ in the same manner as the lateral spinal branches from the vertebral. It anastomoses with the ascending pharyngeal and occipital arteries. The muscular branches supply the depressors of the hyoid bone, the Longus colli, the Scalenus anticus, and the Inferior constrictor of the pharynx. One of the muscular branches passes between the transverse processes of the fourth and fifth cervical vertebræ and reaches the deep muscles of the neck. It is called the **ramus profundus**.

Surgical Anatomy.—The inferior thyroid artery has been tied, in conjunction with the superior thyroid, in cases of bronchocele. An incision is made along the anterior border of the Sterno-mastoid down to the clavicle. After the deep fascia has been divided, the Sterno-mastoid and carotid vessels are drawn outward and the *carotid tubercle* (*Chassaignac's tubercle*) sought for. The vessel will be found just below this tubercle, between the carotid sheath on the outer side of the trachea and œsophagus on the inner side. In passing the ligature great care must be exercised to avoid including the recurrent laryngeal nerve, which is occasionally found crossing in *front* of the vessel. Before extirpating a goitrous lobe of the thyroid the superior and inferior thyroid arteries of the diseased side are to be ligated.

The **Suprascapular** or **Transversalis Humeri Artery** (*a. transversa scapulæ*) (Figs. 392 and 409), smaller than the tranversalis colli, passes obliquely from within outward, across the root of the neck. It at first passes downward and outward across the Scalenus anticus muscle and phrenic nerve, being covered by the Sterno-mastoid; it then crosses the subclavian artery and the cords of the brachial plexus, and runs outward, behind and parallel with the clavicle and Subclavius muscle, and beneath the posterior belly of the Omo-hyoid, to the superior border of the scapula, where it passes over the transverse ligament of the scapula, which separates it from the suprascapular nerve, and reaches the supraspinous fossa. In this situation it lies close to the bone, and ramifies between it and the Supraspinatus muscle, to which it

supplies branches. It then passes downward behind the neck of the scapula, to reach the infraspinous fossa, where it anastomoses with the dorsalis scapulæ branch of the subscapular artery and branches of the posterior scapular arteries. Besides distributing branches to the Sterno-mastoid, Subclavius, and neighboring muscles, it gives off a **suprasternal branch,** which crosses over the sternal end of the clavicle to the skin of the upper part of the chest; and a **supra-acromial branch** (*ramus acromialis*), which, piercing the Trapezius muscle, supplies the skin over the acromion, anastomosing with the acromial thoracic artery. As the artery passes over the transverse ligament of the scapula, a branch descends into the subscapular fossa, ramifies beneath the subscapular muscle, and anastomoses with the posterior and subscapular arteries. The suprascapular artery also sends branches to the acromio-clavicular and shoulder joints, and a nutrient artery to the clavicle.

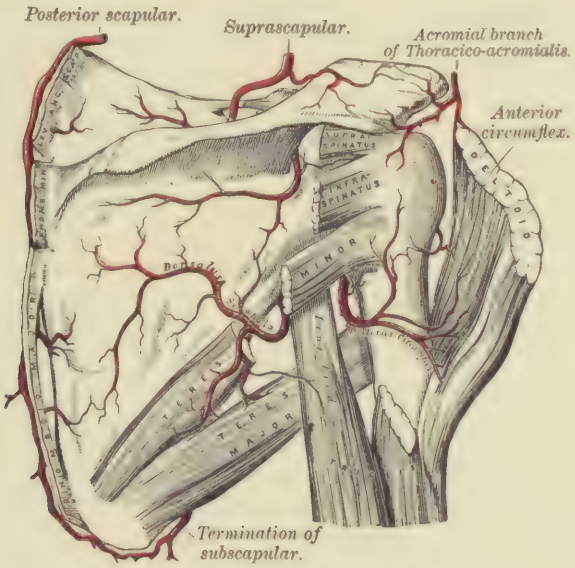

FIG. 409.—The scapular and circumflex arteries.

The **Transverse Cervical** or **Transversalis Colli Artery** (*a. transversa colli*) (Fig. 392) passes transversely outward, across the upper part of the subclavian triangle, to the anterior margin of the Trapezius muscle, beneath which it divides into two branches, the **superficial cervical** and the **posterior scapular.** In its passage across the neck it crosses in front of the phrenic nerve, Scaleni muscles, and the brachial plexus, between the divisions of which it sometimes passes, and is covered by the Platysma, Sterno-mastoid, Omo-hyoid, and Trapezius muscles. The **superficial cervical** (*ramus ascendens*) ascends beneath the anterior margin of the Trapezius, distributing branches to it and to the neighboring muscles and glands in the neck, and anastomosing with the superficial branch of the arteria princeps cervicis. The **posterior scapular** (*ramus descendens*) (Fig. 409) passes beneath the Levator anguli scapulæ muscle to the superior angle of the scapula, and then descends along the posterior border of that bone as far as the inferior angle. In its course it is covered by the Rhomboid muscles, supplying them and the Latissimus dorsi and Trapezius, and anastomosing with the suprascapular and subscapular arteries, and with the posterior branches of some of the intercostal arteries.

Peculiarities. The superficial cervical frequently arises as a separate branch from the thyroid axis; and the posterior scapular, from the third, more rarely from the second, part of the subclavian.

The **Internal Mammary** (*a. mammaria interna*) (Fig. 410) *arises* from the under surface of the first portion of the subclavian artery, opposite the thyroid

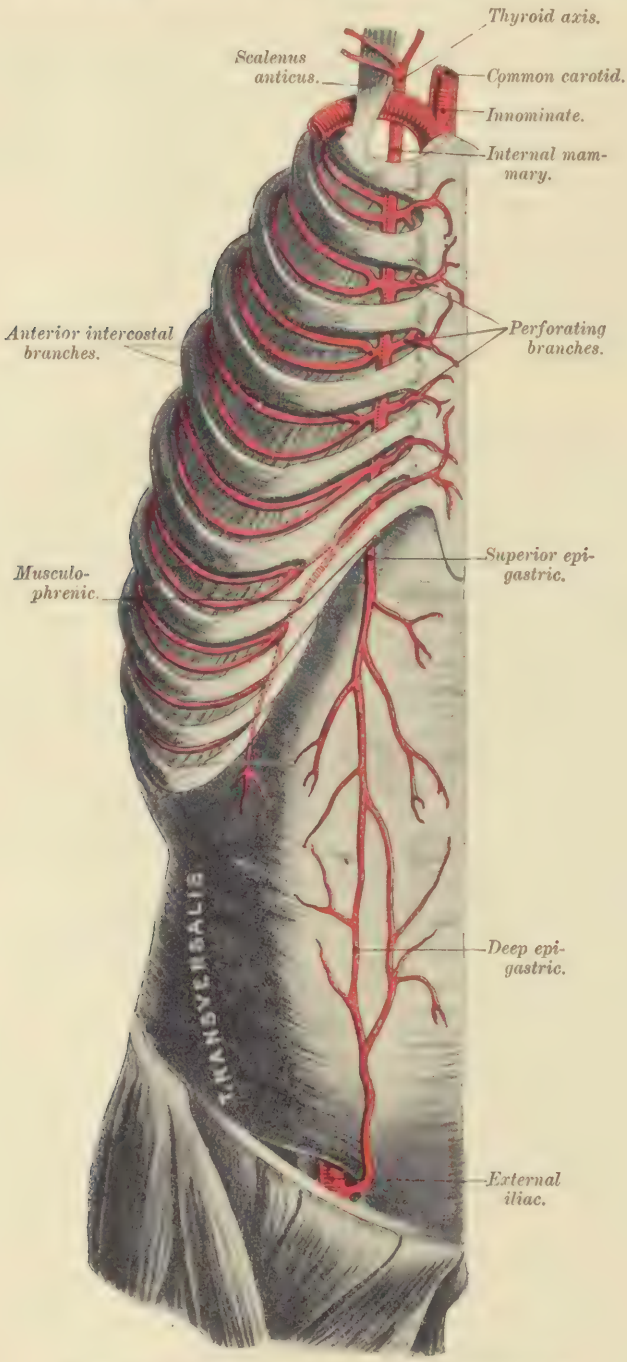

FIG. 410.—The internal mammary artery and its branches.

axis. It passes downward and inward behind the costal cartilage of the first rib to the inner surface of the anterior wall of the chest, resting against the costal cartilages about half an inch from the margin of the sternum; and, at the interval

between the sixth and seventh cartilages, divides into two branches, the **musculo-phrenic** and **superior epigastric.**

Relations.—At its origin it is covered by the internal jugular and subclavian veins, and as it enters the thorax is crossed from without inward by the phrenic nerve, and then passes forward close to the outer side of the innominate vein. In the upper part of the thorax it lies behind the costal cartilages and Internal intercostal muscles, and is crossed by the terminations of the upper six intercostal nerves. At first it lies upon the pleura, but at the lower part of the thorax the Triangularis sterni separates the artery from this membrane. It has two venæ comites; these unite into a single vein, which joins the innominate vein of its own side.

Branches.—The branches of the internal mammary are—

Comes Nervi Phrenici (Superior Phrenic).	Anterior Intercostal.
Mediastinal.	Perforating.
Pericardiac.	Musculo-phrenic.
Sternal.	Superior Epigastric.

The **Comes Nervi Phrenici** or **Superior Phrenic** (*a. pericardiacophrenica*) is a long slender branch which accompanies the phrenic nerve, between the pleura and pericardium, to the Diaphragm. It gives branches to the pericardium and is distributed upon the Diaphragm, anastomosing with the other phrenic branches from the internal mammary and with phrenic branches of the abdominal aorta.

The **Mediastinal Branches** (*aa. mediastinales anteriores*) are small vessels which are distributed to the areolar tissue and lymphatic glands in the anterior mediastinum and to the remains of the thymus gland.

The **Pericardiac Branches** supply the upper part of the anterior surface of the pericardium, the lower part receiving branches from the musculo-phrenic artery.

The **Sternal Branches** (*rami sternales*) are distributed to the Triangularis sterni and to the posterior surface of the sternum.

The mediastinal, pericardiac, and sternal branches, together with some twigs from the comes nervi phrenici, anastomose with branches from the intercostal and bronchial arteries, and form a minute plexus beneath the pleura, which has been named by Turner the **subpleural mediastinal plexus.**

The **Anterior Intercostal Arteries** (*rami intercostales*) supply the five or six upper intercostal spaces. The branch corresponding to each space soon divides into two, or the two branches may come off separately from the parent trunk. The small vessels pass outward in the intercostal spaces, one, the larger, lying near the lower margin of the rib above, and the other, the smaller, near the upper margin of the rib below, and anastomose with the intercostal arteries from the aorta. They are at first situated between the pleura and the Internal intercostal muscles, and then between the Internal and External intercostal muscles. They supply the Intercostal muscles, and, by branches which perforate the External intercostal muscle, reach the Pectoral muscles and the mammary gland.

The **Perforating** or **Anterior Perforating Arteries** (*rami perforantes*) correspond to the five or six upper intercostal spaces. They arise from the internal mammary, pass forward through the intercostal spaces, and, curving outward, supply the Pectoralis major and the integument. Those which correspond to the second, third, and fourth spaces are distributed to the mammary gland. In females, during lactation, these branches are of large size.

The **Musculo-phrenic Artery** (*a. musculophrenica*) is directed obliquely downward and outward, behind the cartilages of the false ribs, perforating the Diaphragm at the eighth or ninth rib, and terminating, considerably reduced in size, opposite the last intercostal space. It gives off anterior intercostal arteries to each of the intercostal spaces across which it passes; these diminish in size as the

spaces decrease in length, and are distributed in a manner precisely similar to the anterior intercostals from the internal mammary. The musculo-phrenic also gives branches to the lower part of the pericardium, and others which run backward to the Diaphragm and downward to the abdominal muscles.

The **Superior Epigastric** (*a. epigastrica superior*) continues in the original direction of the internal mammary; it descends through the cellular interval between the costal and sternal attachments of the Diaphragm, and enters the sheath of the Rectus abdominis muscle, at first lying behind the muscle, and then perforating it and supplying it, and anastomosing with the deep epigastric artery from the external iliac. Some branches perforate the sheath of the Rectus, and supply the muscles of the abdomen and the integument, and a small branch, which passes inward upon the side of the ensiform appendix, anastomoses in front of that cartilage with the superior epigastric artery of the opposite side. It also gives some twigs to the Diaphragm, while from the artery of the right side small branches extend into the falciform ligament of the liver and anastomose with the hepatic artery.

Surgical Anatomy.—The course of the internal mammary artery may be defined by drawing a line across the six upper intercostal spaces half an inch from and parallel with the sternum. The position of the vessel must be remembered, as it is liable to be wounded in stabs of the chest-wall. It is most easily reached by a transverse incision in the second intercostal space.

The **Superior Intercostal** (*truncus costocervicalis*) (Figs. 399 and 416) *arises* from the upper and back part of the subclavian artery, behind the Scalenus anticus muscle on the right side and to the inner side of that muscle on the left side. Passing backward, it gives off the **deep cervical branch,** and then descends behind the pleura in front of the necks of the first two ribs, and inosculates with the first aortic intercostal. As it crosses the neck of the first rib it lies to the inner side of the anterior division of the first dorsal nerve and to the outer side of the first thoracic ganglion of the sympathetic. In the first intercostal space it gives off a branch which is distributed in a manner similar to the distribution of the aortic intercostals. The branch for the second intercostal space usually joins with one from the highest aortic intercostal. Each intercostal gives off a branch to the posterior spinal muscles, and a small branch which passes through the corresponding intervertebral foramen to the spinal cord and its membranes.

The **Deep Cervical Branch** (*a. cervicalis profunda*) *arises*, in most cases, from the superior intercostal, and is analogous to the posterior branch of an aortic intercostal artery; occasionally it arises as a separate branch from the subclavian artery. Passing backward, above the eighth cervical nerve and between the transverse process of the seventh cervical vertebra and the first rib, it runs up the back part of the neck, between the Complexus and Semispinalis colli muscles, as high as the axis vertebra, supplying these and adjacent muscles, and anastomosing with the deep branch of the arteria princeps cervicis of the occipital, and with branches which pass outward from the vertebral. It gives off a special branch which enters the spinal canal through the intervertebral foramen between the seventh cervical and first dorsal vertebræ.

SURGICAL ANATOMY OF THE AXILLA.

The axilla is a pyramidal space, situated between the upper and lateral part of the chest and the inner side of the arm.

Boundaries.—Its *apex*, which is directed upward toward the root of the neck, corresponds to the interval between the first rib, the upper edge of the scapula, and the clavicle, through which the axillary vessels, the brachial plexus of nerves, and the long thoracic nerve pass. This interval is the **cervico-axillary passage.**

The *base*, directed downward, is formed by the integument and a thick layer of fascia, the **axillary fascia** (*fascia axillaris*) (Fig. 313), extending between the lower border of the Pectoralis major in front and the lower border of the Latissimus dorsi behind (page 463). The axillary fascia is perforated at several points. The large central opening is called the **foramen of Langer**. The inner margin of the foramen of Langer is dense and constitutes a part of the **axillary arch**, which is a fibro-muscular slip derived from the latissimus dorsi. The axilla is broad internally at the chest, but narrow and pointed externally at the arm. The *anterior boundary* is formed by the Pectoralis major and minor muscles, the former covering the whole of the anterior wall of the axilla, the latter covering only its central part, the costo-coracoid membrane, the clavicle, and the Subclavius muscle. The *posterior boundary*, which extends somewhat lower than the anterior, is formed by the Subscapularis above, the Teres major and Latissimus dorsi below. On the *inner side* are the first four ribs with their corresponding Intercostal muscles, and part of the Serratus magnus. On the *outer side*, where the anterior and posterior boundaries converge, the space is narrow, and bounded by the humerus, the Coraco-brachialis and Biceps muscles.

Contents.—This space contains the axillary vessels and brachial plexus of nerves, with their branches, some branches of the intercostal nerves, and a large number of lymphatic glands, all connected together by a quantity of fat and loose areolar tissue.

Position of the Contents.—The axillary artery and vein, with the brachial plexus of nerves, extend obliquely along the outer boundary of the axillary space, from its apex to its base, and are placed much nearer the anterior than the posterior wall, the vein lying to the inner or thoracic side of the artery and partially concealing it. At the forepart of the axillary space, in contact with the Pectoral muscles, and along the anterior margin are the thoracic branches of the axillary artery, and along the lower margin of the Pectoralis minor the long thoracic artery extends to the side of the chest. At the back part, in contact with the lower margin of the Subscapularis muscle, are the subscapular vessels and nerves; winding around the outer border of this muscle is the dorsalis scapulæ artery and veins; and, close to the neck of the humerus, the posterior circumflex vessels and the circumflex nerve are seen curving backward to the shoulder.

Along the inner or thoracic side no vessel of any importance exists, the upper part of the space being crossed merely by a few small branches from the superior thoracic artery. There are some important nerves, however, in this situation – viz., the posterior thoracic or external respiratory nerve, descending on the surface of the Serratus magnus, to which it is distributed; and perforating the upper and anterior part of this wall, the intercosto-humeral nerve or nerves, passing across the axilla to the inner side of the arm.

The cavity of the axilla is filled by a quantity of loose areolar tissue and a large number of small arteries and veins, all of which are, however, of inconsiderable size, and numerous lymphatic glands, the position and arrangement of which are described on a subsequent page.

Surgical Anatomy. The axilla is a space of considerable surgical importance. It transmits the large vessels and nerves to the upper extremity, and these may be the seat of injury or disease: it contains numerous lymphatic glands which may require removal when diseased; in it is a quantity of loose connective and adipose tissue which may be readily infiltrated with blood or pus. The axilla may be the seat of rapidly growing tumors. Moreover, it is covered at its base by thin skin, largely supplied with sebaceous and sweat glands, which is frequently the seat of small cutaneous *abscesses* and *boils*, and of eruptions due to irritation.

In *suppuration* in the axilla the arrangement of the fasciæ plays a very important part in the direction which the pus takes. As described on page 464, the costo-coracoid membrane, after covering in the space between the clavicle and the upper border of the Pectoralis minor, splits

to enclose this muscle, and, reblending at its lower border, becomes incorporated with the axillary fascia at the anterior fold of the axilla. This is known as the *clavi-pectoral fascia*. Suppuration may take place either superficial to or beneath this layer of fascia; that is, either between the Pectorals or below the Pectoralis minor: in the former case, the pus would point either at the anterior border of the axillary fold or in the groove between the Deltoid and the Pectoralis major; in the latter, the pus would have a tendency to surround the vessels and nerves and ascend into the neck, that being the direction in which there is least resistance. Its progress toward the skin is prevented by the axillary fascia; its progress backward, by the Serratus magnus; forward, by the clavi-pectoral fascia; inward, by the wall of the thorax; and outward, by the upper limb. The pus in these cases, after extending into the neck, has been known to spread through the superior opening of the thorax into the mediastinum.

In opening an *axillary abscess* the knife should be entered in the floor of the axilla, midway between the anterior and posterior margins and near the thoracic side of the space. It is well to use a director and dressing forceps after an incision has been made through the skin and fascia in the manner directed by the late Mr. Hilton.

The student should attentively consider the relation of the vessels and nerves in the several parts of the axilla, for it is the universal plan, at the present day, to remove the glands from the axilla in operating for *cancer of the breast*. In performing such an operation it will be necessary to proceed with much caution in the direction of the outer wall and apex of the space,

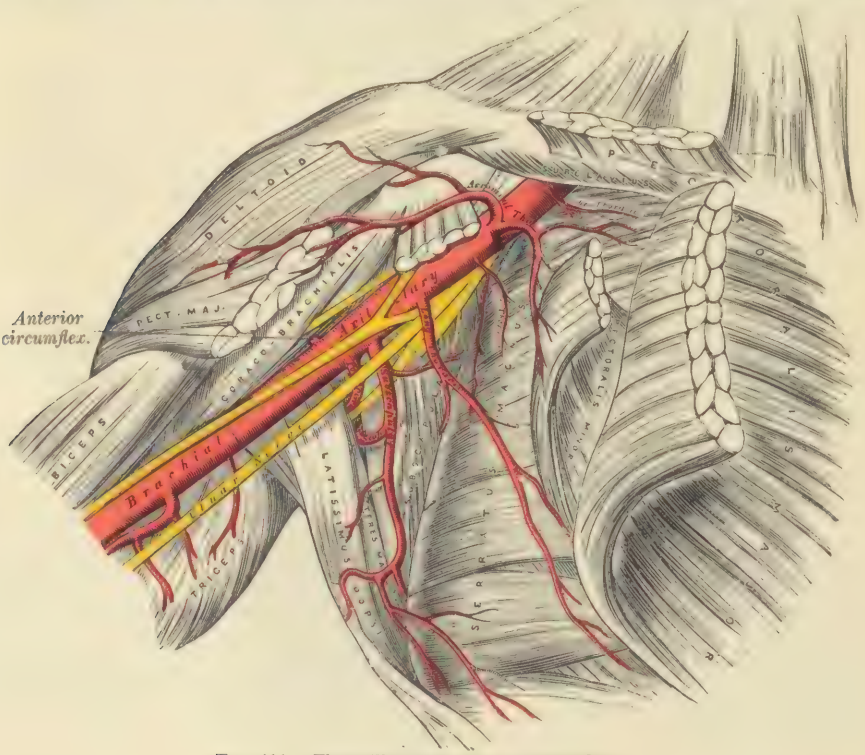

FIG. 411.—The axillary artery and its branches.

as here the axillary vessels will be in danger of being wounded. Toward the posterior wall it will be necessary to avoid the subscapular, dorsalis scapulæ, and posterior circumflex vessels. Along the anterior wall it will be necessary to avoid the thoracic branches. In clearing out the axilla the axillary vein should be first defined and cleared up to the apex of the axilla. When the apex of the space is reached, all fat and glands must be carefully removed and the whole axilla cleared by separating the tissues along the inner and posterior walls, so that when the proceeding is completed, the axilla is cleared of all its contents except the main vessels and nerves.

THE AXILLARY ARTERY (A. AXILLARIS) (Fig. 411).

The axillary artery, the continuation of the subclavian, commences at the outer border of the first rib, and terminates at the lower border of the tendon

of the Teres major muscle, where it takes the name of brachial. Its direction varies with the position of the limb: when the arm lies by the side of the chest, the vessel forms a gentle curve, the convexity being upward and outward; when the arm is directed at right angles with the trunk, the vessel is nearly straight; and when the arm is elevated still higher, the arteries describe a curve the concavity of which is directed upward. At its commencement the artery is very deeply situated, but near its termination it is superficial, being covered only by the skin and fascia. The description of the relations of this vessel is facilitated by its division into three portions, the first portion being above the Pectoralis minor; the second portion behind; and the third below that muscle.

Relations.—The **first portion** of the axillary artery is in relation, *in front*, with the clavicular portion of the Pectoralis major, the costo-coracoid membrane, the external anterior thoracic nerve, and the acromio-thoracic and cephalic veins; *behind*, with the first intercostal space, the corresponding Intercostal muscle, the second and a portion of the third digitation of the Serratus magnus, and the posterior thoracic and internal anterior thoracic nerves; on its *outer side*, with the brachial plexus, from which it is separated by a little cellular interval; on its *inner* or thoracic side, with the axillary vein, which overlaps the artery.

Relations of the First Portion of the Axillary Artery.

In front.
Pectoralis major.
Costo-coracoid membrane.
External anterior thoracic nerve.
Acromio-thoracic and cephalic veins.

Outer side.
Brachial plexus.

Inner side.
Axillary vein.

Behind.
First Intercostal space and Intercostal muscle.
Second and third digitations of Serratus magnus.
Posterior thoracic and Internal anterior thoracic nerves.

The **second portion** of the axillary artery lies beyond the Pectoralis minor. It is covered, *in front*, by the Pectoralis major and minor muscles; *behind*, it is separated from the Subscapularis by a cellular interval; on the *inner side* is the axillary vein, separated from the artery by the inner cord of the plexus and the internal anterior thoracic nerve. The brachial plexus of nerves surrounds the artery on three sides, and separates it from direct contact with the vein and adjacent muscles.

Relations of the Second Portion of the Axillary Artery.

In front.
Pectoralis major and minor.

Outer side.
Outer cord of plexus.

Inner side.
Axillary vein.
Inner cord of plexus.
Internal anterior thoracic nerve.

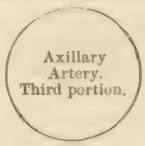
Behind.
Subscapularis.
Posterior cord of plexus.

The **third portion** of the axillary artery lies below the Pectoralis minor. It is in relation, *in front*, with the lower part of the Pectoralis major above, being covered only by the integument and fascia below, where it is crossed by the inner head of the median nerve; *behind*, with the lower part of the Subscapularis and the tendons of the Latissimus dorsi and Teres major; on its *outer side*, with the Coraco-brachialis; on its *inner* or thoracic side, with the axillary vein. The nerves of the brachial plexus bear the following relation to the artery in this part of its course: on the *outer side* is the median nerve, and the musculo-cutaneous for a short distance; on the *inner side*, the ulnar nerve (between the vein and artery) and the lesser internal cutaneous nerve (to the inner side of the vein); in *front* is the internal cutaneous nerve, and *behind*, the musculo-spiral and circumflex, the latter extending only to the lower border of the Subscapularis muscle.

RELATIONS OF THE THIRD PORTION OF THE AXILLARY ARTERY.

In front.
Integument and fascia.
Pectoralis major.
Inner head of median nerve.
Internal cutaneous nerve.

Outer side.
Coraco-brachialis.
Median nerve.
Musculo-cutaneous nerve.



Inner side.
Ulnar nerve.
Axillary vein.
Lesser internal cutaneous nerve.

Behind.
Subscapularis.
Tendons of Latissimus dorsi and Teres major.
Musculo-spiral and circumflex nerves.

Peculiarities.—The axillary artery, in about one case out of every ten, gives off a large branch, which forms either one of the arteries of the forearm or a large muscular trunk. In the first set of cases this artery is most frequently the radial (1 in 33), sometimes the ulnar (1 in 72), and, very rarely, the interosseous (1 in 506). In the second set of cases the trunk has been found to give origin to the subscapular, circumflex, and profunda arteries of the arm. Sometimes only one of the circumflex, or one of the profunda arteries, arose from the trunk. In these cases the brachial plexus surrounded the trunk of the branches and not the main vessel.

Surface Marking.—The course of the axillary artery may be marked out by raising the arm to a right angle with the body and drawing a line from the middle of the clavicle to the point where the tendon of the Pectoralis major crosses the prominence caused by the Coraco-brachialis as it emerges from under cover of the anterior fold of the axilla. The third portion of the artery can be felt pulsating beneath the skin and fascia, at the junction of the anterior with the middle third of the space between the anterior and posterior folds of the axilla, close to the inner border of the Coraco-brachialis muscle.

Surgical Anatomy.—The student, having carefully examined the relations of the axillary artery in its various parts, should now consider in what situation compression of this vessel may be most easily effected, and the best position for the application of a ligature to it when necessary.

Compression of the vessel may be required in the removal of tumors or in amputation of the upper part of the arm; and the only situation in which this can be effectually made is in the lower part of its course; by pressing on it in this situation from within outward against the humerus the circulation may be effectually arrested.

The axillary artery is perhaps more frequently lacerated than any other artery in the body, with the exception of the popliteal, by violent movements of the extremity, especially in those cases where its coats are diseased. It has occasionally been *ruptured* in attempts to reduce old dislocations of the shoulder-joint. This accident is most likely to occur during the preliminary breaking down of adhesions, in consequence of the artery having become fixed to the capsule of the joint. *Aneurism of the axillary artery* is of frequent occurrence, a large percentage of the cases being traumatic in their origin, due to the violence to which the vessel is exposed in the varied, extensive, and often violent movements of the limb.

The application of a ligature to the axillary artery may be required in cases of aneurism of the upper part of the brachial or as a distal operation for aneurism of the sub-

clavian; and there are only two situations in which the vessel can be secured—viz., in the first and in the third parts of its course; for the axillary artery at its central part is so deeply seated, and, at the same time, so closely surrounded with large nerve trunks, that the application of a ligature to it in that situation would be almost impracticable.

In the *third part* of its course the operation is most simple, and may be performed in the following manner: The patient being placed on a bed and the arm separated from the side, with the hand supinated, an incision about two inches in length is made through the integument forming the floor of the axilla, the cut being a little nearer to the anterior than the posterior fold of the axilla. After carefully dissecting through the areolar tissue and fascia, the median nerve and axillary vein are exposed; the former having been displaced to the outer and the latter to the inner side of the arm, the elbow being at the same time bent, so as to relax the structures and facilitate their separation, the ligature may be passed round the artery from the ulnar to the radial side.

This portion of the artery is occasionally crossed by a muscular slip, the *axillary arch*, derived from the Latissimus dorsi, which may mislead the surgeon during an operation. The occasional existence of this muscular fasciculus was spoken of in the description of the muscles. It may easily be recognized by the transverse direction of its fibres.

The *first portion* of the axillary artery may be tied in cases of aneurism encroaching so far upward that a ligature cannot be applied in the lower part of its course. Notwithstanding that this operation has been performed in some few cases, and with success, its performance is attended with much difficulty and danger. The student will remark that in this situation it would be necessary to divide a thick muscle, and, after incising the costo-coracoid membrane, the artery would be exposed at the bottom of a more or less deep space, with the cephalic and axillary veins in such relation with it as must render the application of a ligature to this part of the vessel particularly hazardous. Under such circumstances it is an easier, and at the same time more advisable, operation to tie the subclavian artery in the third part of its course.

The vessel in the first part of its course can best be secured through a curved incision the convexity of which is downward. This incision passes from a point half an inch external to the sterno-clavicular joint to a point half an inch internal to the coracoid process. The limb is to be well abducted and the head inclined to the opposite side, and this incision is carried through the superficial structures, care being taken to avoid the cephalic vein at the outer angle of the incision. The clavicular origin of the Pectoralis major is then divided in the whole extent of the wound. The arm is now to be brought to the side, and the upper edge of the Pectoralis minor defined and drawn downward. The costo-coracoid membrane is to be carefully divided close to the coracoid process, and the axillary sheath exposed; this is to be opened with especial care on account of the vein overlapping the artery. The needle should be passed from below, so as to avoid wounding the vein.

In a case of wound of the vessel the general practice of cutting down upon and tying it above and below the wounded point should be adopted in all cases.

Collateral Circulation after Ligature of the Axillary Artery.—If the artery be tied above the origin of the acromial thoracic, the collateral circulation will be carried on by the same branches as after the ligature of the subclavian; if at a lower point, between the acromial thoracic and subscapular arteries, the latter vessel, by its free anastomoses with the other scapular arteries, branches of the subclavian, will become the chief agent in carrying on the circulation, to which the long thoracic, if it be below the ligature, will materially contribute by its anastomoses with the intercostal and internal mammary arteries. If the point included in the ligature be below the origin of the subscapular artery, it will most probably also be below the origins of the circumflex arteries. The chief agents in restoring the circulation will then be the subscapular and the two circumflex arteries anastomosing with the superior profunda from the brachial, which will be afterward referred to as performing the same office after ligation of the brachial. The cases in which the operation has been performed are few in number, and no published account of dissections of the collateral circulation appears to exist.

Branches.—The branches of the axillary artery are—

From first part { Superior Thoracic. / Acromial Thoracic. } *From second part* { Long Thoracic. / Alar Thoracic. }

From third part { Subscapular. / Posterior Circumflex. / Anterior Circumflex. }

The **Superior Thoracic** (*a. thoracalis suprema*) is a small artery which *arises* from the axillary separately or by a common trunk with the acromial thoracic. Running forward and inward along the upper border of the Pectoralis minor, it

passes between it and the Pectoralis major to the side of the chest. It supplies these muscles and the parietes of the thorax, anastomosing with the internal mammary and intercostal arteries.

The **Acromial Thoracic** or the **Thoracic Axis** (*a. thoracoacromialis*) is a short trunk which *arises* from the forepart of the axillary artery, its origin being generally overlapped by the upper edge of the Pectoralis minor. Projecting forward to the upper border of the Pectoralis minor, it divides into four sets of branches—**thoracic, acromial, descending,** and **clavicular.**

The **Thoracic Branches** (*rami pectorales*), two or three in number, are distributed to the Serratus magnus and Pectoral muscles, anastomosing with the intercostal branches of the internal mammary.

The **Acromial Branch** (*ramus acromialis*) is directed outward toward the acromion, supplying the Deltoid muscle, and anastomosing, on the surface of the acromion, with the suprascapular and posterior circumflex arteries.

The **Descending** or **Humeral Branch** (*ramus deltoideus*) passes in the space between the Pectoralis major and Deltoid, in the same groove as the cephalic vein, and supplies both muscles.

The **Clavicular Branch** (*ramus clavicularis*), which is very small, passes upward to the Subclavius muscle.

The **Long Thoracic** or the **External Mammary** (*a. thoracalis lateralis*) passes downward and inward along the lower border of the Pectoralis minor to the side of the chest, supplying the Serratus magnus, the Pectoral muscles, and mammary gland, and sending branches across the axilla to the axillary glands and Subscapularis; it anastomoses with the internal mammary and intercostal arteries.

The **Alar Thoracic** is a small branch which supplies the glands and areolar tissue of the axilla. Its place is frequently supplied by branches from some of the other thoracic arteries.

The **Subscapular** (*a. subscapularis*), the largest branch of the axillary artery, *arises* opposite the lower border of the Subscapularis muscle, and passes downward and backward along its lower margin to the inferior angle of the scapula, where it anastomoses with the long thoracic and intercostal arteries and with the posterior scapular, a branch of the transversalis colli, from the thyroid axis of the subclavian. About an inch and a half from its origin it gives off a large branch, the **dorsalis scapulæ,** and terminates by supplying branches to the muscles in the neighborhood.

The **Dorsalis Scapulæ** (*a. circumflexa scapulæ*) is given off from the subscapular about an inch and a half from its origin, and is generally larger than the continuation of the vessel. It curves round the axillary border of the scapula, leaving the axilla through the space between the Teres minor above, the Teres major below, and the long head of the Triceps externally (Fig. 409), and enters the infraspinous fossa by passing under cover of the Teres minor, where it anastomoses with the posterior scapular and suprascapular arteries. In its course it gives off two sets of branches: one enters the subscapular fossa beneath the Subscapularis, which it supplies, anastomosing with the posterior scapular and suprascapular arteries; the other is continued along the axillary border of the scapula, between the Teres major and minor, and, at the dorsal surface of the inferior angle of the bone, anastomoses with the posterior scapular. In addition to these, small branches are distributed to the back part of the Deltoid muscle and the long head of the Triceps, anastomosing with an ascending branch of the superior profunda of the brachial.

The **Circumflex Arteries** wind round the surgical neck of the humerus. The **posterior circumflex** (*a. circumflexa humeri posterior*) (Fig. 409), the larger of the two, *arises* from the back part of the axillary opposite the lower border of the Subscapularis muscle, and, passing backward with the circumflex veins and nerve

through the quadrangular space bounded by the Teres major and minor, the scapular head of the Triceps and the humerus, winds round the neck of that bone and is distributed to the Deltoid muscle and shoulder-joint, anastomosing with the anterior circumflex and acromial thoracic arteries, and with the superior profunda branch of the brachial artery. The **anterior circumflex** (*a. circumflexa humeri anterior*) (Figs. 409 and 411), considerably smaller than the preceding, *arises* nearly opposite that vessel from the outer side of the axillary artery. It passes horizontally outward beneath the Coraco-brachialis and short head of the Biceps, lying upon the forepart of the neck of the humerus, and, on reaching the bicipital groove, gives off an ascending branch which passes upward along the groove to supply the head of the bone and the shoulder-joint. The trunk of the vessel is then continued outward beneath the Deltoid, which it supplies, and anastomoses with the posterior circumflex artery.

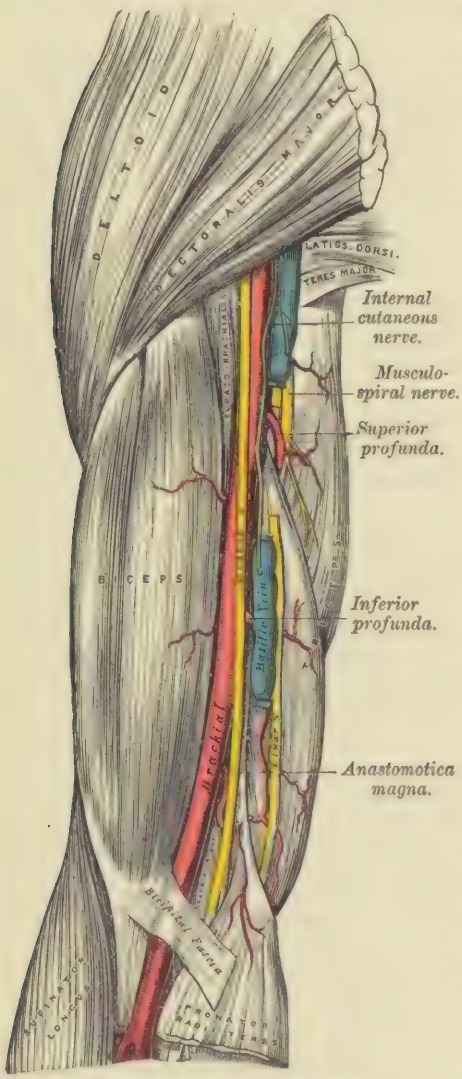


FIG. 412.—The brachial artery.

THE BRACHIAL ARTERY (A. BRACHIALIS) (Fig. 412).

The brachial artery (*a. brachialis*) commences at the lower margin of the tendon of the Teres major, and, passing down the inner and anterior aspect of the arm, terminates about half an inch below the bend of the elbow, where it divides into the **radial** and **ulnar arteries**. At first the brachial artery lies internal to the humerus; but as it passes down the arm it gradually gets in front of the bone, and at the bend of the elbow it lies midway between the two condyles.

Relations.—This artery is superficial throughout its entire extent, being covered, *in front*, by the integument, the superficial and deep fasciæ; the bicipital fascia separates it opposite the elbow from the median basilic vein; the median nerve crosses it at its middle; *behind*, it is separated from the long head of the Triceps by the musculo-spiral nerve and superior profunda artery. It then lies upon the inner head of the Triceps, next upon the insertion of the Coraco-brachialis, and lastly on the Brachialis anticus; by its *outer side*, it is in relation with the commencement of the median nerve and the Coraco-brachialis and Biceps muscles, which overlap the artery to a considerable extent; by its *inner side*, its upper half is in relation with the internal cutaneous and ulnar nerves, its lower half with the median nerve. The basilic vein lies on the inner side of the artery, but is separated from it in the lower part of the arm by the deep fascia. The brachial artery is accompanied by

two venæ comites, which lie in close contact with the artery, being connected together at intervals by short transverse communicating branches.

Plan of the Relations of the Brachial Artery.

In front.

Integument and fasciæ.
Bicipital fascia, median basilic vein.
Median nerve.
Overlapped by Coraco-brachialis and Biceps.

Outer side.
Median nerve (above).
Coraco-brachialis.
Biceps.

Brachial Artery.

Inner side.
Internal cutaneous and Ulnar nerves.
Median nerve (below).
Basilic vein.

Behind.

Triceps (long and inner heads).
Musculo-spiral nerve.
Superior profunda artery.
Coraco-brachialis.
Brachialis anticus.

SURGICAL ANATOMY OF THE BEND OF THE ELBOW.

At the bend of the elbow the brachial artery sinks deeply into a triangular interval, the **antecubital space**, the base of which is directed upward, and may be represented by a line connecting the two condyles of the humerus; the sides are bounded, externally, by the inner edge of the Supinator longus; internally, by the outer margin of the Pronator radii teres; its floor is formed by the Brachialis anticus and Supinator brevis. This space contains the brachial artery with its accompanying veins, the radial and ulnar arteries, the median and musculo-spiral nerves, and the tendon of the Biceps. The brachial artery occupies the middle line of this space, and divides opposite the neck of the radius into the radial and ulnar arteries; it is covered, *in front*, by the integument, the superficial fascia, and the median basilic vein, the vein being separated from direct contact with the artery by the bicipital fascia. *Behind*, it lies on the Brachialis anticus, which separates it from the elbow-joint. The median nerve lies on the inner side of the artery, close to it above, but separated from it below by the coronoid origin of the Pronator radii teres. The tendon of the Biceps lies to the outer side of the space, and the musculo-spiral nerve still more externally, situated upon the Supinator brevis and partly concealed by the Supinator longus.

Peculiarities of the Brachial Artery as Regards its Course.—The brachial artery, accompanied by the median nerve, may leave the inner border of the Biceps and descend toward the inner condyle of the humerus, where it usually curves round a prominence of bone, the supracondylar process. From this process, in most subjects, a fibrous arch is thrown over the artery. The vessel then inclines outward, beneath or through the substance of the Pronator radii teres muscle, to the bend of the elbow. The variation bears considerable analogy to the normal condition of the artery in some of the carnivora: it has been referred to in the description of the humerus (page 180).

As Regards its Division.—Occasionally, the artery is divided for a short distance at its upper part into two trunks, which are united above and below. A similar peculiarity occurs in the main vessel of the lower limb.

The point of bifurcation may be above or below the usual point, the former condition being by far the more frequent. Out of 481 examinations recorded by Mr. Quain, some made on the right and some on the left side of the body, in 386 the artery bifurcated in its normal position. In one case only was the place of division lower than usual, being two or three inches below the elbow-joint. "In 94 cases out of 481, or about 1 in 5¼, there were two arteries instead of one in some part or in the whole of the arm."

There appears, however, to be no correspondence between the arteries of the two arms with respect to their irregular division; for in 61 bodies it occurred on one side only in 43; on both sides, in different positions, in 13; on both sides, in the same position, in 5.

The point of bifurcation takes place at different parts of the arm, being most frequent in the upper part, less so in the lower part, and least so in the middle, the most usual point for the application of a ligature; under any of these circumstances two large arteries would be found in the arm instead of one. The most frequent (in three out of four) of these peculiarities is the high origin of the radial. That artery often arises from the inner side of the brachial, and runs parallel with the main trunk to the elbow, where it crosses it, lying beneath the fascia; or it may perforate the fascia and pass over the artery immediately beneath the integument.

The ulnar sometimes arises from the brachial high up, and accompanies that vessel to the lower part of the arm, and descends toward the inner condyle. In the forearm it generally lies beneath the deep fascia, superficial to the flexor muscles; occasionally between the integument and deep fascia, and very rarely beneath the flexor muscles.

The interosseous artery sometimes arises from the upper part of the brachial or axillary; as it passes down the arm it lies behind the main trunk, and at the bend of the elbow regains its usual position.

In some cases of high origin of the radial the remaining trunk (ulnar interosseous) occasionally passes, together with the median nerve, along the inner margin of the arm to the inner condyle, and then passing from within outward, beneath or through the Pronator radii teres, regains its usual position at the bend of the elbow.

Occasionally the two arteries representing the brachial are connected at the bend of the elbow by a short transverse branch, and are even sometimes reunited.

Sometimes, long slender vessels, **vasa aberrantia**, connect the brachial or axillary arteries with one of the arteries of the forearm or a branch from them. These vessels usually join the radial.

Varieties in Muscular Relations.[1] —The brachial artery is occasionally concealed in some part of its course by muscular or tendinous slips derived from the Coraco-brachialis, Biceps, Brachialis anticus, and Pronator radii teres muscles.

Surface Marking. The direction of the brachial artery is marked by a line drawn along the inner edge of the Biceps from the junction of the anterior and middle thirds of the axillary outlet to the middle of the front of the elbow-joint.

Surgical Anatomy. Compression of the brachial artery is required in cases of amputation and some other operations in the arm and forearm; and it will be observed that it may be effected in almost any part of the course of the artery. If pressure is made in the upper part of the limb, it should be directed from within outward; and if in the lower part, from before backward, as the artery lies on the inner side of the humerus above and in front of the humerus below. The most favorable situation is about the middle of the arm, where it lies on the tendon of the Coraco-brachialis on the inner flat side of the humerus.

The application of a ligature to the brachial artery may be required in case of wound of the vessel and in some cases of wound of the palmar arch. It is also sometimes necessary in cases of aneurism of the brachial, the radial, ulnar, or interosseous arteries. The artery may be secured in any part of its course. The chief guides in determining its position are the surface markings produced by the inner margin of the Coraco-brachialis and Biceps, the known course of the vessel, and its pulsation, which should be carefully felt for before any operation is performed, as the vessel occasionally deviates from its usual position in the arm. In whatever situation the operation is performed, great care is necessary, on account of the extreme thinness of the parts covering the artery and the intimate connection which the vessel has throughout its whole course with important nerves and veins. Sometimes a thin layer of muscular fibre is met with concealing the artery; if such is the case, it must be cut across in order to expose the vessel.

In the upper third of the arm the artery may be exposed in the following manner: The patient being placed supine upon a table, the affected limb should be raised from the side and the hand supinated. An incision about two inches in length should be made on the inner side of the Coraco-brachialis muscle, and the subjacent fascia cautiously divided, so as to avoid wounding the internal cutaneous nerve or basilic vein, which sometimes runs on the surface of the artery as high as the axillary. The fascia having been divided, it should be remembered that the ulnar and internal cutaneous nerves lie on the inner side of the artery, the median on the outer side, the latter nerve being occasionally superficial to the artery in this situation, and that the venæ comites are also in relation with the vessel, one on either side. These being carefully separated, the aneurism needle should be passed round the artery from the inner to the outer side.

If two arteries are present in the arm in consequence of a high division, they are usually placed side by side: and if they are exposed in an operation, the surgeon should endeavor to

[1] See Struther's Anatomical and Physiological Observations.

ascertain, by alternately pressing on each vessel, which of the two communicates with the wound or aneurism, when a ligature may be applied accordingly; or if pulsation or hemorrhage ceases only when both vessels are compressed, both vessels may be tied, as it may be concluded that the two communicate above the seat of disease or are reunited.

It should also be remembered that two arteries may be present in the arm in a case of high division, and that one of these may be found along the inner intermuscular septum, in a line toward the inner condyle of the humerus, or in the usual position of the brachial, but deeply placed beneath the common trunk: a knowledge of these facts will suggest the precautions necessary in every case, and indicate the measures to be adopted when anomalies are met with.

In the middle of the arm the brachial artery may be exposed by making an incision along the inner margin of the Biceps muscle. The forearm being bent so as to relax the muscle, it should be drawn slightly aside, and, the fascia being carefully divided, the median nerve will be exposed lying upon the artery (sometimes beneath); this being drawn inward and the muscle outward, the artery should be separated from its accompanying veins and secured. In this situation the inferior profunda may be mistaken for the main trunk, especially if enlarged, from the collateral circulation having become established; this may be avoided by directing the incision externally toward the Biceps, rather than inward or backward toward the Triceps.

The lower part of the brachial artery is of interest in a surgical point of view, on account of the relation which it bears to the veins most commonly opened in venesection. Of these vessels, the median basilic is the largest and most prominent, and, consequently, the one usually selected for the operation. It should be remembered that this vein runs parallel with the brachial artery, from which it is separated by the bicipital fascia, and that care should be taken in opening the vein not to carry the incision too deeply, so as to endanger the artery.

Collateral Circulation. After the application of a ligature to the brachial artery in the upper third of the arm, the circulation is carried on by branches from the circumflex and subscapular arteries, anastomosing with ascending branches from the superior profunda. If the brachial is tied *below* the origin of the profunda arteries, the circulation is maintained by the branches of the profundæ, anastomosing with the recurrent radial, ulnar, and interosseous arteries. In two cases described by Mr. South,[1] in which the brachial artery had been tied some time previously, in one "a long portion of the artery had been obliterated, and sets of vessels are descending on either side from above the obliteration, to be received into others which ascend in a similar manner from below it. In the other the obliteration is less extensive, and a single curved artery about as big as a crow-quill passes from the upper to the lower open part of the artery."

Branches.—The branches of the brachial artery are—the

Superior Profunda.	Inferior Profunda.
Nutrient.	Anastomotica Magna.
Muscular.	

The **Superior Profunda Artery** (*a. profunda brachii*) *arises* from the inner and back part of the brachial, just below the lower border of the Teres major, and passes backward to the interval between the outer and inner heads of the Triceps muscle; accompanied by the musculo-spiral nerve it winds around the back part of the shaft of the humerus in the spiral groove, between the outer head of the Triceps and the bone, to the outer side of the humerus, where it reaches the external intermuscular septum and divides into two terminal branches. One of these pierces the external intermuscular septum, and descends, in company with the musculo-spiral nerve, to the space between the Brachialis anticus and Supinator longus, where it anastomoses with the recurrent branch of the radial artery; while the other, much the larger of the two, descends along the back of the external intermuscular septum to the back of the elbow-joint, where it anastomoses with the posterior interosseous recurrent, and across the back of the humerus with the posterior ulnar recurrent, the anastomotica magna, and inferior profunda (Fig. 415). The superior profunda supplies the Triceps muscle and gives off a nutrient artery which enters the bone at the upper end of the musculo-spiral groove. Near its commencement it sends off a branch which passes upward between the external and long heads of the Triceps muscle to anastomose with the posterior circumflex

[1] Chelius's Surgery, vol. ii. p. 254. See also White's engravings, referred to by Mr. South, of the anastomosing branches after ligature of the brachial, in White's Cases in Surgery. Porta also gives a case (with drawings) of the circulation after ligature of both brachial and radial (Alterazioni Patoligiche delle Arterie).—Ed. of 15th English edition.

artery, and, while in the groove, a small branch which accompanies a branch of the musculo-spiral nerve through the substance of the Triceps muscle and ends in the Anconeus below the outer condyle of the humerus.

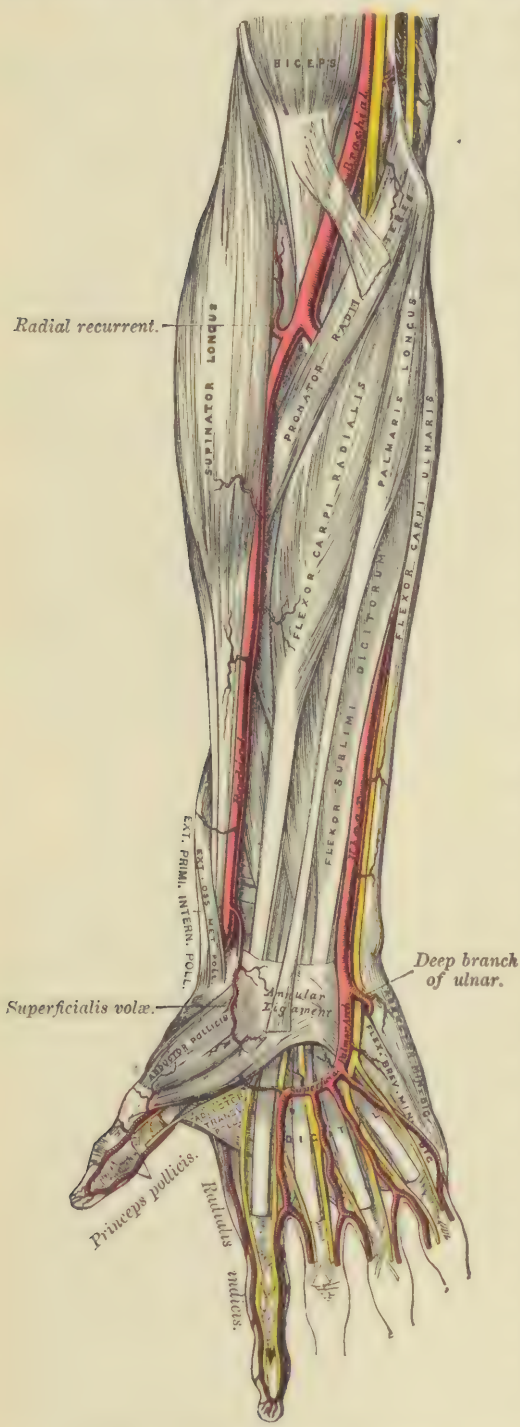

FIG. 413.—The radial and ulnar arteries.

The **Nutrient Artery** (*a. nutricia humeri*) of the shaft of the humerus *arises* from the brachial, about the middle of the arm. Passing downward it enters the nutrient canal of that bone near the insertion of the Coraco-brachialis muscle.

The **Inferior Profunda** (*a. collateralis ulnaris superior*), of small size, *arises* from the brachial, a little below the middle of the arm; piercing the internal intermuscular septum, it descends on the surface of the inner head of the Triceps muscle to the space between the inner condyle and olecranon, accompanied by the ulnar nerve, and terminates by anastomosing with the posterior ulnar recurrent and anastomotica magna. It sometimes supplies a branch to the front of the internal condyle, which anastomoses with the anterior ulnar recurrent.

The **Anastomotica Magna** (*a. collateralis ulnaris inferior*) *arises* from the brachial about two inches above the elbow-joint. It passes transversely inward upon the Brachialis anticus, and, piercing the internal intermuscular septum, winds round the back of the humerus between the Triceps and the bone, forming an arch above the olecranon fossa by its junction with the posterior articular branch of the superior profunda. As this vessel lies on the Brachialis anticus, branches ascend to join the inferior profunda, and others descend in front of the inner condyle to anastomose with the anterior ulnar recurrent. Behind the internal condyle an offset is given off which anastomoses with the inferior profunda and posterior ulnar recurrent arteries and supplies the Triceps.

The **Muscular** (*rami musculares*) are three or four large branches, which are distributed to the muscles in the course of the artery. They supply the Coraco-brachialis, Biceps, and Brachialis anticus muscles.

The Anastomosis around the Elbow-joint (Fig. 415).—The vessels engaged in this anastomosis may be conveniently divided into those situated *in front* and *behind* the internal and external condyles. The branches anastomosing *in front* of the internal condyle are the anastomotica magna, the anterior ulnar recurrent, and the anterior terminal branch of the inferior profunda. Those *behind* the internal condyle are the anastomotica magna, the posterior ulnar recurrent, and the posterior terminal branch of the inferior profunda. The branches anastomosing *in front* of the external condyle are the radial recurrent and the anterior terminal branch of the superior profunda. Those *behind* the external condyle (perhaps more properly described as being situated between the external condyle and the olecranon) are the anastomotica magna, the interosseous recurrent, and the posterior terminal branch of the superior profunda. There is also a large arch of anastomosis above the olecranon, formed by the interosseous recurrent, joining with the anastomotica magna and posterior ulnar recurrent.

From this description it will be observed that the anastomotica magna is the vessel most engaged, the only part of the anastomosis in which it is not employed being that *in front* of the external condyle.

The Radial Artery (A. Radialis) (Figs. 413, 414).

The radial artery appears, from its direction, to be the continuation of the brachial, but in size it is smaller than the ulnar. It commences at the bifurcation of the brachial, just below the bend of the elbow, and passes alongthe radial side of the forearm to the wrist; it then winds backward, round the outer side of the carpus, beneath the extensor tendons of the thumb, to the upper end of the space between the metacarpal bones of the thumb and index finger, and finally passes forward, between the two heads of the First dorsal interosseous muscle, into the palm of the hand, where it crosses the metacarpal bones to the ulnar border of the hand, to form the **deep palmar arch**. At its termination it inosculates with the deep branch of the ulnar artery. The relations of this vessel may thus be conveniently divided into three parts—viz., in the forearm, at the back of the wrist, and in the hand.

Relations.—In the forearm this vessel extends from opposite the neck of the radius to the forepart of the styloid process, being placed to the inner side of the shaft of the bone above and in front of it below. It is overlapped in the upper part of its course by the fleshy belly of the Supinator longus muscle; throughout the rest of its course it is superficial, being covered by the integument, the superficial and deep fasciæ. In its course downward it lies upon the tendon of the Biceps, the Supinator brevis, the Pronator radii teres, the radial origin of the Flexor sublimis digitorum, the Flexor longus pollicis, the Pronator quadratus, and the lower extremity of the radius. In the upper third of its course it lies between the Supinator longus and the Pronator radii teres; in the lower two-thirds, between the tendons of the Supinator longus and the Flexor carpi radialis. The radial nerve lies close to the outer side of the artery in the middle third of its course, and some filaments of the musculo-cutaneous nerve, after piercing the deep fascia, run along the lower part of the artery as it winds round the wrist. The vessel is accompanied by venæ comites throughout its whole course.

PLAN OF THE RELATIONS OF THE RADIAL ARTERY IN THE FOREARM.

Pronator radii teres.
Flexor sublimis digitorum.
Flexor longus pollicis.
Pronator quadratus.
Radius.

At the wrist, as it winds round the outer side of the carpus from the styloid process to the first interosseous space, it lies upon the external lateral ligament, and then upon the scaphoid bone and trapezium, being covered by the extensor tendons of the thumb, subcutaneous veins, some filaments of the radial nerve, and the integument. It is accompanied by two veins and a filament of the musculo-cutaneous nerve.

In the hand it passes from the upper end of the first interosseous space, between the heads of the Abductor indicis or First dorsal interosseous muscle, transversely across the palm, to the base of the metacarpal bone of the little finger, where it inosculates with the communicating branch from the ulnar artery, forming the **deep palmar arch.**

The Deep Palmar Arch (*arcus volaris profundus*) (Fig. 414).—It lies upon the carpal extremities of the metacarpal bones and the Interossei muscles, being covered by the Adductor obliquus pollicis, the flexor tendons of the fingers, the Lumbricales, the Opponens, and Flexor brevis minimi digiti. Alongside of it is the deep branch of the ulnar nerve, but running in the opposite direction; that is to say, from within outward. The branches of the deep palmar arch are the palmar interosseous, perforating and palmar recurrent vessels (page 660).

Peculiarities.—The origin of the radial artery, according to Quain, is, in nearly one case in eight, higher than usual; more frequently arising from the axillary or upper part of the brachial than from the lower part of this vessel. The variations in the position of this vessel in the arm and at the bend of the elbow have been already mentioned. In the forearm it deviates less frequently from its position than the ulnar. It has been found lying over the fascia instead of beneath it. It has also been observed on the surface of the Supinator longus, instead of under its inner border; and in turning round the wrist it has been seen lying over, instead of beneath, the extensor tendons of the thumb.

Surface Marking.—The position of the radial artery in the forearm is represented by a line drawn from the outer border of the tendon of the Biceps in the centre of the hollow in front of the elbow-joint with a straight course to the inner side of the forepart of the styloid process of the radius.

Surgical Anatomy.—The radial artery is much exposed to injury in its lower third, and is frequently wounded by the hand being driven through a pane of glass, by the slipping of a knife or chisel held in the other hand, and similar accidents. The injury is often followed by a *traumatic aneurism*, for which the operation of extirpating or laying open the sac after securing the vessel above and below is required.

The operation of *tying the radial artery* is required in cases of wounds either of its trunk or of some of its branches, or for aneurism; and it will be observed that the vessel may be exposed in any part of its course through the forearm without the division of any muscular fibres. The operation in the middle or inferior third of the forearm is easily performed, but in the upper third, near the elbow, it is attended with some difficulty, from the greater depth of the vessel and from its being overlapped by the Supinator longus muscle.

To tie the artery in the upper third an incision three inches in length should be made through the integument, in a line drawn from the centre of the bend of the elbow to the front of the styloid process of the radius, avoiding the branches of the median vein; the fascia of the arm being divided and the Supinator longus drawn a little outward, the artery will be exposed. The venæ comites should be carefully separated from the vessel, and the ligature passed from the radial to the ulnar side.

In the middle third of the forearm the artery may be exposed by making an incision of similar length on the inner margin of the Supinator longus. In this situation the radial nerve lies in close relation with the outer side of the artery, and should, as well as the veins, be carefully avoided.

In the lower third the artery is easily secured by dividing the integument and fascia in the interval between the tendons of the Supinator longus and Flexor carpi radialis muscles.

Branches (Figs. 413, 414, and 415).—The branches of the radial artery may be divided into three groups, corresponding with the three regions in which the vessel is situated.

- *In the Forearm*
  - Radial Recurrent.
  - Muscular.
  - Anterior Radial Carpal.
  - Superficialis Volæ.
- *Wrist*
  - Posterior Radial Carpal.
  - Metacarpal.
  - Dorsales Pollicis.
  - Dorsalis Indicis.
- *Hand*
  - Princeps Pollicis.
  - Radialis Indicis.
  - Perforating.
  - Palmar Interosseous.
  - Palmar Recurrent.

The **Radial Recurrent** (*a. recurrens radialis*) (Fig. 414) is given off immediately below the elbow. It ascends between the branches of the musculo-spiral nerve lying on the Supinator brevis, and then between the Supinator longus and Brachialis anticus, supplying these muscles and the elbow-joint, and anastomosing with the terminal branches of the superior profunda.

The **Muscular Branches** (*rami musculares*) are distributed to the muscles on the radial side of the forearm.

The **Anterior Radial Carpal** (*ramus carpeus volaris*) (Fig. 414) is a small vessel which *arises* from the radial artery near the lower border of the Pronator quadratus, and, running inward in front of the radius, anastomoses with the anterior carpal branch of the ulnar artery. In this way an arterial anastomosis, the **anterior carpal arch** (*rete carpi volare*), is formed in front of the wrist; it is joined by branches from the anterior interosseous above, and by recurrent branches from the deep palmar arch below, and gives off branches which descend to supply the articulations of the wrist and carpus.

The **Superficialis Volæ** (*ramus volaris superficialis*) (Fig. 414) *arises* from the radial artery, just where this vessel is about to wind round the wrist. Running forward, it passes between, occasionally over, the muscles of the thumb, which it supplies, and sometimes anastomoses with the palmar portion of the ulnar artery, completing the superficial palmar arch. This vessel varies considerably in size: usually it is very small, and terminates in the muscles of the thumb; sometimes it is as large as the continuation of the radial.

The **Posterior Radial Carpal** (*ramus carpeus dorsalis*) (Fig. 415) is a small vessel which *arises* from the radial artery beneath the extensor tendons of the thumb; crossing the carpus transversely to the inner border of the hand, it anastomoses with the posterior carpal branch of the ulnar, forming the **posterior carpal arch** (*rete carpi dorsale*), which is joined by the termination of the anterior interosseous artery. From this arch are given off descending branches, the **dorsal interosseous arteries** (*aa. metacarpeæ dorsales*) for the second, third, and fourth interosseous spaces, which run forward on the Second, Third, and Fourth dorsal interossei muscles, and divide into **dorsal digital branches** (*aa. digitales dorsales*), which supply the adjacent sides of the index, middle, ring, and little fingers respectively, communicating with the digital arteries of the superficial palmar arch. The dorsal interosseous arteries anastomose with the perforating branches from the deep palmar arch (*rami perforantes*).

The **Dorsales Pollicis** (Fig. 415) are two vessels which run along the sides of the dorsal aspect of the thumb. They *arise* separately, or occasionally by a common trunk, near the base of the first metacarpal bone.

The **Dorsalis Indicis** (Fig. 415), also a small branch, runs along the radial side of the back of the index finger, sending a few branches to the Abductor indicis.

The **Princeps Pollicis** (*a. princeps pollicis*) (Fig. 414) *arises* from the radial just as it turns inward to the deep part of the hand; it descends between the Abductor indicis and Adductor obliquu pollicis, then between the Adductor transversus pollicis and Adductor obliquus pollicis, along the ulnar side of the metacarpal bone of the thumb, to the base of the first phalanx, where it divides into two branches, which run along the sides of the palmar aspect of the thumb, and form an arch on the palmar surface of the last phalanx, from which branches are distributed to the integument and pulp of the thumb.

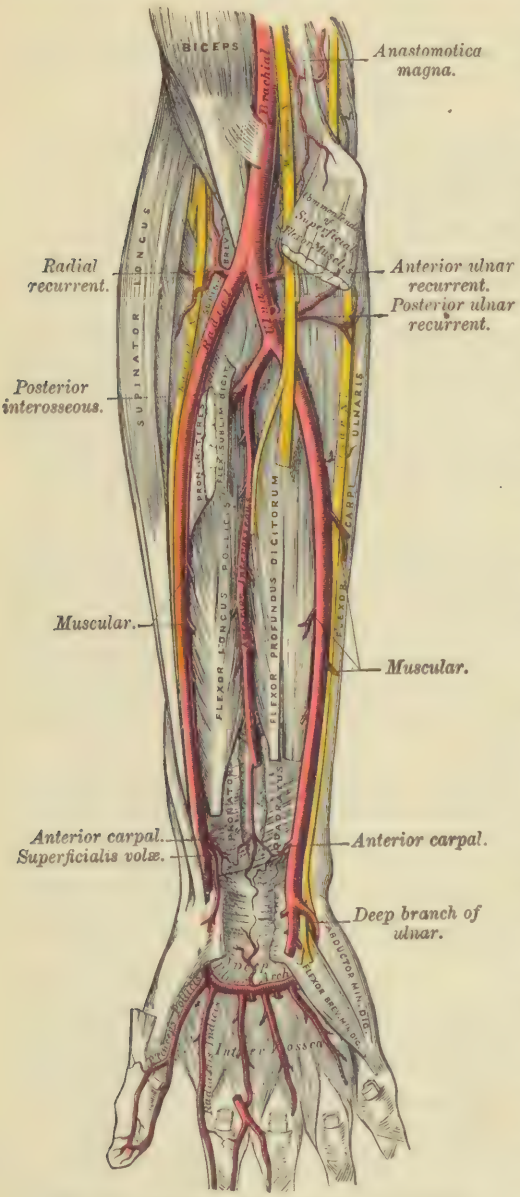

FIG. 414.—Ulnar and radial arteries. Deep view.

The **Radialis Indicis** (*a. volaris indicis radialis*) (Fig. 414) *arises* close to the preceding, descends between the Abductor indicis and Adductor transversus pollicis, and runs along the radial side of the index finger to its extremity, where it anastomoses with the collateral digital artery from the superficial palmar arch. At the lower border of the Adductor transversus pollicis this vessel anastomoses with the princeps pollicis, and gives a communicating branch to the superficial palmar arch.

The **Perforating Arteries** (*rami perforantes*) (Fig. 414), three in number, pass backward from the deep palmar arch between the heads of the last three Dorsal interossei muscles, to inosculate with the dorsal interosseous arteries.

The **Palmar Interosseous** (*aa. metacarpeæ volares*) (Fig. 414), three or four in number, *arise* from the convexity of the deep palmar arch; they run forward upon the Interossei muscles, and anastomose at the clefts of the fingers with the digital branches of the superficial arch.

The **Palmar Recurrent Branches** *arise* from the concavity of the deep palmar arch. They pass upward in front of the wrist, supplying the carpal articulations and anastomosing with the anterior carpal arch.

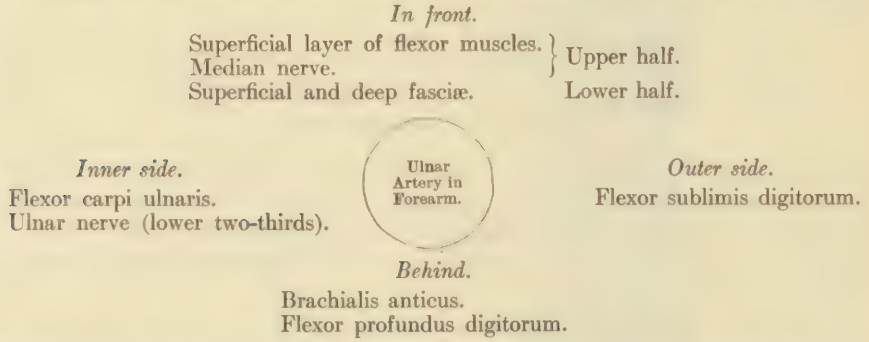
The Ulnar Artery (A. Ulnaris) (Figs. 413, 414).

The ulnar artery, the larger of the two terminal branches of the brachial, commences a little below the bend of the elbow, and crosses obliquely the

inner side of the forearm to the commencement of its lower half; it then runs along its ulnar border to the wrist, crosses the annular ligament on the radial side of the pisiform bone, and immediately beyond this bone divides into two branches which enter into the formation of the superficial and deep palmar arches.

Relations. In the Forearm.—In its *upper half* it is deeply seated, being covered by all the superficial Flexor muscles, excepting the Flexor carpi ulnaris; the median nerve is in relation with the inner side of the artery for about an inch and then crosses the vessel, being separated from it by the deep head of the Pronator radii teres; it lies upon the Brachialis anticus and Flexor profundus digitorum muscles. In the *lower half* of the forearm it lies upon the Flexor profundus, being covered by the integument, the superficial and deep fasciæ, and is placed between the Flexor carpi ulnaris and Flexor sublimis digitorum muscles. It is accompanied by two venæ comites; the ulnar nerve lies on its inner side for the lower two-thirds of its extent, and a small branch from the nerve descends on the lower part of the vessel to the palm of the hand.

PLAN OF RELATIONS OF THE ULNAR ARTERY IN THE FOREARM.



At the wrist (Fig. 413) the ulnar artery is covered by the integument and fascia, and lies upon the anterior annular ligament. On its inner side is the pisiform bone. The ulnar nerve lies at the inner side, and somewhat behind the artery; here the nerve and artery are crossed by a band of fibres, which extends from the pisiform bone to the anterior annular ligament.

Peculiarities.—The ulnar artery has been found to vary in its origin nearly in the proportion of one in thirteen cases, in one case arising lower than usual, about two or three inches below the elbow, and in all other cases much higher, the brachial being a more frequent source or origin than the axillary.

Variations in the position of this vessel are more frequent than in the radial. When its origin is normal the course of the vessel is rarely changed. When it arises high up it is almost invariably superficial to the Flexor muscles in the forearm, lying commonly beneath the fascia, more rarely between the fascia and integument. In a few cases its position was subcutaneous in the upper part of the forearm, subaponeurotic in the lower part.

Surface Marking.—On account of the curved direction of the ulnar artery the line on the surface of the body which indicates its course is somewhat complicated. First, draw a line from the front of the internal condyle of the humerus to the radial side of the pisiform bone; the lower two-thirds of this line represents the course of the middle and lower third of the ulnar artery. Secondly, draw a line from the centre of the antecubital space to the junction of the upper and middle third of the first line; this represents the course of the upper third of the artery.

Surgical Anatomy.—The application of a ligature to this vessel is required in cases of wound of the artery or of its branches, or in consequence of aneurism. In the upper half of the forearm the artery is deeply seated beneath the superficial flexor muscles, and the application of a ligature in this situation is attended with some difficulty. An incision is to be made in the course of a line drawn from the front of the internal condyle of the humerus to the outer side

of the pisiform bone, so that the centre of the incision is three fingers' breadth below the internal condyle. The skin and superficial fascia having been divided and the deep fascia exposed, the white line which separates the Flexor carpi ulnaris from the other flexor muscles is to be sought for, and the fascia incised in this line. The Flexor carpi ulnaris is now to be carefully separated from the other muscles, when the ulnar nerve will be exposed, and must be drawn aside. Some little distance below the nerve the artery will be found accompanied by its venæ comites, and it may be ligatured by passing the needle from within outward. In the middle and lower third of the forearm this vessel may be easily secured by making an incision on the radial side of the tendon of the Flexor carpi ulnaris: the deep fascia being divided, and the Flexor carpi ulnaris and its companion muscle, the Flexor sublimis, being separated from each other, the vessel will be exposed, accompanied by its venæ comites, the ulnar nerve lying on its inner side. The veins being separated from the artery, the ligature should be passed from the ulnar to the radial side, taking care to avoid the ulnar nerve.

Branches (Figs. 413, 414, and 415).—The branches of the ulnar artery may be arranged in the following groups:

Forearm	Anterior Ulnar Recurrent.
	Posterior Ulnar Recurrent.
	Interosseous: Anterior Interosseous. / Posterior Interosseous.
	Muscular.
Wrist	Anterior Carpal.
	Posterior Carpal.
Hand	Deep Palmar or Communicating.
	Superficial Palmar Arch.

The **Anterior Ulnar Recurrent** (*a. recurrentes ulnaris anterior*) (Fig. 414) *arises* immediately below the elbow-joint, passes upward and inward between the Brachialis anticus and Pronator radii teres, supplies twigs to those muscles, and, in front, of the inner condyle anastomoses with the anastomotica magna and inferior profunda.

The **Posterior Ulnar Recurrent** (*a. recurrentes ulnaris posterior*) (Figs. 414 and 415) is much larger, and *arises* somewhat lower than the preceding. It passes backward and inward, beneath the Flexor sublimis, and ascends behind the inner condyle of the humerus. In the interval between this process and the olecranon it lies beneath the Flexor carpi ulnaris, and ascending between the heads of that muscle, in relation with the ulnar nerve; it supplies the neighboring muscles and joint, and anastomoses with the inferior profunda, anastomotica magna, and interosseous recurrent arteries.

The **Interosseous Artery** (*a. interossea communis*) (Fig. 414) is a short trunk about half an inch in length, and of considerable size, which *arises* immediately, below the tuberosity of the radius, and, passing backward to the upper border of the interosseous membrane, divides into two branches, the **anterior** and **posterior interosseous.**

The **Anterior Interosseous** (*a. interossea volaris*) (Fig. 414) passes down the forearm on the anterior surface of the interosseous membrane, to which it is connected by a thin aponeurotic arch. It is accompanied by the interosseous branch of the median nerve, and overlapped by the contiguous margins of the Flexor profundus digitorum and Flexor longus pollicis muscles, giving off in this situation muscular branches and the nutrient arteries of the radius and ulna. At the upper border of the Pronator quadratus a branch, **anterior communicating artery,** descends beneath the muscle to anastomose in front of the carpus with the anterior carpal arch. The continuation of the artery passes behind the Pronator quadratus, and, piercing the interosseous membrane, reaches the back of the forearm, and anastomoses with the posterior interosseous artery (Fig. 415). It then descends to the back of the wrist to join the posterior carpal arch. The anterior interosseous gives

off a long, slender branch, the **median artery** or **artery comes nervi mediana** (*a. mediana*), which accompanies the median nerve and gives offsets to its substance. This artery is sometimes much enlarged, and accompanies the nerve into the palm of the hand.

The **Posterior Interosseous Artery** (*a. interossea dorsalis*) (Figs. 414 and 415) passes backward through the interval between the oblique ligament and the upper border of the interosseous membrane. It appears between the contiguous borders of the Supinator brevis and the Extensor ossis metacarpi pollicis, and runs down the back part of the forearm, between the superficial and deep layer of muscles, to both of which it distributes branches. At the lower part of the forearm it anastomoses with the termination of the anterior interosseous artery. Then, continuing its course over the head of the ulna, it joins the posterior carpal branch of the ulnar artery. This artery gives off, near its origin, the **interosseous recurrent** branch.

The **interosseous recurrent artery** (*a. interossea recurrens*) (Fig. 415) is a large vessel which ascends to the interval between the external condyle and olecranon, on or through the fibres of the Supinator brevis, but beneath the Anconeus, anastomosing with a branch from the superior profunda, and with the posterior ulnar recurrent and anastomotica magna.

The **Muscular Branches** (*rami musculares*) are distributed to the muscles along the ulnar side of the forearm.

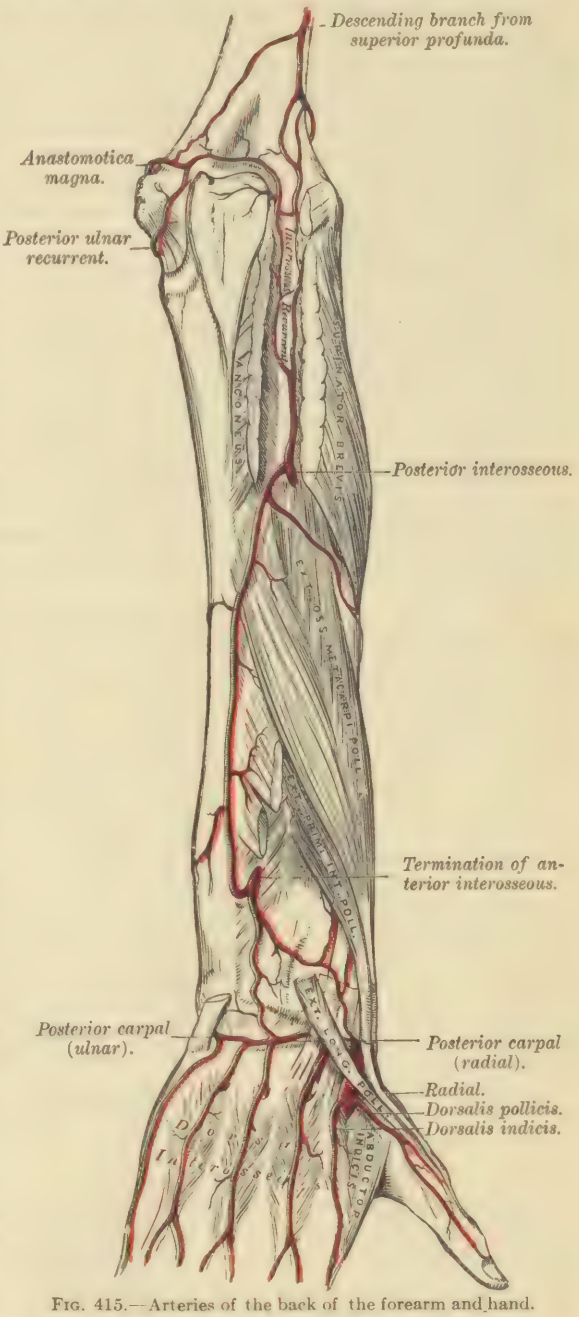


FIG. 415.—Arteries of the back of the forearm and hand.

The **Anterior Carpal** (*ramus carpeus volaris*) (Fig. 414) is a small vessel which crosses the front of the carpus beneath the tendons of the Flexor profundus, and inosculates with a corresponding branch of the radial artery.

The **Posterior Carpal** (*ramus carpeus dorsalis*) (Fig. 415) *arises* immediately above the pisiform bone, and winds backward beneath the tendon of the Flexor carpi ulnaris: it passes across the dorsal surface of the carpus beneath the extensor

tendons, anastomosing with a corresponding branch of the radial artery, and forming the **posterior carpal arch** (*rete carpi dorsale*) (Fig. 415). Immediately after its origin it gives off a small branch which runs along the ulnar side of the metacarpal bone of the little finger, forming one of the **metacarpal arteries**, and supplies the ulnar side of the dorsal surface of the little finger.

The **Deep** or **Communicating Branch** to the **Deep Palmar Arch** (*ramus volaris profundus*) (Fig. 414) passes deeply inward between the Abductor minimi digiti and Flexor brevis minimi digiti, near their origins; it anastomoses with the termination of the radial artery, completing the deep palmar arch.

The continuation of the trunk of the ulnar artery in the hand forms the greater part of the superficial palmar arch.

The **Superficial Palmar Arch** (*arcus volaris superficialis*) (Fig. 413) is formed by the ulnar artery in the hand, and is completed on the outer side by this vessel anastomosing with a branch from the radialis indicis, though sometimes the arch is completed by the ulnar anastomosing with the superficialis volæ or the princeps pollicis of the radial artery. The arch passes across the palm, describing a curve, with its convexity forward, to the space between the ball of the thumb and the index finger, where the above-mentioned anastomosis takes place.

Relations.—The superficial palmar arch is covered by the skin, the Palmaris brevis, and the palmar fascia. It lies upon the annular ligament, the Flexor brevis of the little finger, the tendons of the superficial flexor of the fingers, and the divisions of the median and ulnar nerves.

PLAN OF THE RELATIONS OF THE SUPERFICIAL PALMAR ARCH.

Divisions of median and ulnar nerves.

Branches.—The branches of the Superficial Palmar Arch are the

Digital.

The **Digital Branches** (*aa. digitales volares communes*) (Fig. 413), four in number, are given off from the convexity of the superficial palmar arch. They supply the ulnar side of the little finger and the adjoining sides of the little, ring, middle, and index fingers, the radial side of the index finger and thumb being supplied from the radial artery. The digital arteries at first lie superficial to the flexor tendons, but as they pass forward with the digital nerves to the clefts between the fingers they lie between them, and are there joined by the interosseous branches from the deep palmar arch. The digital arteries on the sides of the fingers lie beneath the digital nerves; and about the middle of the last phalanx the two branches for each finger form an arch, from the convexity of which branches pass to supply the pulp of the finger.

Surface Marking.—The superficial palmar arch is represented by a curved line, starting from the outer side of the pisiform bone and carried downward as far as the middle third of the palm, and then curved outward on a level with the upper end of the cleft between the thumb and index finger. The deep palmar arch is situated about half an inch nearer to the carpus.

Surgical Anatomy.—*Wounds of the palmar arches* are of special interest, and are always difficult to deal with. When the superficial arch is wounded it is generally possible, by enlarging the wound if necessary, to secure the vessel and tie it; or in cases where it is found impossible to encircle the vessel with a ligature, a pair of hæmostatic forceps may be applied and left on for twenty-four or forty-eight hours. Wounds of the deep arch are not so easily dealt with. It may be possible to secure the vessel by ligature or by forcipressure forceps, which may be left on; or, failing in this, the wound may be carefully plugged with gauze and an outside dressing carefully bandaged on. The plug should be allowed to remain untouched for three or four days. In wounds of the deep palmar arch a ligature may be applied to the bleeding points from the dorsum of the hand by resection of the upper part of the third metacarpal bone. It is useless in these cases to ligate one of the arteries of the forearm alone, and indeed simultaneous ligation of both radial and ulnar arteries above the wrist is often unsuccessful, on account of the anastomosis carried on by the carpal arches. Therefore, if unable to ligate the divided ends of the arch, upon the failure of pressure to arrest hemorrhage, it is expedient to apply a ligature to the brachial artery.

ARTERIES OF THE TRUNK.

THE DESCENDING AORTA (Figs. 416, 417).

The descending aorta is divided into two portions, the **thoracic** and **abdominal**, in correspondence with the two great cavities of the trunk in which it is situated.

The Thoracic Aorta (Aorta Thoracalis) (Fig. 416).

The thoracic aorta commences at the lower border of the fourth dorsal vertebra, on the left side, and terminates at the aortic opening in the Diaphragm, in front of the lower border of the last dorsal vertebra. At its commencement it is situated on the left side of the spine; it approaches the median line as it descends, and at its termination lies directly in front of the spinal column. The direction of this vessel being influenced by the spine, upon which it rests, it describes a curve which is concave forward in the dorsal region. As the branches given off from it are small, the diminution in the size of the vessel is inconsiderable. It is contained in the back part of the posterior mediastinum.

Relations.—It is in relation, *in front*, from above downward, with the root of the left lung, the pericardium, the œsophagus, and the Diaphragm: *behind*, with the vertebral column and the venæ azygos minor; on the *right side*, with the vena azygos major and thoracic duct; on the *left side*, with the left pleura and lung. The œsophagus, with its accompanying nerves, lies on the right side of the aorta *above;* but at the lower part of the thorax it gets in front of the aorta, and close to the Diaphragm is situated to its left side.

The aorta is occasionally found to be obliterated at a particular spot—viz., at the junction of the arch with the thoracic aorta just below the ductus arteriosus. Whether this is the result of disease or of congenital malformation is immaterial to our present purpose; it affords an interesting opportunity of observing the resources of the collateral circulation. The course of the anastomosing vessels, by which the blood is brought from the upper to the lower part of the artery, will be found well described in an account of two cases in the *Pathological Transactions*, vols. viii. and x. In the former (p. 162) Mr. Sydney Jones thus sums up the detailed description of the anastomosing vessels: "The principal communications by which the circulation was carried on, were—Firstly, the internal mammary, anastomosing with the intercostal arteries, with the phrenic of the abdominal aorta by means of the musculo-phrenic and comes nervi phrenici, and largely with the deep epigastric. Secondly, the superior intercostal, anastomosing anteriorly by means of a large branch with the first aortic intercostal, and posteriorly with the posterior branch of the same artery. Thirdly, the inferior thyroid, by means of a branch about the size of an ordinary radial, formed a communication with the first aortic intercostal. Fourthly, the transversalis colli, by means of very large communications with the posterior branches of the intercostals. Fifthly, the branches (of the subclavian and axillary) going to the side of the chest were large, and anastomosed freely with the lateral branches of the intercostals." In the second case also (vol. x. p. 97) Mr. Wood describes the anastomoses in a somewhat similar manner, adding the remark that "the blood which was brought into the aorta through the anastomoses of the intercostal arteries appeared to be expended principally in supplying the abdomen and pelvis, while the supply to the lower extremities had passed through the internal mammary and epigastrics."

Surgical Anatomy.—The student should now consider the effects likely to be produced by *aneurism of the thoracic aorta*, a disease of common occurrence. When we consider the great depth of the vessel from the surface and the number of important structures which surround it on every side, it may easily be conceived what a variety of obscure symptoms may arise from disease of this part of the arterial system, and how they may be liable to be mistaken for those of other affections. Aneurism of the thoracic aorta most usually extends backward along the left side of the spine, producing absorption of the bodies of the vertebræ, with curvature of the spine; whilst the irritation or pressure on the cord will give rise to pain, either in the chest, back, or loins, with radiating pain in the left upper intercostal spaces, from pressure on the intercostal nerves; at the same time the tumor may project backward on each side of the spine, beneath the integument, as a pulsating swelling, simulating abscess connected with diseased bone, or it may displace the œsophagus and compress the lung on one or the other side. If the tumor extend forward, it may press upon and displace the heart, giving rise to palpitation and other symptoms of disease of that organ; or it may displace, or even compress, the œsophagus, causing pain and difficulty of swallowing, as in stricture of that tube; and ultimately even open into it by ulceration, producing fatal hemorrhage. If the disease extends to the right side, it may press upon the thoracic duct; or it may burst into the pleural cavity or into the trachea or lung; and, lastly, it may open into the posterior mediastinum.

Branches.—Branches of the thoracic aorta supply the thoracic viscera. They are known as **rami viscerales**. The rami viscerales are the **bronchial, œsophageal, pericardial,** and **mediastinal arteries**. Other branches of the thoracic aorta supply the walls of the chest. They are known as **rami parietales** or **intercostal arteries**.

The **Bronchial Arteries** (*aa. bronchiales*) are the nutrient vessels of the lungs, and vary in number, size, and origin. That of the right side arises from the first aortic intercostal, or by a common trunk with the left bronchial from the front of the thoracic aorta. Those of the left side, usually two in number, arise from the thoracic aorta, one a little lower than the other. Each vessel is directed to the back part of the corresponding bronchus along which it runs, dividing and subdividing along the bronchial tube, supplying them, the cellular tissue of the lungs, the bronchial glands, and the œsophagus.

The **Œsophageal Arteries** (*aa. œsophageæ*), usually four or five in number, *arise* from the front of the aorta, and pass obliquely downward to the œsophagus, forming a chain of anastomoses along that tube, anastomosing with the œsophageal branches of the inferior thyroid arteries above, and with ascending branches from the phrenic and gastric arteries below.

The **Pericardiac** (*rami pericardiaci*) are a few small vessels, irregular in their origin, distributed to the pericardium.

The **Posterior Mediastinal Arteries** (*rami mediastinales*) are numerous small vessels which supply the glands and loose areolar tissue in the mediastinum.

The lower mediastinal branches are known as the **superior phrenic arteries** (*aa. phrenicæ superiores*), and are distributed to the posterior portion of the Diaphragm.

The **Intercostal Arteries** (*aa. intercostales*) (Fig. 416) *arise* from the back of the aorta. The aortic intercostals are usually nine in number on each side, the two superior intercostal spaces being supplied by the superior intercostal, a branch of the subclavian. The second space usually receives a considerable branch from the first aortic intercostal, which joins with the branch from the superior intercostal of the subclavian. The branch which runs along the lower border of the last rib is named the **subcostal artery**. The right intercostals are longer than the left, on account of the position of the aorta on the left side of the spine: they pass outward, across the bodies of the vertebræ, to the intercostal spaces, being covered by the pleura, the œsophagus, thoracic duct, sympathetic nerve, and the vena azygos major; the left, passing outward, are crossed by the sympathetic; the upper two are also crossed by the superior intercostal vein, the lower by the azygos minor veins. In each intercostal space the artery passes outward, the External intercostal muscle being behind, the pleura and a thin fascia being in front. It then passes between the two layers of Intercostal muscles, and, having ascended obliquely to the lower border of the rib above it, is continued forward in the groove on its lower border and anastomoses with the anterior intercostal branches of the internal mammary. The first aortic intercostal anastomoses with the superior intercostal branch of the subclavian, and the last three intercostals pass between the abdominal muscles, inosculating with the epigastric in front and with the phrenic and lumbar arteries. Each intercostal artery is accompanied by a vein and nerve, the former being above, and the latter below, except in the upper intercostal spaces, where the nerve is at first above the artery. The arteries are protected from pressure during the action of the Intercostal muscles by fibrous arches thrown across, and attached by each extremity to the bone. The lower intercostal arteries are continued anteriorly from the intercostal spaces into the abdominal wall, except the *subcostal*, which lies throughout its whole course in the abdominal wall, since it is placed below the last rib. They pass behind the costal cartilages between the Internal oblique and Transversalis muscle to the sheath of the Rectus, where they anastomose with the internal mammary and the deep epigastric arteries. Behind, the subcostal artery anastomoses with the first lumbar artery.

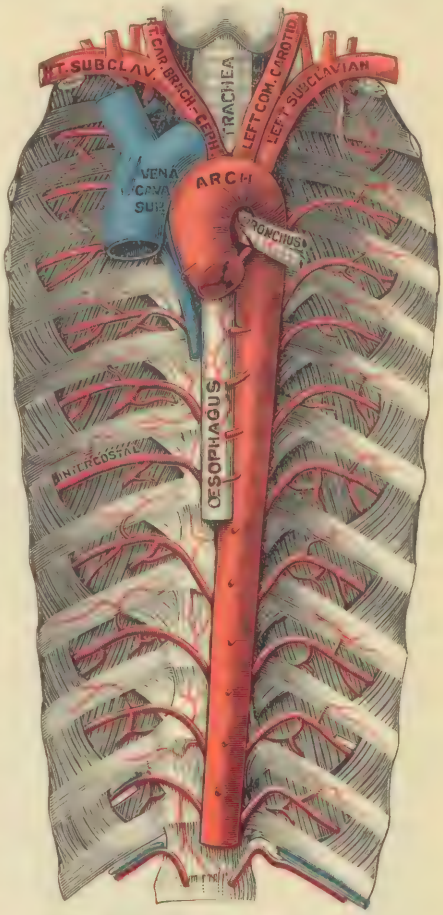

FIG. 416.—Thoracic aorta. (Testut.)

Branches.—Each intercostal artery gives off numerous muscular branches (*rami musculares*).

Lateral cutaneous.
Posterior or dorsal branch.
Muscular.
Collateral intercostal.

Lateral Cutaneous Branches (*rami cutanei laterales*) come off from each intercostal and take a similar course to that of the lateral cutaneous branch of the intercostal nerve. These arteries are distributed to the walls of the chest and to the mammary gland (*rami mammarii laterales*).

Small branches pass to the mammary gland through the fourth, fifth, and sixth interspaces (*rami mammarii medialis*), and to the skin to the inner side of the nipple (*rami cutanei arteriores*).

The portion of the artery considered here as the prolongation of the main trunk is called by Spalteholz and others the **anterior branch** (*ramus anterior*).

The **Posterior** or **Dorsal Branch** (*ramus posterior*) of each intercostal artery passes backward to the inner side of the anterior costo-transverse ligament, and divides into an **external branch** (*ramus cutaneus lateralis*), and an **internal branch** (*ramus cutaneus medialis*), which are distributed to the muscles and integument of the back. **Muscular branches** (*rami musculares*) are given off by the dorsal branch soon after its origin. A **spinal branch** (*ramus spinalis*) comes off from the dorsal branch of the intercostal. It traverses the vertebral arches and enters the spinal canal through the intervertebral foramen, is distributed to the spinal cord and its membranes, and to the bodies of the vertebræ in the same manner as the lateral spinal branches from the vertebral. It gives off three branches, the **neural,** which accompanies the spinal nerve-roots, and is distributed to the membranes of the spinal cord. The **post-central branch** divides into ascending and descending branches, which, anastomosing with similar branches above and below, form a series of vertical arches in the back of the bodies of the vertebræ.[1] The **prelaminar branch** is distributed to "the posterior wall of the spinal canal."[2]

The **Collateral Intercostal Branch** comes off from the intercostal artery near the angle of the rib, and descends to the upper border of the rib below, along which it courses to anastomose with the anterior intercostal branch of the internal mammary or its branch, the musculo-phrenic.

The two lower intercostals on each side have not constant collateral branches. Even when present they are of small size and end in the wall of the abdomen. Each collateral intercostal branch gives off muscular branches.

Surgical Anatomy.—The position of the intercostal vessels should be borne in mind in performing the operation of *paracentesis thoracis*. The puncture should never be made nearer the middle line posteriorly than the angle of the rib, as the artery crosses the space internal to this point. In the lateral portion of the chest, where the puncture is usually made, the artery lies at the upper part of the intercostal space, and therefore the puncture should be made just above the upper border of the rib forming the lower boundary of the space.

The Abdominal Aorta (Aorta Abdominalis) (Fig. 417).

The abdominal aorta commences at the aortic opening of the Diaphragm, in front of the lower border of the body of the last dorsal vertebra, and, descending a little to the left side of the vertebral column, terminates on the body of the fourth lumbar vertebra, commonly a little to the left of the middle line,[3] where it divides into the two common iliac arteries. It diminishes rapidly in size, in consequence of the many large branches which it gives off. As it lies upon the bodies of the vertebræ, the curve which it describes is convex forward, the greatest convexity corresponding to the third lumbar vertebra, which is a little above and to the left side of the umbilicus.

[1] Cunningham's Text-book of Anatomy. [2] Ibid.

[3] Lord Lister, having accurately examined 30 bodies in order to ascertain the exact point of termination of this vessel, found it "either absolutely, or almost absolutely, mesial in 15, while in 13 it deviated more or less to the left, and in 2 was slightly to the right" (System of Surgery, edited by T. Holmes, 2d ed., vol. v. p. 652). —Ed. of 15th English edition.

Relations.—It is covered, *in front*, by the lesser omentum and stomach, behind which are the branches of the cœliac axis and the solar plexus; below these, by the splenic vein, the pancreas, the left renal vein, the transverse portion of the duodenum, the mesentery, and aortic plexus. *Behind*, it is separated from the lumbar vertebræ and intervening disks by the anterior common ligament and left

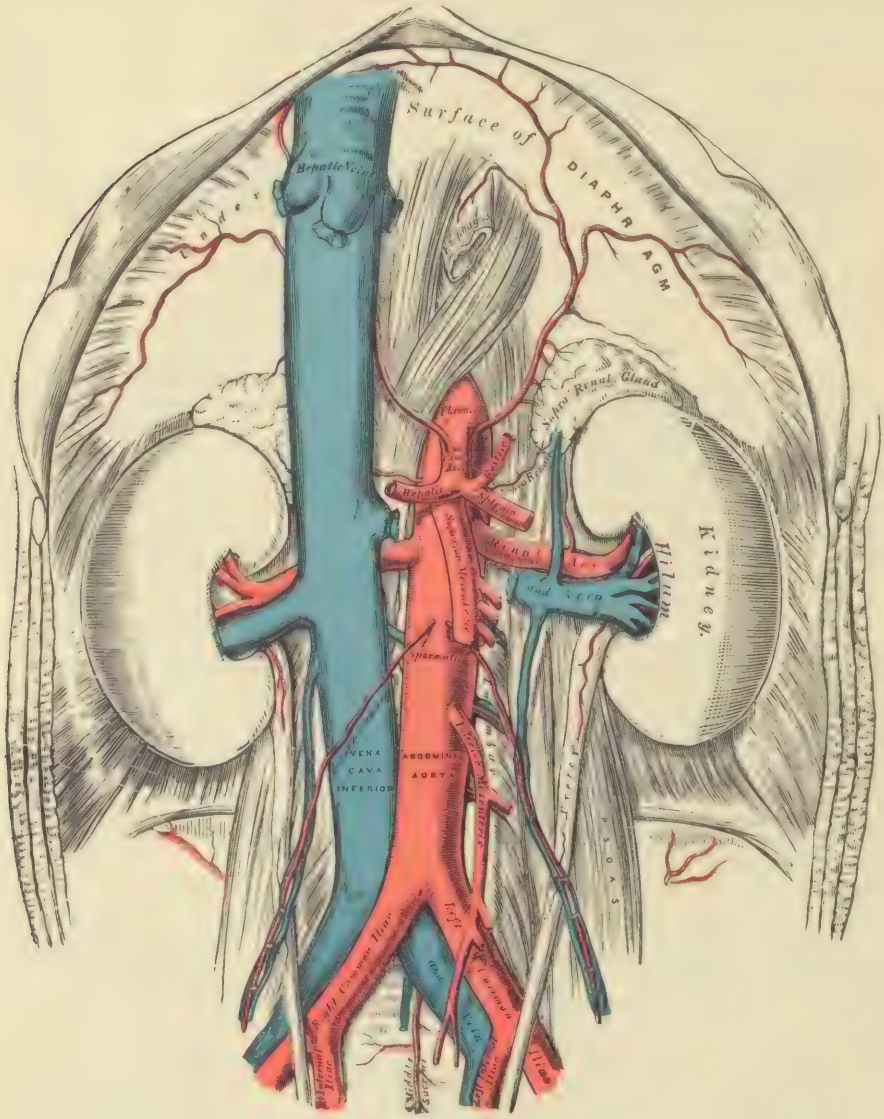

FIG. 417.—The abdominal aorta and its branches.

lumbar veins. On the *right side* it is in relation with the inferior vena cava (the right crus of the Diaphragm being interposed above), the vena azygos major, thoracic duct, and right semilunar ganglion; on the *left side*, with the sympathetic nerve and left semilunar ganglion.

Surface Marking.—In order to map out the abdominal aorta on the surface of the abdomen, a line must be drawn from the middle line of the body, on a level with the distal extremity of the seventh costal cartilage, downward and slightly to the left, so that it just skirts the umbilicus, to a zone drawn round the body opposite the highest point of the crest of the ilium. This point is generally half an inch below and to the left of the umbilicus, but as the position of this structure varies with the obesity of the individual, it is not a reliable landmark as to the situation of the bifurcation of the aorta.

Surgical Anatomy.—*Aneurisms of the abdominal aorta* near the cœliac axis communicate in nearly equal proportion with the anterior and posterior parts of the artery.

When an aneurismal sac is connected with the back part of the abdominal aorta, it usually produces absorption of the bodies of the vertebræ, and forms a pulsating tumor that presents itself in the left hypochondriac or epigastric regions, and is accompanied by symptoms of disturbance in the alimentary canal. Pain is invariably present, and is usually of two kinds—a fixed and constant pain in the back, caused by the tumor pressing on or displacing the branches of the solar plexus and splanchnic nerves; and a sharp lancinating pain, radiating along those branches of the lumbar nerves which are pressed on by the tumor; hence the pain in the loins, the testes, the hypogastrium, and in the lower limb (usually of the left side). This form of aneurism usually bursts into the peritoneal cavity or behind the peritoneum in the left hypochondriac region; or it may form a large aneurismal sac, extending down as low as Poupart's ligament; hemorrhage in these cases being generally very extensive, but slowly produced, and not rapidly fatal.

When an aneurismal sac is connected with the front of the aorta near the cœliac axis it forms a pulsating tumor in the left hypochondriac or epigastric regions, usually attended with symptoms of disturbance of the alimentary canal, as sickness, dyspepsia, or constipation, and is accompanied by pain, which is constant, but nearly always fixed in the loins, epigastrium, or some part of the abdomen; the radiating pain being rare, as the lumbar nerves are seldom implicated. This form of aneurism may burst into the peritoneal cavity or behind the peritoneum, between the layers of the mesentery, or, more rarely, into the duodenum; it seldom extends backward so as to affect the spine.

The abdominal aorta has been tied 15 times, and although none of the patients permanently recovered, still, as Prof. Keen's lived 48 days, the possibility of the re-establishment of the circulation is proved. In the lower animals this artery has been often successfully tied. The vessel may be reached in several ways. In the original operation, performed by Sir A. Cooper, in 1817, an incision was made in the linea alba, the peritoneum opened in front, the finger carried down amongst the intestines toward the spine, the peritoneum again opened behind by scratching through the mesentery, and the vessel thus reached. Or either of the operations described below for securing the common iliac artery may, by extending the dissection a sufficient distance upward, be made use of to expose the aorta. The chief difficulty in the dead subject consists in isolating the artery in consequence of its great depth; but in the living subject the embarrassment resulting from the proximity of the aneurismal tumor, and the great probability of disease in the vessel itself, add to the dangers and difficulties of this formidable operation so greatly that it is very doubtful whether it ought ever to be performed.

The collateral circulation would be carried on by the anastomosis between the internal mam-

mary and the deep epigastric; by the free communication between the superior and inferior mesenterics if the ligature were placed above the latter vessel; or by the anastomosis between the inferior mesenteric and the internal pudic when (as is more common) the point of ligature is below the origin of the inferior mesenteric; and possibly by the anastomoses of the lumbar arteries with the branches of the internal iliac.

During an amputation at the hip the circulation through the abdominal aorta may be commanded by an assistant, who throws the entire weight of his body upon his rigidly extended forearm, the fist of which lies directly upon the patient's aorta (Macewen's method). The abdominal tourniquet is no longer used, as modern methods enable the surgeon to do a practically bloodless hip-joint amputation (Wyeth's method, Senn's method, McBurney's method).

Branches (Fig. 417).—The branches of the abdominal aorta are—the

Phrenic		Superior Mesenteric.	Ovarian in female.
Cœliac Axis	Gastric.	Suprarenal.	Inferior Mesenteric.
	Hepatic.	Renal.	Lumbar.
	Splenic.	Spermatic in male.	Sacra Media.

Branches.—The branches of the abdominal aorta may be divided into two sets: 1. Those supplying the **viscera** (*rami viscerales*). 2. Those distributed to the walls of the **abdomen** (*rami parietales*).

Visceral Branches.	*Parietal Branches.*
Cœliac Axis: Gastric.	
Cœliac Axis: Hepatic.	Inferior Phrenic.
Cœliac Axis: Splenic.	Lumbar.
Superior Mesenteric.	Sacra Media.
Inferior Mesenteric.	
Suprarenal.	
Renal.	
Spermatic or Ovarian.	

To expose the cœliac axis raise the liver, draw down the stomach, and then tear through the layers of the lesser omentum.

The Cœliac Axis or Artery (*a. cœliaca*) (Figs. 417, 418, and 419).—The cœliac axis is a short thick trunk, about half an inch in length, which *arises* from the aorta, close to the margin of the opening in the Diaphragm, behind the posterior parietal peritoneum, above the pancreas, and below the twelfth dorsal vertebra, and, passing nearly horizontally forward (in the erect posture), divides into three large branches, the **gastric**, **hepatic**, and **splenic**, occasionally giving off one of the phrenic arteries.

Relations.—It is covered by the lesser omentum. On the *right side* it is in relation with the right semilunar ganglion and the lobus Spigelii; on the *left side*, with the left semilunar ganglion and cardiac end of the stomach. *Below*, it rests upon the upper border of the pancreas.

The **Gastric** or **Coronary Artery** (*a. gastrica sinistra*) (Figs. 418 and 419), the smallest of the three branches of the cœliac axis, passes upward and to the left side, behind the peritoneum of the lesser peritoneal cavity, raising this portion of the peritoneum into a fold, known as the **left** or **secondary pancreatico-gastric fold**. It continues this course until it nearly reaches the lesser curvature of the stomach just below the cardia. It then turns to the front and curves forward to the cardiac orifice of the stomach, distributing branches to the œsophagus which anastomose with the aortic œsophageal arteries; others supply the cardiac end of the stomach, inosculating with branches of the splenic artery; it then passes from left to right, along and upon the lesser curvature of the stomach and beneath the peritoneum to the pylorus, lying in its course between the layers of the lesser omentum, and sometimes dividing into two vessels, which run along each side

of the lesser curvature. One vascular arch gives branches to the anterior wall of the stomach and the other to the posterior wall (Fig. 886), and both give them to the lesser omentum or the single artery gives branches to both surfaces of the organ and to the lesser omentum: at its termination it anastomoses with the pyloric branch or the two pyloric branches of the hepatic. It gives off **gastric branches** to both the anterior and posterior surfaces of the stomach, branches to the lesser omentum, **a small hepatic branch**, to the left lobe of the liver and **œsophageal branches** (*rami œsophagei*) which anastomose with œsophageal branches from the thoracic aorta and the inferior phrenic.

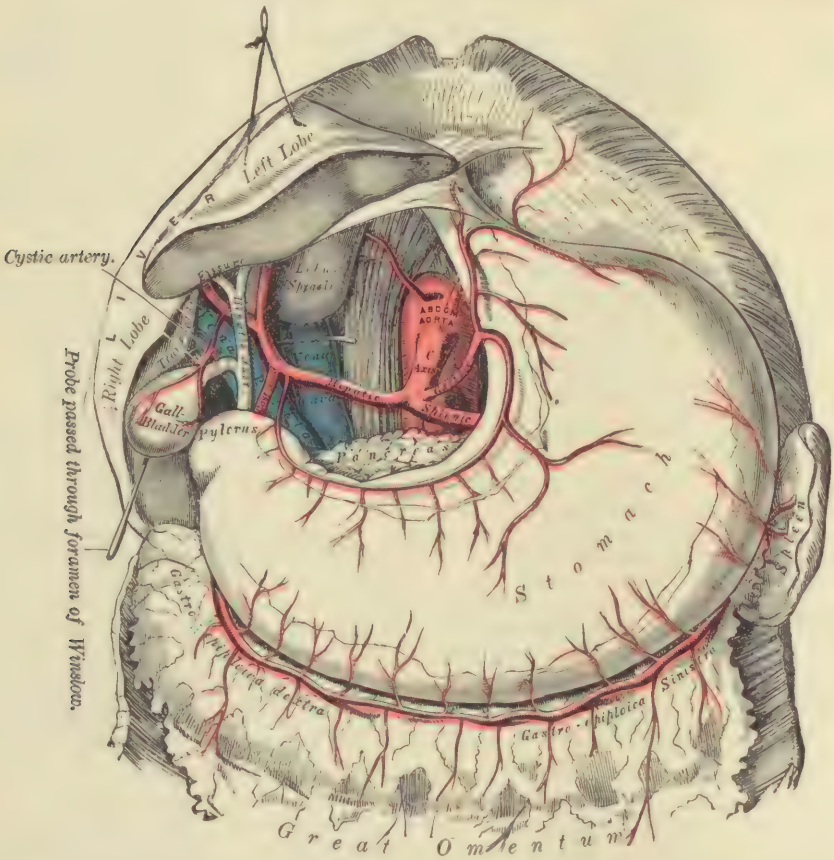

Fig. 418.—The cœliac axis and its branches, the liver having been raised and the lesser omentum removed.

The **Hepatic Artery** (*a. hepatica*) (Figs. 418 and 419) in the adult is intermediate in size between the gastric and splenic; in the fœtus it is the largest of the three branches of the cœliac axis. It is first directed forward and to the right, in the right pancreatico-gastric fold, to the upper margin of the pyloric end of the stomach, forming the lower boundary of the foramen of Winslow. It then passes upward between the layers of the lesser omentum, and in front of the foramen of Winslow, to the transverse fissure of the liver, where it divides into two branches, right and left, which supply the corresponding lobes of that organ, accompanying the ramifications of the vena portæ and hepatic duct. The hepatic artery, in its course along the right border of the lesser omentum, is in relation with the ductus communis choledochus and portal veins, the duct lying to the right of the artery and the vena portæ behind.

Its **branches** (Figs. 418 and 419) are—the

Pyloric.

Gastro-duodenalis { Gastro-epiploica Dextra. / Pancreatico-duodenalis Superior

Cystic.

The **pyloric** or **superior pyloric branch** (*a. gastrica dextra*) arises from the hepatic, above the pylorus, descends between the layers of the lesser omentum to the pyloric end of the stomach, and passes from right to left along its lesser curvature, supplying it with branches and inosculating with the gastric branches of the coronary artery. The vessel often divides into two vascular arches to anastomose with two vascular arches from the gastric.

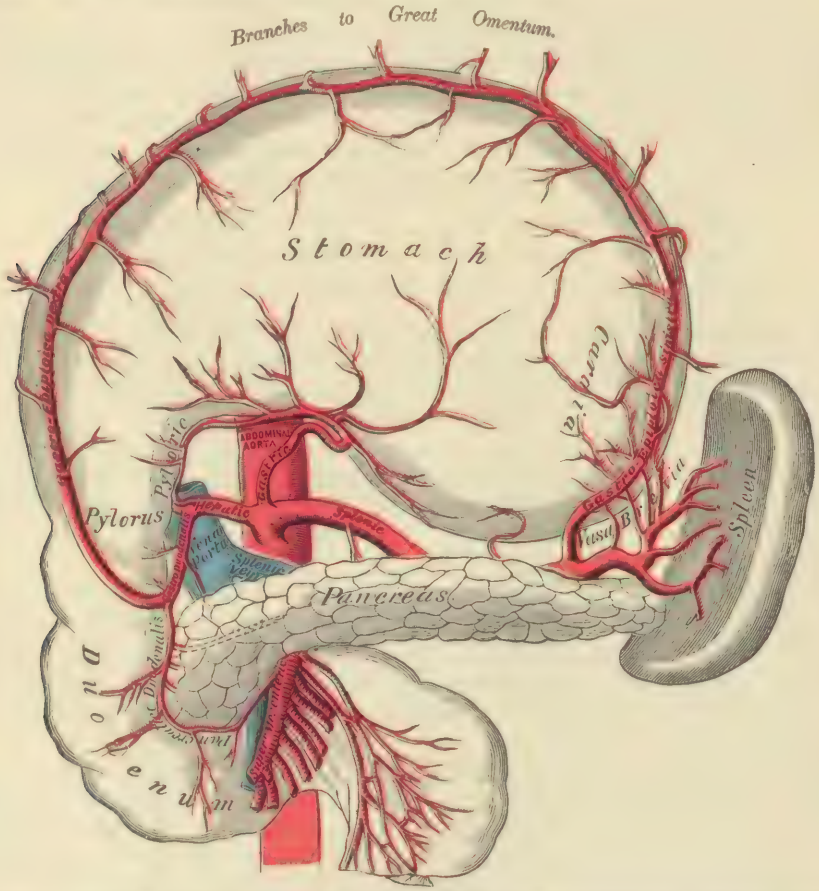

FIG. 419.—The cœliac axis and its branches, the stomach having been raised and the transverse mesocolon removed (semi-diagrammatic).

The **gastro-duodenalis** (Fig. 419) is a short but large branch, which descends near the pylorus, behind the first portion of the duodenum, and divides at the lower border of this viscus into two branches, the **gastro-epiploica dextra** and the **pancreatico-duodenalis superior**. Previous to its division, it gives off two or three small **inferior pyloric branches**, to the pyloric end of the stomach and pancreas.

The **gastro-epiploica dextra** runs from right to left along but distinctly below the greater curvature of the stomach, between the layers of the great omentum, anastomosing about the middle of the lower border of the stomach with the gastro-epiploica sinistra from the splenic artery. This vessel gives off numerous branches,

some of which ascend to supply both surfaces of the stomach, whilst others descend to supply the great omentum (*rami epiploici*).

The **pancreatico-duodenalis superior** descends between the contiguous margins of the duodenum and pancreas. It supplies the head of the pancreas by means of the *rami pancreatica*, and the duodenum by means of the *rami duodenalis*, and anastomoses with the inferior pancreatico-duodenal branch of the superior mesenteric artery and with the pancreatic branches of the splenic.

The **cystic artery** (*a. cystica*) (Fig. 418), usually a branch of the right hepatic, passes downward and forward along the cystic duct to the gall-bladder, and divides into two branches, one of which ramifies on its free surface beneath the peritoneum, the other between the gall-bladder and the substance of the liver.

The **Splenic Artery** (*a. lienalis*) (Figs. 418 and 419), in the adult, is the largest of the three branches of the cœliac axis, and is remarkable for the extreme tortuosity of its course. It passes horizontally to the left side, behind the peritoneum and along the upper border of the pancreas, accompanied by the splenic vein, which lies below it, and on arriving near the spleen divides into branches, some of which enter the hilum of that organ to be distributed to its structure, whilst others are distributed to the pancreas and great end of the stomach. Its **branches** are—the

Pancreaticæ Parvæ.	Gastric (Vasa Brevia).
Pancreatica Magna.	Gastro-epiploica Sinistra.
Rami Lienalis.	

The **pancreatic branches** (*rami pancreatici*) are numerous small branches derived from the splenic as it runs behind the upper border of the pancreas, supplying its middle and left parts. One of these, larger than the rest, is given off from the splenic near the left extremity of the pancreas; it runs from left to right near the posterior surface of the gland, following the course of the pancreatic duct, and is called the **pancreatica magna**. The others are called the *pancreaticæ parvæ*. These vessels anastomose with the pancreatic branches of the pancreatico-duodenal arteries, derived from the hepatic on the one hand and superior mesenteric on the other.

The **gastric branches** or **vasa brevia** (*aa. gastricæ breves*) consists of from five to seven small branches, which arise either from the termination of the splenic artery or from its terminal branches, and, passing from left to right, between the layers of the gastro-splenic omentum, are distributed to the great curvature of the stomach, anastomosing with branches of the gastric and gastro-epiploica sinistra arteries.

The **gastro-epiploica sinistra,** the largest branch of the splenic, runs from left to right along but distinctly below the great curvature of the stomach, between the layers of the great omentum, and anastomoses with the gastro-epiploica dextra. In its course it distributes several branches to the stomach, which ascend upon both surfaces; others descend to supply the omentum.

The **rami lienales** leave the splenic artery in the hilum and pass into the spleen.

Surgical Anatomy.—The operation of *pylorectomy* can be made an almost bloodless procedure by tying the gastric, the pyloric, and the right and left gastro-epiploic arteries. "The gastric is doubly tied about one inch below the cardiac orifice at a point where it joins the lesser curvature and is divided between the ligatures. The superior pyloric is doubly tied and divided. The fingers are passed beneath the pylorus, raising the gastro-colic omentum from the transverse mesocolon, and in this way safe ligation behind the pylorus of the right gastro-epiploic artery, or in most cases its parent vessel, the gastro-duodenal, is secured. The left gastro-epiploic is now tied at an appropriate point, and the necessary amount of gastro-colic omentum doubly tied and cut."[1]

[1] William J. Mayo. Annals of Surgery, March, 1904.

The Superior Mesenteric Artery (*a. mesenterica superior*) (Figs. 417 and 420).—The superior mesenteric artery supplies the whole length of the small intestine, except the first part of the duodenum; it also supplies the cæcum and the ascending and transverse colon; it is a vessel of large size, *arising* from the forepart of the aorta about a quarter of an inch below the cœliac axis; being covered at its origin by the splenic vein and pancreas. It passes forward, between the pancreas and the transverse portion of the duodenum, crosses in front of this portion of the intestine, and descends between the layers of the mesentery to the right iliac fossa, where, considerably diminished in size, it anastomoses with one of its own branches—viz., the ileo-colic. In its course it forms an arch, the convexity of which is directed forward and downward to the left side, the concavity backward and upward to the right. It is accompanied by the superior mesenteric vein, and is surrounded by the superior mesenteric plexus of nerves.

In order to expose the superior mesenteric artery raise the great omentum and transverse colon, draw down the small intestines, and cut through the peritoneum where the transverse mesocolon and mesentery join; the artery will then be exposed just as it issues from beneath the lower border of the pancreas

Branches.—Its branches are—the

Inferior Pancreatico-duodenal.	Ileo-colic.
Vasa Intestini Tenuis.	Right Colic.
Middle Colic.	

The **Inferior Pancreatico-duodenal** (*a. pancreaticoduodenalis inferior*) is given off from the superior mesenteric, or from its first intestinal branch behind the pancreas. It courses to the right between the head of the pancreas and duodenum, and then ascends to anastomose with the superior pancreatico-duodenal artery. It distributes branches to the head of the pancreas and to the transverse and descending portions of the duodenum.

The **Vasa Intestini Tenuis** (*aa. intestinales*) arise from the convex side of the superior mesenteric artery. They are usually from twelve to fifteen in number, and are distributed to the jejunum (*aa. jejunales*) and ileum (*aa. ileæ*). They run parallel with one another between the layers of the mesentery, each vessel dividing into two branches, which unite with similar branches on each side, forming a series of arches the convexities of which are directed toward the intestine. From this first set of arches branches arise, which again unite with similar branches from either side, and thus a second series of arches is formed; and from these latter, a third and a fourth, or even a fifth, series of arches is constituted, diminishing in size the nearer they approach the intestine. From the terminal arches numerous small straight vessels arise which encircle the intestine, upon which they are distributed, ramifying between its coats. Throughout their course small branches are given off to the glands and other structures between the layers of the mesentery. (See the description of the vascular loops in the section upon the Intestines. The form and arrangement of the loops have been studied by Monks, of Boston.)

The **Ileo-colic Artery** (*a. ileocolica*) is the lowest branch given off from the concavity of the superior mesenteric artery. It descends between the layers of the mesentery to the right iliac fossa, where it divides into two branches. Of these, the inferior division inosculates with the termination of the superior mesenteric artery, forming with it an arch, from the convexity of which branches proceed to supply the termination of the ileum, the cæcum, the vermiform appendix, and the ileo-cæcal valve. The superior division inosculates with the colica dextra and supplies the commencement of the colon.

The **Right Colic Artery** (*a. colica dextra*) *arises* from about the middle of the concavity of the superior mesenteric artery, and, passing behind the peritoneum

to the middle of the ascending colon, divides into two branches—a **descending branch,** which inosculates with the ileo-colic, and an **ascending branch,** which anastomoses with the colica media. These branches form arches, from the convexity of which vessels are distributed to the ascending colon. The branches of this vessel are covered with peritoneum only on their anterior aspect.

The **Middle Colic Artery** (*a. colica media*) *arises* from the upper part of the concavity of the superior mesenteric, and, passing forward between the layers of the transverse mesocolon, divides into two branches, the one on the right side inosculating with the colica dextra; that on the left side, with the colica sinistra, a branch of the inferior mesenteric. From the arches formed by their inosculation branches are distributed to the transverse colon. The branches of this vessel lie between the two layers of the transverse mesocolon.

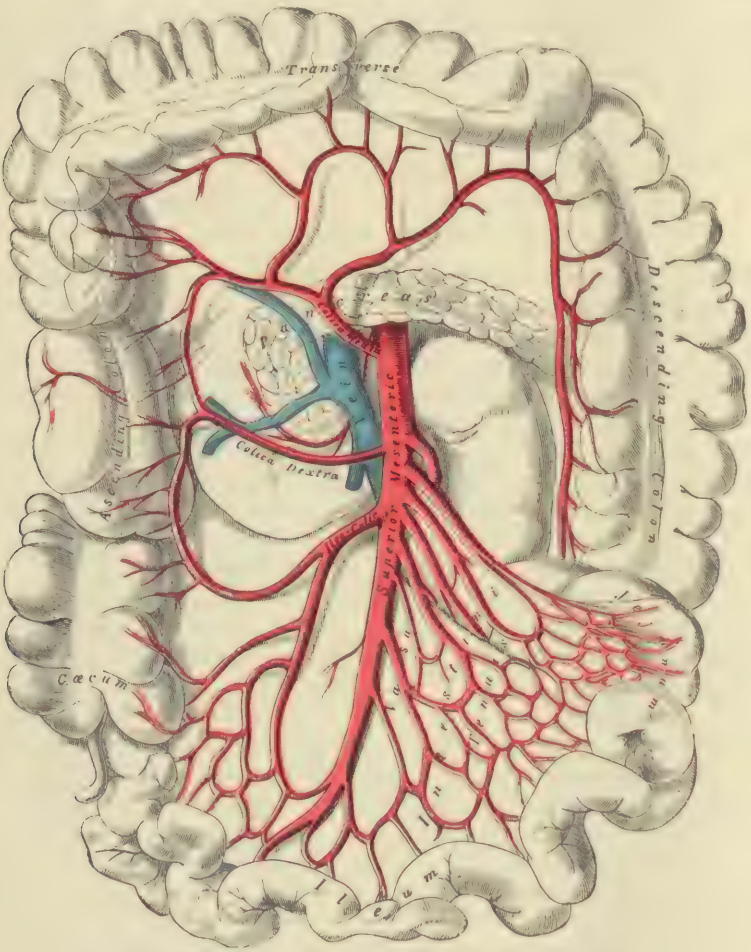

FIG. 420.—The superior mesenteric artery and its branches.

Blood-supply of the Right Iliac Fossa.—The descending branch of the right colic artery by anastomosing with the ascending branch of the ileo-colic artery forms a vascular loop. The union of the descending branch of the ileo-colic artery with the terminal vessel of the superior mesenteric artery forms another vascular loop. These two loops give off secondary loops, and from the secondary loops come the vessels which supply the appendix, the cæcum, and the lower end of the ileum. The branch which goes to the appendix is called the **appendicular artery** (*a. appendicularis*). If there is a distinct meso-appendix the artery passes along its unattached edge. If there is a rudimentary meso-appendix or no meso-appendix the artery

usually lies upon the appendix from base to tip beneath the peritoneal covering. In females the appendix may receive an additional vessel from the ovarian, which vessel lies in the appendiculo-ovarian ligament.

The Inferior Mesenteric Artery (*a. mesenterica inferior*) (Figs. 417 and 421).—The inferior mesenteric artery supplies the descending colon, the sigmoid flexure of the colon and the greater part of the rectum. It is smaller than the superior mesenteric, and *arises* from the left side of the aorta, between one and two inches above the division of that vessel into the common iliacs. It passes downward to the left iliac fossa, and then descends between the layers of the mesorectum,

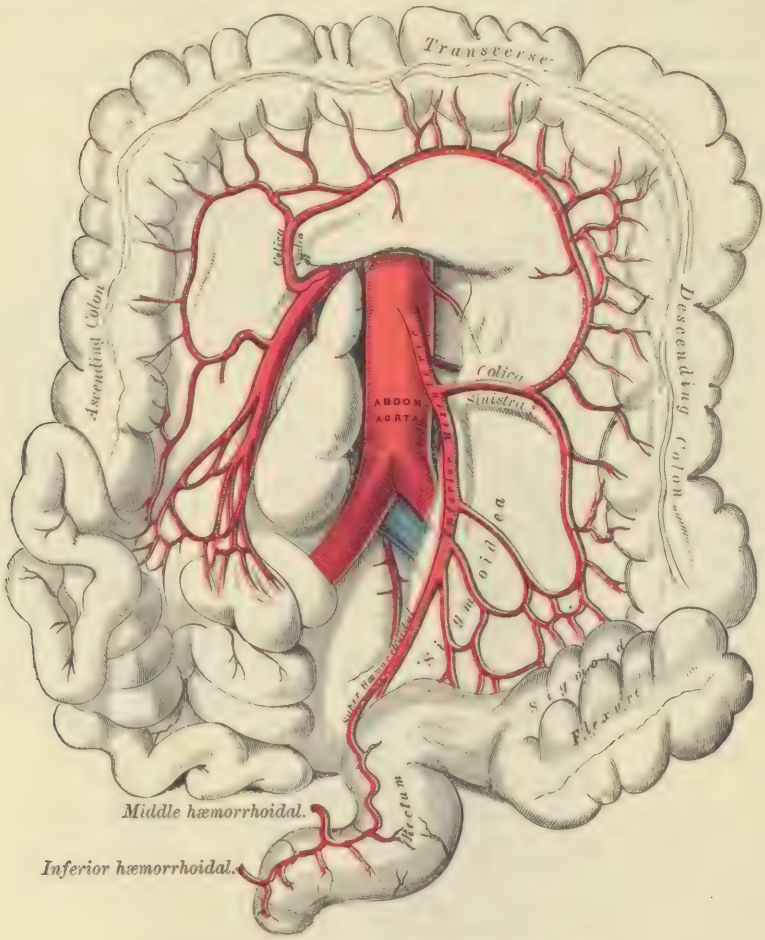

FIG. 421.—The inferior mesenteric and its branches.

into the pelvis, under the name of the **superior hæmorrhoidal artery**. It lies at first in close relation with the left side of the aorta, and then passes as the superior hæmorrhoidal in front of the left common iliac artery.

In order to expose the inferior mesenteric artery draw the small intestines and mesentery over to the right side of the abdomen, raise the transverse colon toward the thorax, and divide the peritoneum covering the front of the aorta.

Branches.—Its branches are—the

Left Colic. Sigmoid.

Superior Hæmorrhoidal.

The **Left Colic Artery** (*a. colica sinistra*) passes behind the peritoneum, in front of the left kidney, to reach the descending colon, and divides into two branches—an ascending branch, which inosculates with the colica media; and a descending branch, which anastomoses with the sigmoid artery. From the arches formed by these inosculations branches are distributed to the descending colon.

The Sigmoid Arteries (*aa. sigmoideæ*).—As a rule there are two of these vessels, but may be three. They run obliquely downward across the Psoas muscle to the sigmoid flexure of the colon, and divide into branches which supply that part of the intestine, anastomosing above with the left colic, and below with the superior hæmorrhoidal artery.

The **Superior Hæmorrhoidal Artery** (*a. hæmorrhoidalis superior*) (Figs. 421 and 424), the continuation of the inferior mesenteric, descends into the pelvis between the layers of the mesorectum, crossing, in its course, the ureter and left common iliac vessels. Opposite the middle of the sacrum it divides into two branches, which descend one on each side of the rectum, and about five inches from the anus break up into several small branches, which pierce the muscular coat of the bowel and run downward, as straight vessels, placed at regular intervals from each other in the wall of the gut between its muscular and mucous coat, to the level of the internal sphincter; here they form a series of loops around the lower end of the rectum, and communicate with the middle hæmorrhoidal arteries which are branches of the internal iliac and with the inferior hæmorrhoidal branches of the internal pudic.

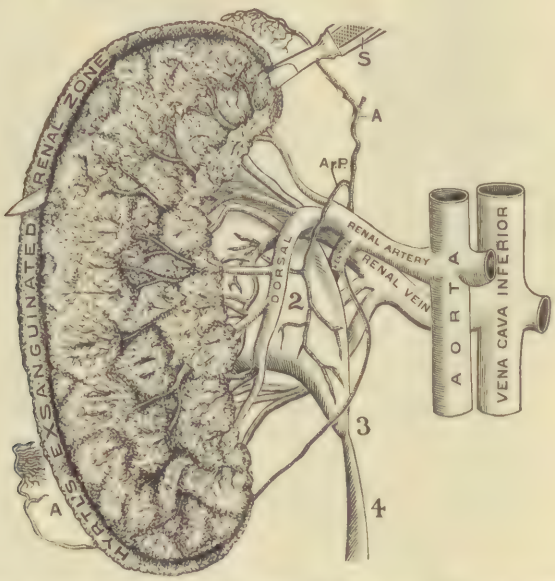

FIG. 422.—Corrosion anatomy. Hyrtl's exsanguinated renal zone. (Byron Robinson.)

The Suprarenal Artery (*a. suprarenalis media*) (Fig. 417).—A suprarenal or capsular artery *arises*, one on each side of the aorta, opposite the superior mesenteric artery. It is a small vessel which passes obliquely upward and outward, over the crura of the Diaphragm, to the under surface of the suprarenal capsule, to which it is distributed, anastomosing with capsular branches from the phrenic and renal arteries. In the adult these arteries are of small size; in the fœtus they are as large as the renal arteries.

The Renal Arteries (*aa. renales*) (Fig. 417).—The renal arteries are two large trunks which *arise* from the sides of the aorta immediately below the superior

mesenteric artery. Each is directed outward across the crus of the Diaphragm, so as to form nearly a right angle with the aorta. The right is longer than the left, on account of the position of the aorta; it passes behind the inferior vena cava. The left is somewhat higher than the right. Before reaching the hilum of the kidney, each artery usually divides into four branches. Two of these vessels enter the anterior portion and two the posterior portion of the kidney. There may be but one renal artery; there may be two, three, four, or five branches. The greater number of the branches generally lie between the renal vein and ureter, the vein being in front of the arteries, the ureter behind. The anterior branches supply three-fourths of the kidney, the posterior supply one-fourth. Each vessel gives off a small branch to the suprarenal capsule (*a. suprarenalis inferior*) and branches to the ureter, **ureteral branches**, and to the surrounding cellular tissue and muscles, **perirenal branches**. Hyrtl, in 1870, pointed out that the renal artery gives off a branch which divides and supplies the dorsal or posterior portion of the kidney and

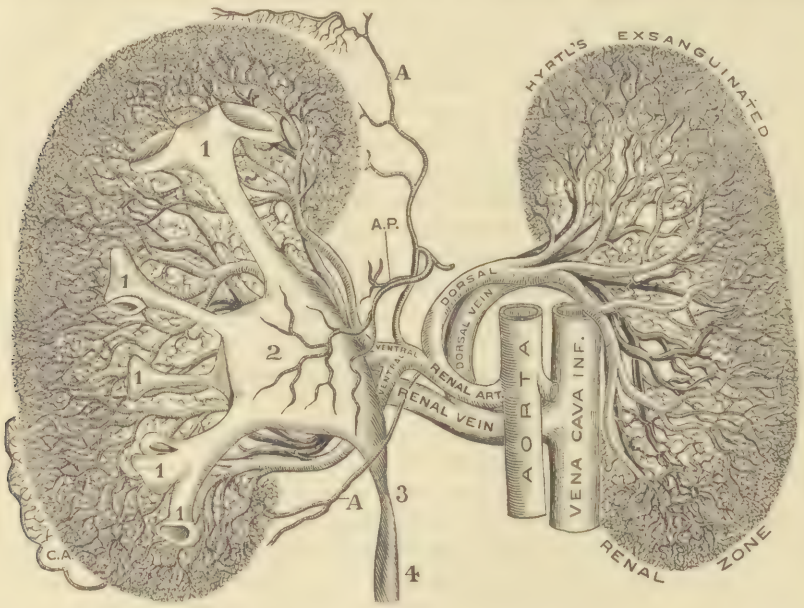

FIG. 423.—Corrosion anatomy. The renal vascular blades opened like a book. (Byron Robinson.)

its pelvis, and a branch which divides and supplies the ventral or anterior portion of the kidney and its pelvis. The two circulations are distinct and do not anastomose even at the periphery. Between these two sets of vessels is a bloodless zone called by Byron Robinson the **exsanguinated renal zone of Hyrtl**, which does not correspond to the median line, but is "one-half inch dorsal to the lateral longitudinal renal border."[1] The ventral or anterior segment is much the larger. In very rare instances the bloodless zone corresponds to the median line (Kümmel). An incision of the middle third of the kidney exactly at the junction of the two segments does not divide vessels. As the incision approaches either pole there is danger of cutting a branch (Schede). Frequently there is a second renal artery, which is given off from the abdominal aorta either above or below the renal artery proper, the former being the more common position. Instead of entering the kidney at the hilum, an accessory renal artery usually pierces the upper or the lower part of the gland.

The Spermatic Arteries (*aa. spermaticæ internæ*) (Fig. 417).—The internal spermatic arteries are distributed to the testes. They are two slender vessels of

[1] Byron Robinson. The Circulation of the Kidney, American Journal of Surgery.

considerable length, which *arise* from the front of the aorta a little below the renal arteries. Each artery passes obliquely outward and downward behind the peritoneum, resting on the Psoas muscle, the right spermatic lying in front of the inferior vena cava, the left behind the sigmoid flexure of the colon. It then crosses obliquely over the ureter (to which it sends a few branches) and the lower part of the external iliac artery to reach the internal abdominal ring, through which it passes, and accompanies the other constituents of the spermatic cord along the inguinal canal to the scrotum, where it becomes tortuous and is prolonged as the *testicular artery*, which accompanies the vas deferens, anastomosing with the *artery of the vas deferens* and is distributed to the epididymis, the back part of the tunica albuginea, and the substance of the testes. The spermatic artery in the inguinal canal gives off **cremasteric branches** to supply the Cremaster muscle. In the canal and scrotum the artery lies behind the pampiniform plexus and in front of the vas deferens.

The Ovarian Arteries (*aa. ovaricæ*).—The ovarian arteries (Fig. 425) are the corresponding arteries in the female to the spermatic in the male. They supply the ovaries, are shorter than the spermatic, and do not pass out of the abdominal cavity. The origin and course of the first part of the artery are the same as the spermatic in the male, but on arriving at the margin of the pelvis the ovarian artery passes inward, between the two layers of the broad ligament of the uterus, to be distributed to the ovary, **ovarian branches**. Branches go to the Fallopian tube, **tubal branches**, the ureter, **ureteral branches**, and the broad ligament, **ligamentous branches**. A branch passes on to the side of the uterus and anastomoses with the uterine arteries, **uterine branch**. Other offsets are continued along the round ligament through the inguinal canal, to the integument of the labium and groin.

At an early period of fœtal life, when the testes or ovaries lie by the side of the spine below the kidneys, the spermatic or ovarian arteries are short; but as these organs descend from the abdomen into the scrotum or pelvis, the arteries become gradually lengthened.

The Inferior Phrenic Arteries (*aa. phrenicæ inferiores*)(Fig. 417).—The inferior phrenic arteries are two small vessels which present much variety in their origin. They may *arise* separately from the front of the aorta, immediately above the cœliac axis, or by a common trunk, which may spring either from the aorta or from the cœliac axis. Sometimes one is derived from the aorta, and the other from one of the renal arteries. In only one out of thirty-six cases examined did these arteries arise as two separate vessels from the aorta. They diverge from one another across the crura of the Diaphragm, and then pass obliquely upward and outward upon the under surface of the Diaphragm. The **left phrenic** passes behind the œsophagus and runs forward on the left side of the œsophageal opening. The **right phrenic** passes behind the inferior vena cava, and ascends along the right side of the aperture for transmitting that vein. Near the back part of the central tendon each vessel divides into two branches. The **internal branch** runs forward to the front of the thorax, supplying the Diaphragm and anastomosing with its fellow of the opposite side, and with the **musculo-phrenic** and **comes nervi phrenici** branches of the internal mammary. The **external branch** passes toward the side of the thorax and inosculates with the **intercostal arteries**. The internal branch of the right phrenic gives off a few vessels to the inferior vena cava, and the left one some branches to the œsophagus. Each vessel also sends **capsular branches** (*rami suprarenales superior*) to the suprarenal capsule of its own side. The spleen on the left side and the liver on the right also receive a few branches from these vessels.

The Lumbar Arteries (*aa. lumbales*).—The lumbar arteries are analogous to the intercostals. They are usually four in number on each side, and *arise* from the back part of the aorta, nearly at right angles with that vessel. They pass

outward and backward, around the sides of the bodies of the lumbar vertebræ, behind the sympathetic nerve and the Psoas magnus muscle, those on the right side being covered by the inferior vena cava, and the two upper ones on each side by the crura of the Diaphragm. In the interval between the transverse processes of the vertebræ each artery gives off a **dorsal branch.**

After the formation of the dorsal branch the artery passes outward, having a variable relation to the Quadratus lumborum muscle. Most frequently the first lumbar passes in front of the muscle and the others behind it; sometimes the order is reversed and the lowest lumbar passes in front of the muscle. At the outer border of the Quadratus they are continued between the abdominal muscles, anastomose with branches of the epigastric and internal mammary *in front*, the intercostals *above*, and branches of the ilio-lumbar and circumflex iliac *below*. The lumbar arteries are also distributed to the skin of the sides of the abdomen.

The **Dorsal Branch** (*ramus dorsalis*) gives off, immediately after its origin, a **spinal branch,** which enters the spinal canal. The dorsal branch then continues its course backward between the transverse processes, and is distributed to the muscles and integument of the back, anastomosing with similar branches of the adjacent lumbar arteries and with the posterior branches of the intercostal arteries.

The **Spinal Branch** (*ramus spinalis*) enters the spinal canal through the intervertebral foramen, to be distributed to the spinal cord and its membranes and to the bodies of the vertebræ in the same manner as the lateral spinal branches from the vertebral (see page 638).

The Middle Sacral Artery (*a. sacralis media*) (Fig. 424).—The middle sacral artery is a small vessel, which *arises* from the back part of the aorta just at its bifurcation. It descends upon the last lumbar vertebra, and along the middle line of the front of the sacrum, to the upper part of the coccyx, where it anastomoses with the lateral sacral arteries, and terminates in a minute branch, which runs down to the situation of the body described as Luschka's gland. It gives off on each side opposite the body of the fifth lumbar vertebra a branch known as the *a. lumbalis ima*. From the middle sacral artery branches arise which run through the mesorectum to supply the posterior surface of the rectum. Other branches are given off on each side, which anastomose with the lateral sacral arteries, and send off small offsets which enter the anterior sacral foramina.

The artery is the representative of the caudal prolongation of the aorta of animals, and its lateral branches correspond to the intercostal and lumbar arteries in the dorsal and lumbar regions.

THE COMMON ILIAC ARTERIES (AA. ILIACÆ COMMUNES) (Figs. 417, 424).

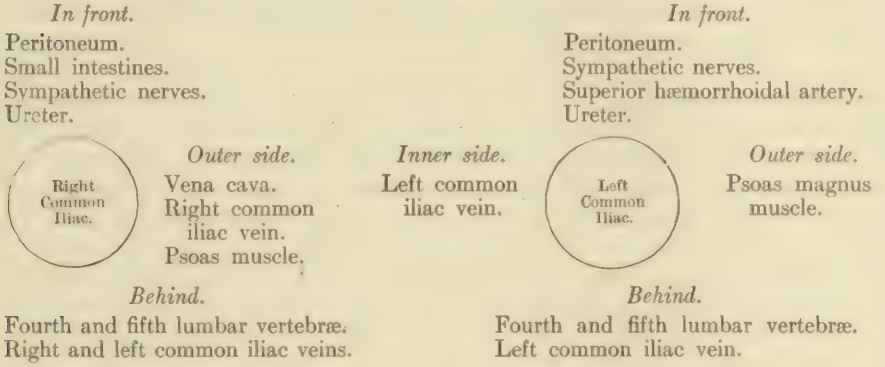
The abdominal aorta divides into the two **common iliac arteries.** The bifurcation usually takes place on the left side of the body of the fourth lumbar vertebra. The common iliac arteries are about two inches in length; diverging from the termination of the aorta, they pass downward and outward to the margin of the pelvis, each divides opposite the intervertebral substance, between the last lumbar vertebra and the sacrum, into two branches, the **internal** and **external iliac arteries,** the latter supplying the lower extremity; the former, the viscera and parietes of the pelvis.

The **right common iliac** is somewhat longer than the left, and passes more obliquely across the body of the last lumbar vertebra. In *front* of it are the peritoneum, the small intestines, branches of the sympathetic nerve, and, at its point of division, the ureter. *Behind*, it is separated from the fourth and fifth

lumbar vertebræ, with the intervening intervertebral disk, by the two common iliac veins. On its *outer side*, it is in relation with the inferior vena cava and the right common iliac vein, above, and the Psoas magnus muscle below.

The **left common iliac** is in relation, in *front*, with the peritoneum, branches of the sympathetic nerve, and the superior hæmorrhoidal artery; and is crossed at its point of bifurcation by the ureter. It rests on the bodies of the fourth and fifth lumbar vertebræ, with the intervening intervertebral disk. The left common iliac vein lies partly on the inner side, and partly beneath the artery; on its outer side, the artery is in relation with the Psoas magnus muscle.

PLAN OF THE RELATIONS OF THE COMMON ILIAC ARTERIES.



Branches.—The common iliac arteries give off small branches to the peritoneum, Psoas magnus, ureters, and the surrounding cellular tissue, and occasionally give origin to the ilio-lumbar or renal arteries.

Peculiarities.—The *point of origin* varies according to the bifurcation of the aorta. In three-fourths of a large number of cases the aorta bifurcated either upon the fourth lumbar vertebra or upon the intervertebral disk between it and the fifth, the bifurcation being, in one case out of nine below, and in one out of eleven above, this point. In ten out of every thirteen cases the vessel bifurcated within half an inch above or below the level of the crest of the ilium, more frequently below than above.

The point of division is subject to great variety. In two-thirds of a large number of cases it was between the last lumbar vertebra and the upper border of the sacrum, being above that point in one case out of eight and below it in one case out of six. The left common iliac artery divides lower down more frequently than the right.

The *relative length*, also, of the two common iliac arteries varies. The right common iliac was the longer in sixty-three cases, the left in fifty-two, whilst they were both equal in fifty-three. The length of the arteries varied in five-sevenths of the cases examined from an inch and a half to three inches; in about half of the remaining cases the artery was longer and in the other half shorter, the minimum length being less than half an inch, the maximum four and a half inches. In two instances the right common iliac has been found wanting, the external and internal iliacs arising directly from the aorta.

Surface Marking.—Draw a zone around the body opposite the highest part of the crest of the ilium; in this line take a point half an inch to the left of the middle line. From this draw two lines to points midway between the anterior superior spines of the ilium and the symphysis pubis. These two diverging lines will represent the course of the common and external iliac arteries. Draw a second zone round the body corresponding to the level of the anterior superior spines of the ilium: the portion of the diverging lines between the two zones will represent the course of the common iliac artery; the portion below the lower zone, that of the external iliac artery.

Surgical Anatomy.—The application of a ligature to the common iliac artery may be required on account of aneurism or hemorrhage implicating the external or internal iliacs. Now that the surgeon no longer dreads opening the peritoneal cavity, there can be no question that the easiest and best method of tying the artery is by a transperitoneal route. The abdomen is opened by an incision in either the semilunar line or the linea alba; the intestines are drawn to one side and the peritoneum covering the artery divided. The sheath is then opened, and the needle passed from within outward. On the right side great care must be exercised in

passing the needle, since both the common iliac veins lie behind the artery. After the vessel has been tied the incision in the peritoneum over the artery should be sutured. Formerly there were two different methods by which the common iliac artery was tied without opening the peritoneal cavity: 1, an anterior or iliac incision, by which the vessel is approached more directly from the front; and 2, a posterior abdominal or lumbar incision, by which the vessel is reached from behind. If the surgeon select the iliac region, a curved incision, from five to eight inches in length, according to the amount of fat, is made, commencing just outside the middle of Poupart's ligament and a finger's breadth above it, and carried outward toward the anterior superior iliac spine, then upward toward the ribs, and finally curving inward toward the umbilicus. The abdominal muscles and transversalis fascia are divided, and the peritoneum raised upward and inward until the Psoas is reached. The artery will be found on the inner side of this muscle, and is to be cleared with a director, especial care being taken on the right side, as here the common iliac veins lie behind the artery. The aneurism needle is to be passed from within outward. But if the aneurismal tumor should extend high up in the abdomen, along the external iliac, it is better to select the posterior or lumbar route, making an incision partly in the abdomen, partly in the loin. The incision is commenced at the anterior extremity of the last rib, proceeding directly downward to the ilium; it is then curved forward along the crest of the ilium and a little above it to the anterior superior spine of that bone. The abdominal muscles having been cautiously divided in succession, the transversalis fascia must be carefully cut through, and the peritoneum, together with the ureter, separated from the artery and pushed aside; the sacro-iliac articulation must then be felt for, and upon it the vessel will be felt pulsating, and may be fully exposed in close connection with the accompanying vein. On the right side both common iliac veins, as well as the inferior vena cava, are in close connection with the artery, and must be carefully avoided. On the left side the vein usually lies on the inner side and behind the artery; but it occasionally happens that the two common iliac veins are joined on the left instead of the right side, which would add much to the difficulty of an operation in such a case. The common iliac artery may be so short that danger may be apprehended from secondary hemorrhage if a ligature is applied to it. It would be preferable, in such a case, to tie both the external and internal iliacs near their origin.

Collateral Circulation.—The principal agents in carrying on the collateral circulation after the application of a ligature to the common iliac are—the anastomoses of the hæmorrhoidal branches of the internal iliac with the superior hæmorrhoidal from the inferior mesenteric; the anastomoses of the uterine and ovarian arteries and of the vesical arteries of opposite sides; of the lateral sacral with the middle sacral artery; of the epigastric with the internal mammary, inferior intercostal, and lumbar arteries; of the circumflex iliac with the lumbar arteries; of the ilio-lumbar with the last lumbar artery; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side and with the deep epigastric.

Compression of the Common Iliac Arteries. The common iliac arteries may be compressed by Davy's lever. The instrument consists of a gum-elastic tube about two feet long, in which fits a round wooden "lever" considerably longer than the tube. A small quantity of olive oil having been injected into the rectum, the gum-elastic tube, softened in hot water, is passed into the bowel sufficiently far to permit its pressing upon the common iliac artery as it lies in the groove between the last lumbar vertebra and the Psoas muscle. The wooden lever is then inserted into the tube, and the projecting end carried toward the opposite thigh and raised, when it acts as a lever of the first order, the anus being the fulcrum. In cases where the mesorectum is abnormally short it may be impossible, without unjustifiable force, to compress the artery on the right side. In amputation of the hip-joint the common iliac can be compressed most certainly and safely by opening the abdomen and compressing the vessel by means of the fingers against the Psoas muscle (McBurney's method).

The Internal Iliac Artery (Figs. 417, 424).

The internal iliac or **hypogastric artery** (*a. hypogastrica*) supplies the walls and viscera of the pelvis, the generative organs, and inner side of the thigh. It is a short thick vessel, smaller in the adult than the external iliac, and about an inch and a half in length. It *arises* at the point of bifurcation of the common iliac, and, passing downward to the upper margin of the great sacro-sciatic foramen, divides into two large trunks, an **anterior** and **posterior**; from its anterior division a partially obliterated cord, a part of the **fœtal hypogastric artery**, extends forward to the bladder.

Relations.—*In front*, with the ureter, which is between the artery and the peritoneum. *Behind*, with the internal iliac vein, the lumbo-sacral cord, and Pyriformis muscle. By its *outer side*, near its origin, with the Psoas magnus muscle.

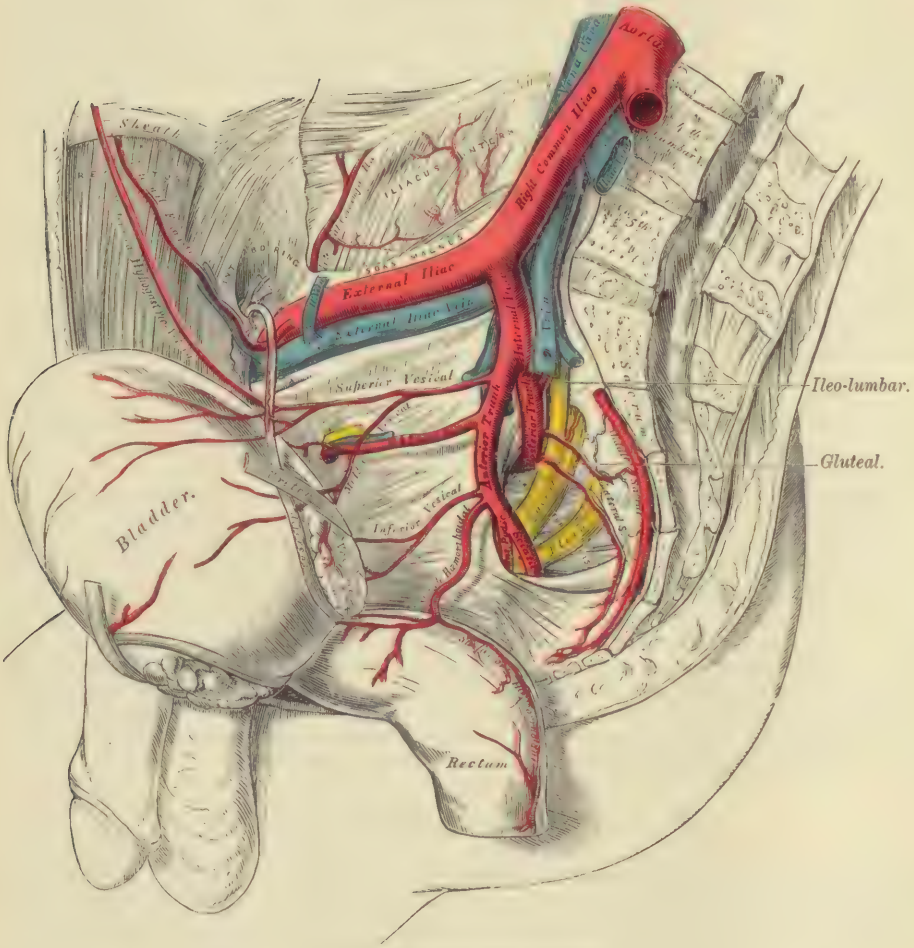

FIG. 424.—Arteries of the pelvis.

In the fœtus the hypogastric artery is twice as large as the external iliac, and appears to be the continuation of the common iliac. Instead of dipping into the pelvis, it passes forward to the bladder, and ascends along the sides of that viscus to its summit, to which it gives branches; it then passes upward along the back part of the anterior wall of the abdomen to the umbilicus, converging toward its fellow of the opposite side. Having passed through the umbilical

opening, the two arteries twine round the umbilical vein in the umbilical cord, and ultimately ramify in the placenta. The portion of the vessel within the abdomen is called the **hypogastric artery**; the portion external to that cavity, the **umbilical artery**.

At birth, when the placental circulation ceases, the upper portion of the hypogastric artery, extending from the summit of the bladder to the umbilicus, contracts, and ultimately dwindles to a solid fibrous cord; but the lower portion, extending from its origin (in what is now the internal iliac artery) for about an inch and a half to the wall of the bladder, and thence to the summit of that organ, is not totally impervious, though it becomes considerably reduced in size, and serves to convey blood to the bladder under the name of the **superior vesical artery**.

Peculiarities as Regards Length.—In two-thirds of a large number of cases the length of the internal iliac varied between an inch and an inch and a half; in the remaining third it was more frequently longer than shorter, the maximum length being three inches, the minimum half an inch.

The lengths of the common and internal iliac arteries bear an inverse proportion to each other, the internal iliac artery being long when the common iliac is short, and *vice versa*.

As Regards its Place of Division.—The place of division of the internal iliac varies between the upper margin of the sacrum and the upper border of the sacro-sciatic foramen.

The arteries of the two sides in a series of cases often differed in length, but neither seemed constantly to exceed the other.

Surgical Anatomy. The application of a ligature to the internal iliac artery may be required in cases of aneurism or hemorrhage affecting one of its branches. The vessel may be secured by making an incision through the abdominal parietes in the iliac region in a direction and to an extent similar to that for securing the common iliac; the transversalis fascia having been cautiously divided, and the peritoneum pushed inward from the iliac fossa toward the pelvis, the finger may feel the pulsation of the external iliac at the bottom of the wound, and by tracing this vessel upward the internal iliac is arrived at, opposite the sacro-iliac articulation. It should be remembered that the vein lies behind and on the right side, a little external to the artery, and in close contact with it; the ureter and peritoneum, which lie in front, must also be avoided. The degree of facility in applying a ligature to this vessel will mainly depend upon the length of the vessel. It has been seen that in the great majority of the cases examined the artery was short, varying from an inch to an inch and a half; in these cases the artery is deeply seated in the pelvis; when, on the contrary, the vessel is longer, it is found partly above that cavity. If the artery is very short, as occasionally happens, it would be preferable to apply a ligature to the common iliac or to both the external and internal iliacs at their origin.

A better method of tying the internal iliac artery is by an abdominal section in the median line and reaching the vessel through the peritoneal cavity. This plan has been advocated by Dennis, of New York, on the following grounds: (1) It in no way increases the danger of the operation; (2) it prevents a series of accidents which have occurred during ligature of the artery by the older methods; (3) it enables the surgeon to ascertain the exact extent of disease in the main arterial trunk, and select his spot for the application of the ligature; and (4) it occupies much less time.

Collateral Circulation.—In Professor Owen's dissection of a case in which the internal iliac artery had been tied by Stevens ten years before death for aneurism of the sciatic artery, the internal iliac was found impervious for about an inch above the point where the ligature had been applied, but the obliteration did not extend to the origin of the external iliac, as the iliolumbar artery arose just above this point. Below the point of obliteration the artery resumed its natural diameter, and continued so for half an inch, the obturator, lateral sacral, and gluteal arising in succession from the latter portion. The obturator artery was entirely obliterated. The lateral sacral artery was as large as a crow's quill, and had a very free anastomosis with the artery of the opposite side and with the middle sacral artery. The sciatic artery was entirely obliterated as far as its point of connection with the aneurismal tumor, but on the distal side of the sac it was continued down along the back of the thigh nearly as large in size as the femoral, being pervious about an inch below the sac by receiving an anastomosing vessel from the profunda.[1] The circulation was carried on by the anastomoses of the uterine and ovarian arteries; of the opposite vesical arteries; of the hemorrhoidal branches of the internal iliac with those from the inferior mesenteric; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side and with the epigastric and internal circumflex; of the circumflex

[1] Medico-Chirurgical Transactions, vol. xvi.

and perforating branches of the profunda femoris with the sciatic; of the gluteal with the posterior branches of the sacral arteries; of the ilio-lumbar with the last lumbar; of the lateral sacral with the middle sacral; and of the circumflex iliac with the ilio-lumbar and gluteal.

Branches (Fig. 424).—The branches of the internal iliac are:

From the Anterior Trunk.	*From the Posterior Trunk.*
Superior Vesical.	Ilio-lumbar.
Middle Vesical.	Lateral Sacral.
Inferior Vesical.	Gluteal.
Middle Hæmorrhoidal.	
Obturator.	
Internal Pudic.	
Sciatic.	
In female { Uterine.	
In female { Vaginal.	

The **Superior Vesical** (*a. vesicalis superior*) (Fig. 424) is that part of the fœtal hypogastric artery, which remains pervious after birth. It extends to the side of the bladder, distributing numerous branches to the apex and body of the organ. From one of these a slender vessel is derived which accompanies the vas deferens in its course to the testis, where it anastomoses with the spermatic artery. This is the **artery of the vas deferens**. Other branches supply the ureter.

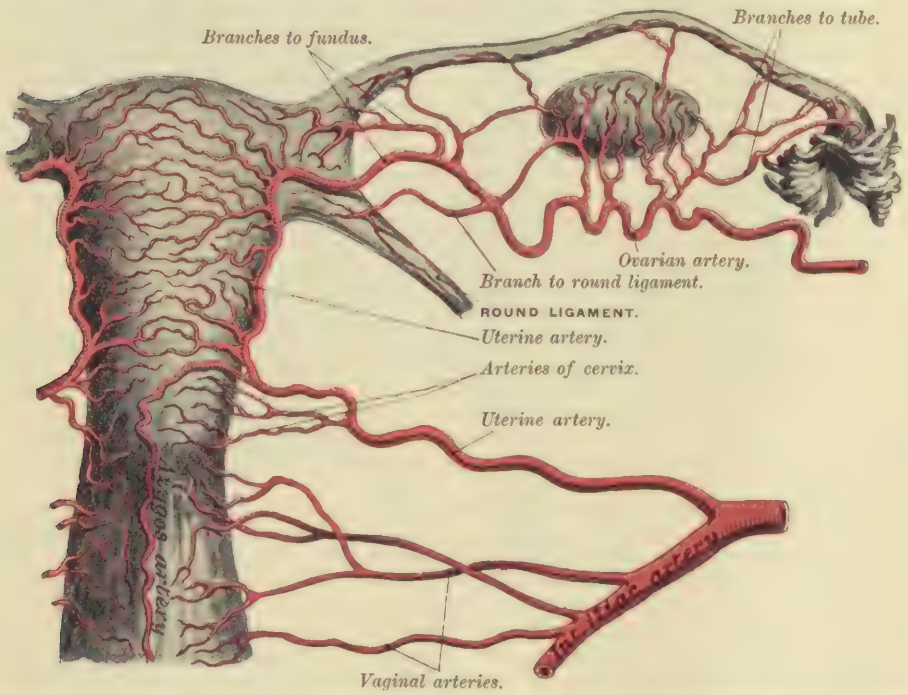

FIG. 425.—The arteries of the internal organs of generation of the female, seen from behind. (After Hyrtl.)

The **Middle Vesical** (*a. vesicalis medialis*) (Fig. 424), usually a branch of the superior, is distributed to the base of the bladder and under surface of the vesiculæ seminales.

The **Inferior Vesical** (*a. vesicalis inferior*) (Fig. 424) *arises* from the anterior division of the internal iliac, frequently in common with the middle hemorrhoidal, and is distributed to the base of the bladder, the prostate gland, and vesiculæ

seminales. The branches distributed to the prostate communicate with the corresponding vessel of the opposite side.

The **Middle Hæmorrhoidal Artery** (*a. hæmorrhoidalis media*) (Fig. 424) usually arises together with the preceding vessel. It supplies the anus and parts outside the rectum, anastomosing with the other hemorrhoidal arteries.

The **Uterine Artery** (*a. uterina*) (Fig. 425) passes inward from the anterior trunk of the internal iliac to the neck of the uterus. Ascending in a tortuous course on the side of this viscus, between the layers of the broad ligament, it distributes branches to its substance and to the round ligament and the Fallopian tube (*ramus tubarius*), anastomosing, near its termination, with the ovarian artery. It gives a branch to the ovary (*ramus ovarii*), which anastomoses with a branch from the ovarian branches to the cervix uteri (*cervico-uteri*), and a branch which descends

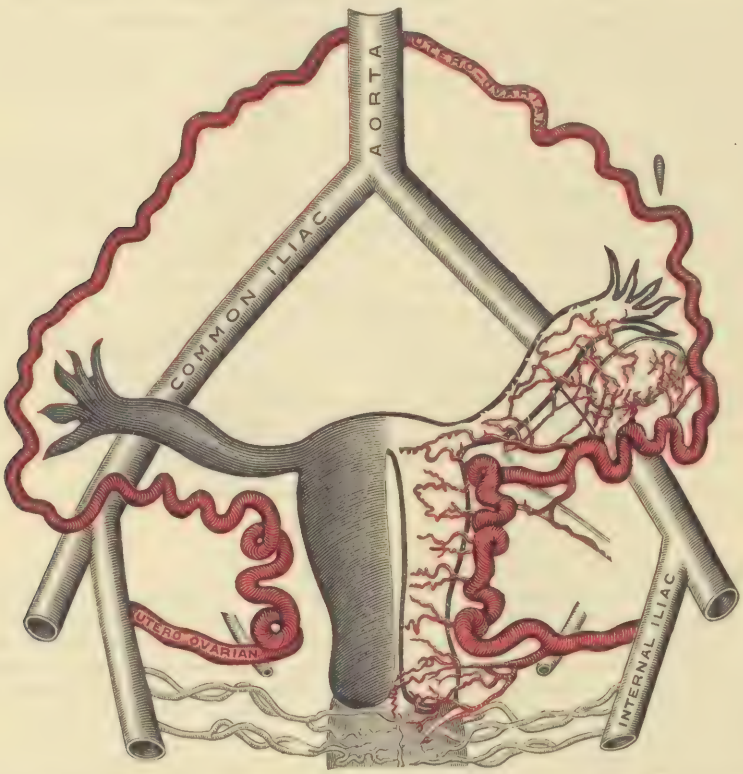

FIG. 426.—The utero-ovarian artery forming the circle described by Byron Robinson.

on the vagina (*cervico-vaginal*), and, joining with branches from the vaginal arteries, form a median longitudinal vessel both in front and behind; these descend on the anterior and posterior surfaces of the vagina, and are named the **azygos arteries of the vagina.**

The **Vaginal Artery** (*a. vaginalis*) (Fig. 426) is analogous to the inferior vesical in the male; it descends upon the vagina, supplying its mucous membrane, and sending branches to the neck of the bladder and contiguous part of the rectum. There may be several vaginal arteries. The vaginal artery assists in forming the **azygos arteries** of the vagina, which are anterior and posterior vessels, running longitudinally, and due to anastomoses of the branches of the vaginal from each side and the cervico-vaginal artery.

Luschka, Hyrtl, Waldeyer, Byron Robinson, and others, instead of describing the ovarian and uterine arteries as two distinct vessels, regard them as constituting

the chief parts of one vessel, the **arteria uterina ovarica**. What has been called "the circle of Byron Robinson" is composed of a spiral segment (the arteria uterina ovarica), with a portion of the abdominal aorta, common iliacs, and internal iliacs (Fig. 426).

Byron Robinson[1] has made a careful study of this vascular circle; he shows that it is of great importance in certain surgical procedures, and that its remarkable "capacity for extension" saves it from damage when the uterus is enormously distended by pregnancy, or when it is "drawn through the pudendum with traction forceps for palpation, inspection, or repair."

The author just quoted says further that the utero-ovarian artery has three origins, because it develops from the Wolffian body: The **ovarian segment** *arises* from the abdominal aorta. The **uterine segment** *arises* from the anterior branch of the internal iliac artery. The **artery of the round ligament** *arises* from the deep epigastric. The arteria uterina ovarica artery secures nutrition to the uterus by bringing blood from three sources. It is spiral throughout its entire course, in certain parts is convoluted or looped, and it is accompanied by the pampiniform plexus of veins.

The three origins of this vessel are freely united by anastomoses, and rami laterales are given off, which unite the bilateral vessels in the median line. Robinson describes three bifurcations of the utero-ovarian artery. The **distal bifurcation,** which is "about midway between the uterus and the pelvic wall," and forms an acute angle with the main vessel. This bifurcation indicates the point of division of the external from the internal genitals. The cervico-vaginal artery supplies the external genitals. The **proximal bifurcation** marks the situation of the ovary. The artery bifurcates at an acute angle into two branches to supply the ovary and Fallopian tube. The **middle bifurcation** consists of (1) the division of the uterine segment at the angle formed by the uterus and oviduct ("forming the ramus oviductus and ramus ovarii") and (2) "the bifurcation of the ramus oviductus forming the ramus oviductus and the ramus ligamenti teretis, or the segment of the round ligament."[2] The relations of the utero-ovarian artery and the ureter are shown in Fig. 426.

Surgical Anatomy.—As pointed out by Byron Robinson, the source of bleeding after vaginal hysterectomy is usually the torn and unclamped cervico-vaginal artery.

As previously pointed out, the spiral and convoluted shape of the utero-ovarian artery allows the uterus, ovary, and tube to be drawn into the vagina without injury to the vessels. Bryon Robinson points out that in vaginal hysterectomy the genital circle is not divided and only the rami laterales which go to the uterus are cut, the ovaries retaining a normal blood-supply and continuing to functionate.

The **Obturator Artery** (*a. obturatoria*) (Fig. 424) usually *arises* from the anterior trunk of the internal iliac; frequently from the posterior. It passes forward, below the brim of the pelvis, to the upper part of the obturator foramen, accompanied by the obturator nerve and vein, and, escaping from the pelvic cavity through a short canal formed by a groove on the under surface of the ascending ramus of the os pubis and the arched border of the obturator membrane, it divides into an **internal** and **external branch**. In the pelvic cavity this vessel lies upon the pelvic fascia, beneath the peritoneum, and a little below the obturator nerve.

Branches.—*Within the pelvis*, the obturator artery gives off an **iliac branch** (*ramus iliacus*) to the iliac fossa, which supplies the bone and the Iliacus muscle, and anastomoses with the ilio-lumbar artery; a **vesical branch** (*ramus vesicalis*), which runs backward to supply the bladder; and a **pubic branch** (*ramus pubicus*), which is given off from the vessel just before it leaves the pelvic cavity. This branch ascends upon the back of the os pubis, communicating with offsets from

[1] The Utero-ovarian Artery.

[2] Byron Robinson. The Utero-ovarian Artery.

the deep epigastric artery and with the corresponding vessel of the opposite side. It is placed on the inner side of the femoral ring. External to the pelvis, the obturator artery divides into an **internal** and an **external branch**, which are deeply situated beneath the Obturator externus muscle.

The **Internal Branch** (*ramus anterior*) curves downward along the inner margin of the obturator foramen, lying beneath the Obturator externus muscle; it distributes branches to the Obturator externus, Pectineus, Adductors, and Gracilis, and anastomoses with the external branch and with the internal circumflex artery.

The **External Branch** (*ramus posterior*) curves round the outer margin of the obturator foramen, also lying beneath the Obturator externus muscle, to the space between the Gemellus inferior and Quadratus femoris, where it divides into two branches: one, smaller, courses inward around the lower margin of the foramen and anastomoses with the internal branch and with the internal circumflex; the other inclines outward in the groove below the acetabulum (*a. acetabulis*), and supplies the muscles attached to the tuberosity of the ischium and anastomoses with the sciatic artery. It sends a branch to the hip-joint through the cotyloid notch, which ramifies on the round ligament as far as the head of the femur.

Peculiarities (Fig. 427). In two out of every three cases the obturator arises from the internal iliac; in one case in three and a half from the epigastric; and in about one in seventy-two cases by two roots from both vessels. It arises in about the same proportion from the external iliac artery. The origin of the obturator from the epigastric is not commonly found on both sides of the same body.

FIG. 427.—Variations in origin and course of the obturator artery.

When the obturator artery arises at the front of the pelvis from the epigastric, it descends almost vertically to the upper part of the obturator foramen. The artery in this course usually lies in contact with the external iliac vein and on the outer side of the femoral ring (Fig. 427, *A*); in such cases it would not be endangered in the operation for femoral hernia. Occasionally, however, it curves inward along the free margin of Gimbernat's ligament (Fig. 427, *B*), and under such circumstances would almost completely encircle the neck of a hernial sac (supposing a hernia to exist in such a case), and would be in great danger of being wounded if an operation was performed.

The **Internal Pudic Artery** (*a. pudenda interna*) (Figs. 424, 428, and 429) is the smaller of the two terminal branches of the anterior trunk of the internal iliac, and supplies the external organs of generation. Though the course of the artery is the same in the two sexes, the vessel is much smaller in the female than in the male, and the distribution of its branches somewhat different. The description of its arrangement in the male will first be given, and subsequently the differences which it presents in the female will be mentioned.

The **Internal Pudic Artery in the Male** passes downward and outward to the lower border of the great sacro-sciatic foramen, and emerges from the pelvis between the Pyriformis and Coccygeus muscles: it then crosses the spine of the ischium and re-enters the pelvis through the lesser sacro-sciatic foramen. The artery now crosses the Obturator internus muscle along the outer wall of the ischio-rectal fossa, being situated about an inch and a half above the lower margin of the ischial tuberosity. It is here contained in a sheath of the obturator fascia, and

gradually approaches the margin of the ramus of the ischium, along which it passes forward and upward, pierces the base of the superficial layer of the triangular ligament of the urethra, and runs forward along the inner margin of the ramus of the os pubis, and divides into its two terminal branches, the **dorsal artery of the penis** and the **artery of the corpus cavernosum.**

Relations.—In the first part of its course, within the pelvis, it lies in front of the Pyriformis muscle and sacral plexus of nerves, and the sciatic artery, and on the outer side of the rectum (on the left side). As it crosses the spine of the ischium it is covered by the Gluteus maximus and overlapped by the great sacro-sciatic ligament. Here the obturator nerve lies to the inner side and the nerve to the Obturator internus to the outer side of the vessel. In the pelvis it lies on the outer side of the ischio-rectal fossa, upon the surface of the Obturator internus muscle, contained in a fibrous canal, the **canal of Alcock,** formed by the splitting of the obturator fascia. It is accompanied by the pudic veins and the pudic nerve.

Peculiarities.—The internal pudic is sometimes smaller than usual, or fails to give off one or two of its usual branches; in such cases the deficiency is supplied by branches derived from an additional vessel, the *accessory pudic*, which generally arises from the internal pudic artery before its exit from the great sacro-sciatic foramen. It passes forward along the lower part of the bladder and across the side of the prostate gland to the root of the penis, where it perforates the triangular ligament and gives off the branches usually derived from the pudic artery. The deficiency most frequently met with is that in which the internal pudic ends as the artery of the bulb, the artery of the corpus cavernosum and arteria dorsalis penis being derived from the accessory pudic. Or the pudic may terminate as the superficial perineal, the artery of the bulb being derived, with the other two branches, from the accessory vessel. Occasionally the accessory pudic artery is derived from one of the other branches of the internal iliac, most frequently the inferior vesical or the obturator.

Surgical Anatomy.—The relation of the accessory pudic to the prostate gland and urethra is of the greatest interest in a surgical point of view, as this vessel is in danger of being wounded in the operation of *lateral lithotomy*. The student should also study the position of the internal pudic artery and its branches, when running a normal course with regard to the same operation. The superficial and the transverse perineal arteries are, of necessity, divided in this operation, but the hemorrhage from these vessels is seldom excessive; should a ligature be required, it can readily be applied on account of their superficial position. The artery of the bulb may be divided if the incision be carried too far forward, and injury of this vessel may be attended with serious or even fatal consequences. The main trunk of the internal pudic artery may be wounded if the incision be carried too far outward; but, being bound down by the strong obturator fascia and under cover of the ramus of the ischium, the accident is not very likely to occur unless the vessel runs an anomalous course.

Branches.—The branches of the internal pudic artery are—the

Muscular.	Transverse Perineal.
Inferior Hæmorrhoidal.	Artery of the Bulb.
Superficial Perineal.	Artery of the Corpus Cavernosum.

Dorsal Artery of the Penis.

The **Muscular Branches** consist of two sets—one given off in the pelvis, the other as the vessel crosses the ischial spine. The former are several small offsets which supply the Lævator ani, the Obturator internus, the Pyriformis, and the Coccygeus muscles. The branches given off outside the pelvis are distributed to the adjacent part of the Gluteus maximus and External rotator muscles. They anastomose with branches of the sciatic artery.

The **Inferior Hæmorrhoidal Artery** (*a. hæmorrhoidalis inferior*) *arises* from the internal pudic as it passes above the tuberosity of the ischium. Crossing the ischio-rectal fossa it is distributed by two or three terminal branches to the muscles and integument of the anal region. Instead of one inferior hemorrhoidal artery two or three small vessels may arise from the internal pudic.

The **Superficial Perineal Artery** (*a. perinei*) (Fig. 428) supplies the scrotum and the muscles and integument of the perinæum. It *arises* from the internal pudic in front

of the preceding branches, and turns upward, crossing either over or under the Transversus perinei superficialis muscle, and runs forward, parallel to the pubic arch, in the interspace between the Accelerator urinæ and Erector penis muscles, both of which it supplies, and is finally distributed to the skin and dartos of the scrotum. In its passage through the perinæum it lies beneath the superficial perineal fascia.

The **Transverse Perineal Artery** is a small branch which *arises* either from the internal pudic or from the superficial perineal artery as it crosses the Transversus perinæi muscle. It runs transversely inward along the cutaneous surface of the Transversus perinei superficialis muscle, which it supplies, as well as the structures between the anus and bulb of the urethra, and anastomoses with the like vessel of the opposite side.

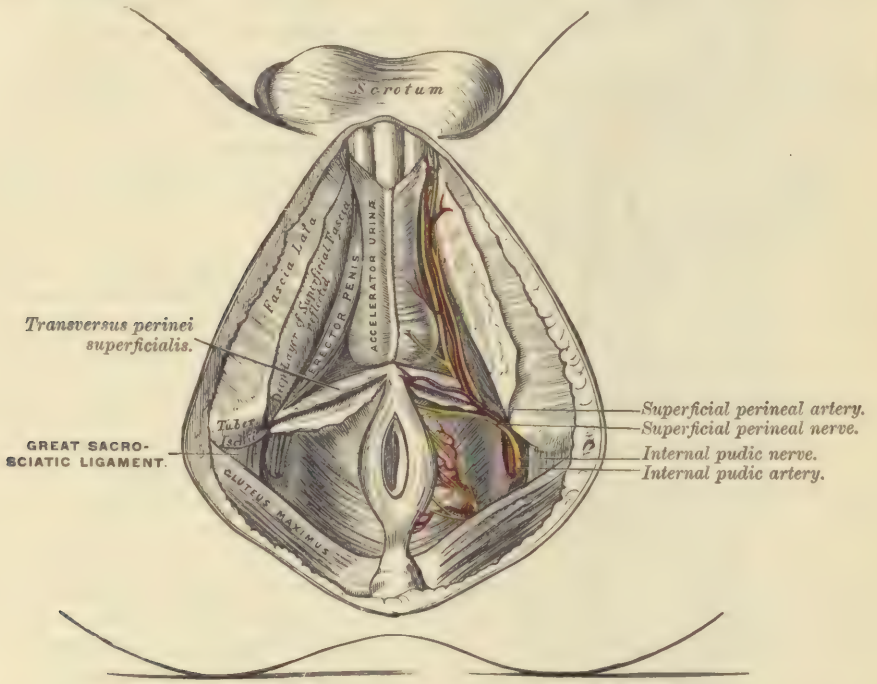

FIG. 428.—The superficial muscles and vessels of the perinæum.

The **Artery of the Bulb** (*a. bulbi urethræ*) is a large but very short vessel which *arises* from the internal pudic between the two layers of the triangular ligament, and, passing nearly transversely inward, between the fibres of the Compressor urethræ muscle, it pierces the bulb of the urethra, which it supplies, and continues anteriorly in the corpus spongiosum to the glans and anastomoses with its fellow of the opposite side. It gives off a small branch which descends to supply Cowper's gland.

Surgical Anatomy.—This artery is of considerable importance in a surgical point of view, as it is in danger of being wounded in the median or the lateral operation of lithotomy—an accident usually attended in the adult with alarming hemorrhage. The vessel is sometimes very small, occasionally wanting, or even double. It sometimes arises from the internal pudic earlier than usual, and crosses the perinæum to reach the back part of the bulb. In such a case the vessel could hardly fail to be wounded in the performance of the lateral operation of lithotomy. If, on the contrary, it should arise from an accessory pudic, it lies more forward than usual and is out of danger in the operation.

The **Artery of the Corpus Cavernosum** (*a. profunda penis*), one of the terminal branches of the internal pudic, *arises* from that vessel while it is situated between

the two layers of the triangular ligament; it pierces the superficial layer, and, entering the crus penis obliquely, it runs forward in the centre of the corpus cavernosum, to which its branches are distributed.

The **Dorsal Artery of the Penis** (*a. dorsalis penis*) ascends between the crus and pubic symphysis, and, piercing the triangular ligament, passes between the two layers of the suspensory ligament of the penis, and runs forward on the dorsum of the penis to the glans, where it divides into two branches which supply the glans and prepuce. On the dorsum of the penis it lies immediately beneath the integument, parallel with the dorsal vein and the corresponding artery of the opposite side. It supplies the integument and fibrous sheath of the corpus cavernosum, sending branches through the sheath to anastomose with the preceding vessel.

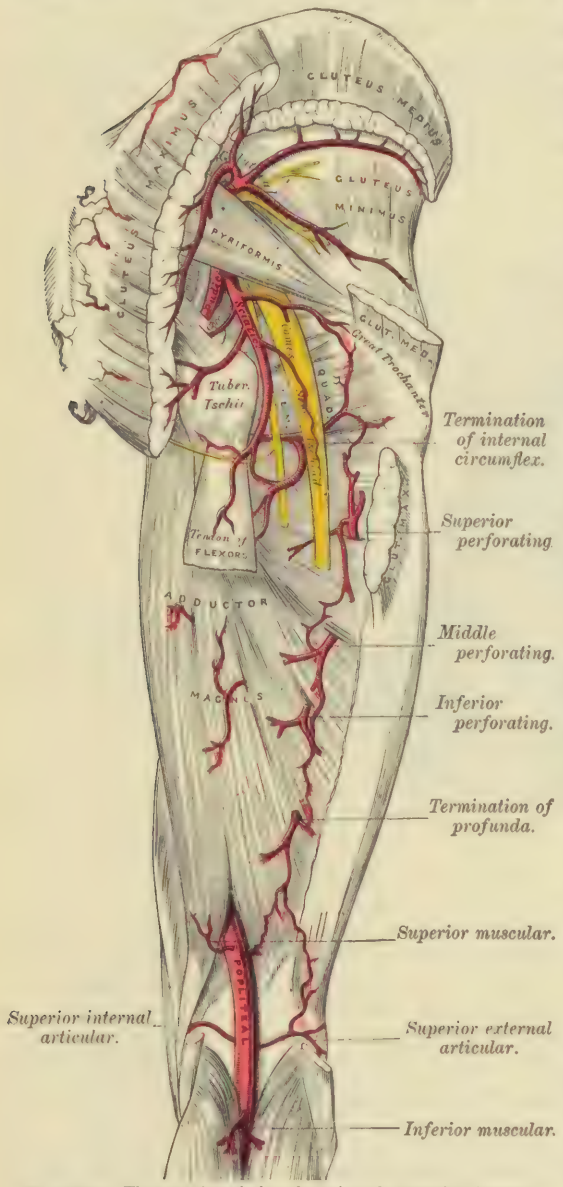

FIG. 429.— The arteries of the gluteal and posterior femoral regions.

The **Internal Pudic Artery in the Female** is smaller than in the male. Its origin and course are similar, and there is considerable analogy in the distribution of its branches. The superficial perineal artery supplies the labia pudendi; the artery of the bulb supplies the bulbi vestibuli and the erectile tissue of the vagina; the artery of the corpus cavernosum (*a. profunda clitoridis*) supplies the cavernous body of the clitoris; and the arteria dorsalis clitoridis supplies the dorsum of that organ, and terminates in the glans and in the membranous fold corresponding to the prepuce of the male.

The **Sciatic Artery** (*a. glutæa inferior*) (Fig. 429), the larger of the two terminal branches of the anterior trunk of the internal iliac, is distributed to the muscles at the back of the pelvis. It passes down to the lower part of the great sacro-sciatic foramen behind the internal pudic artery, resting on the sacral plexus of nerves and Pyriformis muscle, and escapes from the pelvis through this foramen between the Pyriformis and Coccygeus. It then descends in the interval between the trochanter major and tuberosity of the ischium, accompanied by the sciatic nerves, and covered by the Gluteus maximus, and is continued down the back of the thigh supplying the skin, and anastomosing with branches of the perforating arteries.

Within the pelvis it distributes branches to the Pyriformis, Coccygeus, and Levator ani muscles; some hemorrhoidal branches, which supply the rectum, and occasionally take the place of the middle hemorrhoidal artery; and vesical branches to the base and neck of the bladder, vesiculæ seminales, and prostate gland. *External to the pelvis* it gives off the following branches:

Coccygeal.	Muscular.
Inferior Gluteal.	Anastomotic.
Comes Nervi Ischiadici.	Articular.

The **Coccygeal Branch** runs inward, pierces the great sacro-sciatic ligament, and supplies the Gluteus maximus, the integument, and other structures on the back of the coccyx.

The **Inferior Gluteal Branches**, three or four in number, supply the Gluteus maximus muscle, anastomosing with the gluteal artery in the substance of the muscle.

The **Comes Nervi Ischiadici** (*a. comitans n. ischiadici*) is a long, slender vessel which accompanies the great sciatic nerve for a short distance; it then penetrates it and runs in its substance to the lower part of the thigh.

The **Muscular Branches** supply the Gluteus maximus, anastomosing with the gluteal artery in the substance of the muscle; the external rotators, anastomosing with the internal pudic artery; and the muscles attached to the tuberosity of the ischium, anastomosing with the external branch of the obturator and the internal circumflex arteries.

The **Anastomotic Artery** is directed downward across the external rotators and assists in forming the so-called **crucial anastomosis** by anastomosing with the superior perforating and the internal and external circumflex arteries.

The **Articular Branch**, generally derived from the anastomotic, is distributed to the capsule of the hip-joint.

The **Ilio-lumbar Artery** (*a. ilio lumbalis*), given off from the posterior trunk of the internal iliac, turns upward and outward between the obturator nerve and lumbo-sacral cord, to the inner margin of the Psoas muscle, behind which it divides into a **lumbar** and an **iliac branch**.

The **Lumbar Branch** (*ramus lumbalis*) supplies the Psoas and Quadratus lumborum muscles, anastomosing with the last lumbar artery, and sends a small **spinal branch** (*ramus spinalis*) through the intervertebral foramen, between the last lumbar vertebra and the sacrum, into the spinal canal, to supply the cauda equina.

The **Iliac Branch** (*ramus iliacus*) descends to supply the Iliacus muscle; some offsets, running between the muscle and the bone, anastomose with the iliac branch of the obturator; one of these enters an oblique canal to supply the diploë, whilst others run along the crest of the ilium, distributing branches to the Gluteal and Abdominal muscles, and anastomose in their course with the gluteal, circumflex iliac, and external circumflex arteries.

The **Lateral Sacral Artery** (*a. sacralis lateralis*) (Fig. 424) runs downward. It may be single, but usually there are two on each side, the **superior** and **inferior divisions.**

The **Superior Division**, which is of large size, passes inward, and, after anastomosing with branches from the middle sacral, enters the first or second anterior sacral foramen, gives **spinal branches** (*rami spinalis*) to the contents of the sacral canal, and, escaping by the corresponding posterior sacral foramen, supplies the skin and muscles on the dorsum of the sacrum, anastomosing with the gluteal.

The **Inferior Division** passes obliquely across the front of the Pyriformis muscle and sacral nerves to the inner side of the anterior sacral foramina, descends on the front of the sacrum, and anastomoses over the coccyx with the middle sacral and opposite lateral sacral arteries. In its course it gives off **spinal branches** which

enter the anterior sacral foramina (*rami spinales*); these, after supplying the contents of the sacral canal, escape by the posterior sacral foramina, and are distributed to the muscles and skin on the dorsal surface of the sacrum, anastomosing with the gluteal.

The **Gluteal Artery** (*a. glutæa superior*) (Fig. 429) is the largest branch of the internal iliac, and appears to be the continuation of the posterior division of that vessel. It is a short thick trunk, which passes out of the pelvis above the upper border of the Pyriformis muscle, and immediately divides into a **superficial** and **deep branch**. Within the pelvis it gives off a few muscular branches to the Iliacus, Pyriformis, and Obturator internus, and, just previous to emerging from that cavity, a nutrient artery, which enters the ilium.

The **Superficial Branch** passes beneath the Gluteus maximus and divides into numerous branches, some of which supply that muscle, whilst others perforate its tendinous origin, and supply the integument covering the posterior surface of the sacrum, anastomosing with the posterior branches of the sacral arteries.

The **Deep Branch** runs between the Gluteus medius and minimus, and subdivides into two. Of these, the **superior division** (*ramus superior*), continuing the original course of the vessel, passes along the upper border of the Gluteus minimus to the anterior superior spine of the ilium, anastomosing with the circumflex iliac and ascending branches of the external circumflex artery. The **inferior division** (*ramus inferior*) crosses the Gluteus minimus obliquely to the trochanter major, distributing branches to the Glutei muscles, and inosculates with the external circumflex artery. Some branches piece the Gluteus minimus to supply the hip-joint.

Surface Marking.—The position of the three main branches of the internal iliac, the sciatic, internal pudic, and gluteal, which may occasionally be the object of surgical interference, is indicated on the surface in the following way: A line is to be drawn from the posterior superior iliac spine to the posterior superior angle of the great trochanter, with the limb slightly flexed and rotated inward: the point of emergence of the gluteal artery from the upper part of the sciatic notch will correspond with the junction of the upper with the middle third of this line. A second line is to be drawn from the same point to the outer part of the tuberosity of the ischium; the junction of the lower with the middle third marks the point of emergence of the sciatic and pudic arteries from the great sciatic notch.

Surgical Anatomy.—Any of these three vessels may require *ligating* for a wound or for aneurism, which is generally traumatic. The gluteal artery is ligated by turning the patient two-thirds over on his face and making an incision from the posterior superior spine of the ilium to the upper and posterior angle of the great trochanter. This must expose the Gluteus maximus muscle, and its fibres are to be separated through the whole thickness of the muscle and pulled apart with retractors. The contiguous margins of the gluteus medius and Pyriformis are now to be separated from each other, and the artery will be exposed emerging from the sciatic notch. In ligation of the sciatic artery, the incision should be made parallel with that for ligation of the gluteal, but one inch and a half lower down. After the fibres of the Gluteus maximus have been separated, the vessel is to be sought for at the lower border of the Pyriformis; the great sciatic nerve, which lies just above it, forming the chief guide to the artery. The internal pudic can be reached through the incision used to reach the sciatic.

The External Iliac Artery (A. Iliaca Externa) (Fig. 424).

The external iliac artery is larger in the adult than is the internal iliac. It passes obliquely downward and outward along the inner border of the Psoas muscle, from the bifurcation of the common iliac to Poupart's ligament, where it enters the thigh and becomes the femoral artery.

Relations.—*In front*, with the peritoneum, subperitoneal areolar tissue or *Abernethy's fascia*, the termination of the ileum on the right side, and the sigmoid flexure on the left, and a thin layer of fascia derived from the iliac fascia, which surrounds the artery and vein. At its origin it is occasionally crossed by the ureter. The spermatic vessels descend for some distance upon it near its termination, and it is

crossed in this situation by the genital branch of the genito-crural nerve and the deep circumflex iliac vein; the vas deferens curves down along its inner side. *Behind*, it is in relation with the external iliac vein, which, at Poupart's ligament, lies at its inner side; on the left side the vein is altogether internal to the artery. *Externally*, it rests against the Psoas muscle, from which it is separated by the iliac fascia. The artery rests upon this muscle, near Poupart's ligament. Numerous lymphatic vessels and glands are found lying on the front and inner side of the vessel.

PLAN OF THE RELATIONS OF THE EXTERNAL ILIAC ARTERY.

In front.
Peritoneum, intestines, and fascia.

Near Poupart's Ligament.

Psoas magnus.
Iliac fascia.

External Iliac.

Inner side.
External iliac vein and vas deferens near Poupart's ligament.

Behind.
External iliac vein.
Psoas magnus.

Surface Marking.—The surface line indicating the course of the external iliac artery has been already given (see page 682).

Surgical Anatomy.—The application of a *ligature* to the external iliac may be required in cases of aneurism of the femoral artery or for a wound of the artery. This vessel may be secured in any part of its course, excepting near its upper end, which is to be avoided on account of the proximity of the great stream of blood in the internal iliac, and near its lower end, which should also be avoided, on account of the proximity of the deep epigastric and circumflex iliac vessels. The patient having been placed in the supine position, an incision should be made, commencing below at a point about three-quarters of an inch above Poupart's ligament, and a little external to its middle, and running upward and outward, parallel to Poupart's ligament, to a point one inch internal and one inch above the anterior superior spine of the ilium. When the artery is deeply seated more room will be required, and may be obtained by curving the incision from the point last named inward toward the umbilicus for a short distance. Another mode of ligating the vessel is the plan advocated by Sir Astley Cooper, by making an incision close to Poupart's ligament from about half an inch outside of the external abdominal ring to one inch internal to the anterior superior spine of the ilium. This incision, being made in the course of the fibres of the aponeurosis of the external oblique, is less likely to be followed by a ventral hernia, but there is danger of wounding the epigastric artery, and only the lower end of the vessel can be ligated. Abernethy, who first tied this artery, made his incision in the course of the vessel. The abdominal muscles and transversalis fascia having been cautiously divided, the peritoneum should be separated from the iliac fossa and raised toward the pelvis; and on introducing the finger to the bottom of the wound, the artery may be felt pulsating along the inner border of the Psoas muscle. The external iliac vein is generally found on the inner side of the artery, and must be cautiously separated from it by the finger-nail or handle of the knife, and the aneurism needle should be introduced on the inner side, between the artery and the vein.

Ligation of the external iliac artery has recently been performed by a transperitoneal method. An incision four inches in length is made in the semilunar line, commencing about an inch below the umbilicus and carried through the abdominal wall into the peritoneal cavity. The intestines are then pushed upward and held out of the way by a broad abdominal retractor, and an incision is made through the peritoneum at the margin of the pelvis in the course of the artery, and the vessel is secured in any part of its course which may seem desirable to the operator. The advantages of this operation appear to be that if it is found necessary, the common iliac artery can be ligated instead of the external iliac without extension or modification of the incision; and secondly, that the vessel can be ligated without in any way interfering with the coverings of the sac of an aneurism. Possibly a disadvantage may exist in the greater risk of hernia after this method.

Collateral Circulation.—The principal anastomoses in carrying on the collateral circulation, after the application of a ligature to the external iliac, are the ilio-lumbar with the circumflex iliac; the gluteal with the external circumflex; the obturator with the internal circumflex; the sciatic with the superior perforating and circumflex branches of the profunda artery; and the internal pudic with the external pudic. When the obturator arises from the epigastric it is supplied with blood by branches, either from the internal iliac, the lateral sacral, or the internal pudic. The epigastric receives its supply from the internal mammary and inferior intercostal arteries, and from the internal iliac by the anastomoses of its branches with the obturator.

In the dissection of a limb eighteen years after the successful ligature of the external iliac artery by Sir A. Cooper, the report of which is to be found in *Guy's Hospital Reports*, vol. i. p. 50, the anastomosing branches are described in three sets: *An anterior set.*—1, a very large branch from the ilio-lumbar artery to the circumflex iliac; 2, another branch from the ilio-lumbar, joined by one from the obturator, and breaking up into numerous tortuous branches to anastomose with the external circumflex; 3, two other branches from the obturator, which passed over the brim of the pelvis, communicated with the epigastric, and then broke up into a plexus to anastomose with the internal circumflex. *An internal set.*—Branches given off from the obturator, after quitting the pelvis, which ramified among the adductor muscles on the inner side of the hip-joint, and joined most freely with branches of the internal circumflex. *A posterior set.*—1, three large branches from the gluteal to the external circumflex; 2, several branches from the sciatic around the great sciatic notch to the internal and external circumflex, and the perforating branches of the profunda.

Branches.—Besides several small branches to the Psoas muscle and the neighboring lymphatic glands, the external iliac gives off two branches of considerable size—the **deep epigastric** and **deep circumflex iliac arteries.**

The **Internal** or **Deep Epigastric Artery** (*a. epigastrica inferior*) (Fig. 424) *arises* from the external iliac a few lines above Poupart's ligament. It at first descends to reach this ligament, and then ascends obliquely along the inner margin of the internal abdominal ring, lying between the transversalis fascia and peritoneum, and, continuing its course upward, it pierces the transversalis fascia, and passing over the semilunar fold of Douglas, enters the sheath of the Rectus muscle. It then ascends on the posterior surface of the muscle, and finally divides into numerous branches which anastomose, above the umbilicus, with the superior epigastric branch of the internal mammary and with the inferior intercostal arteries (Fig. 410). The deep epigastric artery bears a very important relation to the internal abdominal ring as it passes obliquely upward and inward from its origin from the external iliac. In this part of its course it lies along the lower and inner margin of the ring and beneath the commencement of the spermatic cord. As it passes to the inner side of the internal abdominal ring it is crossed by the vas deferens in the male and the round ligament in the female.

Branches.—The branches of this vessel are the following: The **cremasteric** (*a. spermatica externa in the male, a. ligamenti teretis uteri in the female*), which accompanies the spermatic cord, and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic artery in the male, and which accompanies the round ligament in the female; a **pubic branch** (*ramus pubicus*), which runs along Poupart's ligament, and then descends behind the os pubis to the inner side of the femoral ring, and anastomoses with offsets from the obturator artery; **muscular branches,** some of which are distributed to the abdominal muscles and peritoneum, anastomosing with the lumbar and circumflex iliac arteries; **cutaneous branches** perforate the tendon of the External oblique, and supply the integument, anastomosing with branches of the superficial epigastric.

Peculiarities. The origin of the deep epigastric may take place from any part of the external iliac between Poupart's ligament and two inches and a half above it, or it may arise below this ligament, from the common femoral or from the deep femoral.

Union with Branches.—It frequently arises from the external iliac by a common trunk with the obturator. Sometimes the epigastric arises from the obturator, the latter vessel being furnished by the internal iliac, or the epigastric may be formed by two branches, one derived from the external iliac, the other from the internal iliac.

Surgical Anatomy.—The deep epigastric artery follows a line drawn from the middle of Poupart's ligament toward the umbilicus; but shortly after this line crosses the linea semilunaris the direction changes, and the course of the vessel is directly upward in the line of junction of the inner third with the outer two-thirds of the Rectus muscle. It has important surgical relations, in addition to the fact that it is one of the principal means, through its anastomosis with the internal mammary, in establishing the collateral circulation after ligature of either the common or external iliac arteries. It lies close to the internal abdominal ring, and is therefore *internal* to an oblique inguinal hernia, but *external* to a direct inguinal hernia, as the hernia emerges from the abdomen. It forms the outer boundary of Hesselbach's triangle. It is in close relationship with the spermatic cord, which lies in front of it in the inguinal canal, separated only by the transversalis fascia. The vas deferens hooks round its outer side.

The **Deep Circumflex Iliac Artery** (*a. circumflexa ilium profunda*) (Fig. 424) *arises* from the outer side of the external iliac nearly opposite the epigastric artery. It ascends obliquely outward behind Poupart's ligament, contained in a fibrous sheath formed by the junction of the transversalis and iliac fascia, to the anterior superior spinous process of the ilium. It then runs along the inner surface of the crest of the ilium to about its middle, where it pierces the Transversalis, and runs backward between that muscle and the Internal oblique, to anastomose with the ilio-lumbar and gluteal arteries. Opposite the anterior superior spine of the ilium it gives off a large branch which ascends between the Internal oblique and Transversalis muscles, supplying them, and anastomosing with the lumbar and epigastric arteries. It also gives off cutaneous branches.

ARTERIES OF THE LOWER EXTREMITY.

The artery which supplies the greater part of the lower extremity is the direct continuation of the external iliac. It continues as a single trunk from Poupart's ligament to the lower border of the Popliteus muscle, and here divides into two branches, the anterior and posterior tibial, an arrangement exactly similar to what occurs in the upper limb. For convenience of description, the upper part of the main trunk is named **femoral**, the lower part, **popliteal**.

THE FEMORAL ARTERY (A. FEMORALIS) (Figs. 430, 431, 432).

The femoral artery commences immediately behind Poupart's ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, and, passing down the forepart and inner side of the thigh, terminates at the opening in the Adductor magnus, at the junction of the middle with the lower third of the thigh, where it becomes the popliteal artery. The vessel, at the upper part of the thigh, lies in front of the hip-joint, just on a line with the innermost part of the head of the femur; in the lower part of its course it is in close relation with the inner side of the shaft of the bone, and between these two parts the vessel is some distance from the bone. In the upper third of the thigh it is contained in a triangular space called **Scarpa's triangle**. In the middle third of the thigh it is contained in an aponeurotic canal called **Hunter's canal**.

Scarpa's Triangle (*trigonum femorale*).—Scarpa's triangle corresponds to the depression seen immediately below the fold of the groin. It is a triangular space, the apex of which is directed downward, and the sides formed externally by the Sartorius, internally by the inner margin of the Adductor longus, and above by Poupart's ligament. The floor of the space is formed from without inward by the Iliacus, Psoas, Pectineus (in some cases a small part of the Adductor brevis), and the Adductor longus muscles; and it is divided into two nearly equal parts by the femoral vessels, which extend from the middle of its base to its apex, the artery

giving off in this situation its superficial and profunda branches, the vein receiving the deep femoral and internal saphenous. On the outer side of the femoral artery is the anterior crural nerve dividing into its branches. In the outer corner of the space is the external cutaneous nerve. Within the sheath of the artery, and lying upon the outer side of the vessel, is the crural branch of the genito-crural nerve. At the base of the triangle the vein is to the inner side of the artery; at the apex of the triangle it is passing behind the artery. Besides the vessels and nerves, this space contains some fat and lymphatics.

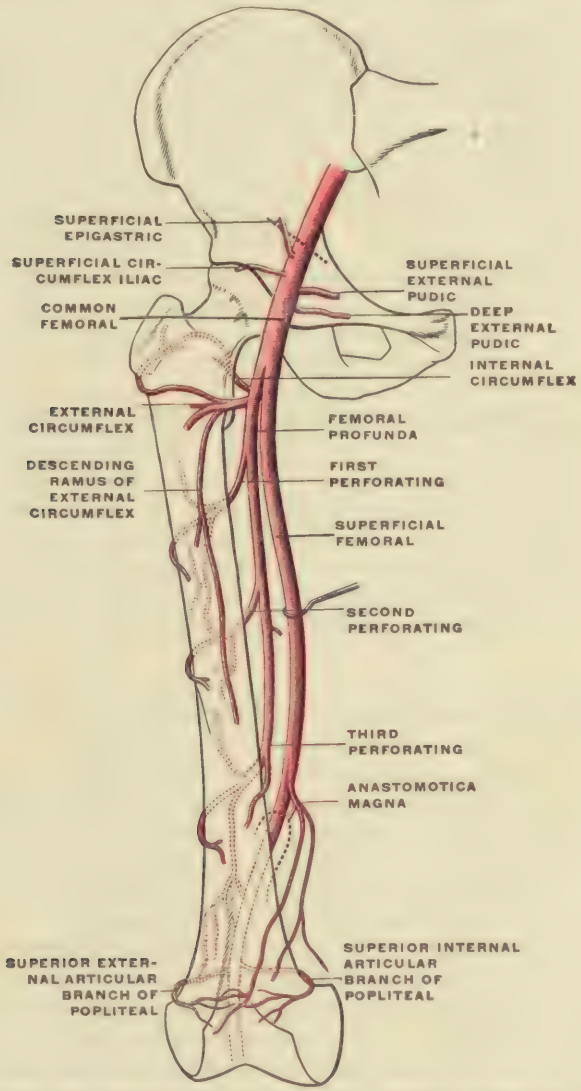

FIG. 430.—Scheme of the femoral artery. (Poirier and Charpy.)

Hunter's Canal or the Adductor Canal (*canalis adductorius* [*Hunteri*]).—This is the aponeurotic space in the middle third of the thigh, extending from the apex of Scarpa's triangle to the **femoral opening** in the Adductor magnus muscle. It is bounded, externally, by the Vastus internus; internally by the Adductors longus and magnus muscles; and is covered in by a strong aponeurosis which extends transversely from the Vastus internus across the femoral

vessels to the Adductor longus and magnus; lying on which aponeurosis is the Sartorius muscle. It contains the femoral artery and vein enclosed in their own sheath of areolar tissue, the vein being behind and on the outer side of the artery, and the internal or long saphenous nerve lying at first on the outer side and then in front of the vessels.

For convenience of description, and also in reference to its surgical anatomy, the femoral artery is divided into a short trunk, about an inch and a half or two inches long, which is known as the **common femoral artery**, while the remainder of the vessel is termed the **superficial femoral artery**, to distinguish it from the **deep femoral** (*profunda femoris*), a large branch given off from the common femoral at its termination, and which, by its derivation, from the parent trunk, marks the commencement of the superficial femoral artery.

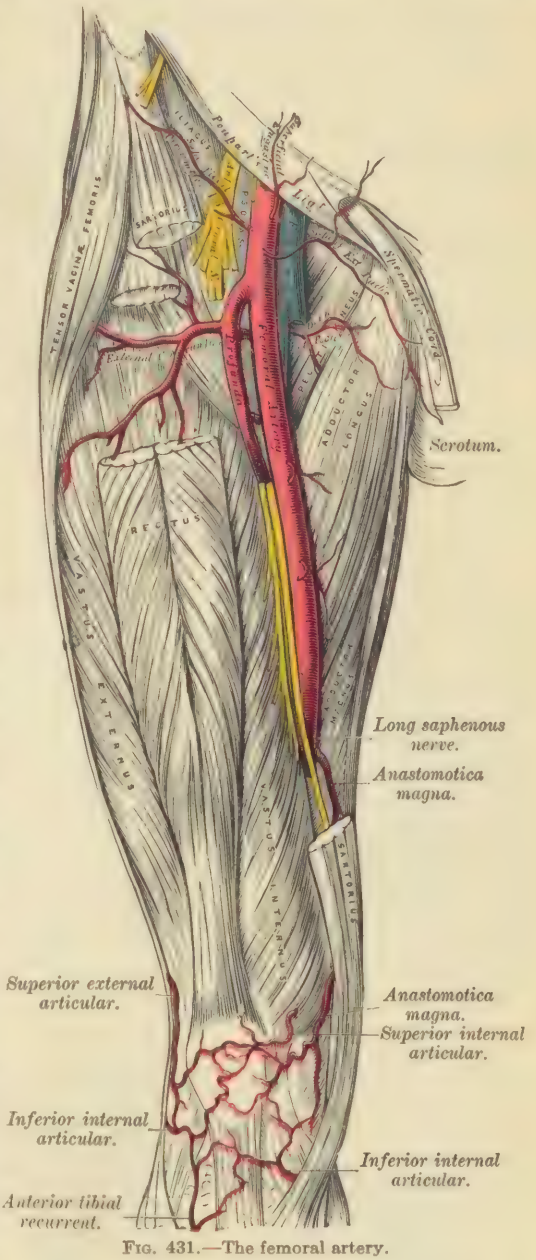

FIG. 431.—The femoral artery.

The Common Femoral Artery
(Figs. 430, 431, 432).

The common femoral artery is very superficial, being covered by the skin and superficial fascia, superficial inguinal lymphatic glands, the iliac portion of the fascia lata, and the prolongation downward of the transversalis fascia, which forms the anterior part of the sheath of the vessels. It has in front of it filaments from the crural branch of the genito-crural nerve, the superficial circumflex iliac vein, and occasionally the superficial epigastric vein. It rests on the inner margin of the Psoas muscle, which separates it from the capsular ligament of the hip-joint, and a little lower on the Pectineus muscle; and crossing behind it is the branch to the Pectineus from the anterior crural nerve. Separating the artery from the Pectineus muscles is the pubic portion of the fascia lata and the prolongation from the fascia covering the Iliacus muscle, which forms the posterior layer of the sheath of the vessels. The anterior crural nerve lies about half an inch to the outer side of the common femoral artery, being separated from the artery by a small part of the Psoas muscle. To the inner side of the artery is the femoral vein, between the margins of the Pectineus and Psoas muscles. The two vessels are

enclosed in a strong fibrous sheath formed by the proper sheath of the vessels, strengthened by fascia (see page 509); the artery and vein are separated, however, from one another by a thin fibrous partition.

The Superficial Femoral Artery (Figs. 430, 431, 432).

The superficial femoral artery is only superficial where it lies in Scarpa's triangle. Here it is covered by the skin, superficial and deep fascia, and crossed by the internal cutaneous branch of the anterior crural nerve. In Hunter's canal it is more deeply seated, being covered by the integument, the superficial and deep fascia, the Sartorius and the aponeurotic covering of Hunter's canal. The internal saphenous nerve crosses the artery from without inward. Behind, the artery lies at its upper part on the femoral vein and the profunda artery and vein, which separate it from the Pectineus muscle, and lower down on the Adductor longus and Adductor magnus muscles. To the outer side is the long saphenous nerve and the nerve to the Vastus internus, the Vastus internus muscle, and, at its lower part, the femoral vein. To the inner side is the Adductor longus above and the Adductor magnus and Sartorius below.

Pectineus muscle.
Adductor longus.
Adductor magnus.

The **femoral vein**, at Poupart's ligament, lies close to the inner side of the artery, separated from it by a thin fibrous partition; but lower down it is behind it, and then to its outer side.

The **internal saphenous nerve** is situated on the outer side of the artery, in the middle third of the thigh, beneath the aponeurotic covering of Hunter's canal, but not usually within the sheath of the vessels. The internal cutaneous nerve passes obliquely across the upper part of the sheath of the femoral artery.

Peculiarities. Double Femoral Reunited.—Several cases are recorded in which the femoral artery divided into two trunks below the origin of the profunda, and became reunited near the opening of the Adductor magnus so as to form a single popliteal artery. One of them occurred in a patient operated upon for popliteal aneurism.

Change of Position.—A few cases have been recorded in which the femoral artery was situated at the back of the thigh, the vessel being continuous above with the internal iliac, escaping from the pelvis through the great sacro-sciatic foramen, and accompanying the great sciatic nerve to the popliteal space, where its division occurred in the usual manner. The external iliac in these cases was small, and terminated in the profunda.

Position of the Vein. The femoral vein is occasionally placed along the inner side of the artery, throughout the entire extent of Scarpa's triangle, or it may be slit so that a large vein is placed on each side of the artery for a greater or less extent.

Origin of the Profunda. This vessel occasionally arises from the inner side, and, more rarely, from the back of the common trunk; but the more important peculiarity, in a surgical point of view, is that which relates to the height at which the vessel arises from the femoral. In three-fourths of a large number of cases it arose between one or two inches below Poupart's ligament; in a few cases the distance was less than an inch; more rarely, opposite the ligament; and in one case, above Poupart's ligament, from the external iliac. Occasionally, the distance between the origin of the vessel and Poupart's ligament exceeds two inches, and in one case it was found to be as much as four inches.

Surface Marking.—The upper two-thirds of a line drawn from a point midway between the anterior superior spine of the ilium and the symphysis pubis to the adductor tubercle on the inner condyle of the femur, with the thigh abducted and rotated outward, will indicate the course of the femoral artery.

Surgical Anatomy.—*Compression* of the femoral artery, which is constantly requisite in amputations and other operations on the lower limbs, and also for the cure of popliteal aneurisms, is most effectually made immediately below Poupart's ligament. In this situation the artery is very superficial, and is merely separated from the ascending ramus of the os pubis by the Psoas muscle; so that the surgeon, by means of his thumb or a compressor, may effectually control the circulation through it. This vessel may also be compressed in the middle third of the thigh by placing a compress over the artery, beneath the tourniquet, and directing the pressure from within outward, so as to compress the vessel against the inner side of the shaft of the femur.

The **application of a ligature** to the femoral artery may be required in the cases of wound or aneurism of the arteries of the leg, of the popliteal or femoral;[1] and the vessel may be exposed and tied in any part of its course. The great depth of this vessel at its lower part, its close connection with important structures, and the density of its sheath render the operation in this situation one of much greater difficulty than the application of a ligature at its upper part, where it is more superficial.

Ligature of the common femoral artery is usually considered unsafe, on account of the connection of large branches with it—viz., the deep epigastric and the deep circumflex iliac arising just above Poupart's ligament; on account of the number of small branches which arise from it in its short course; and on account of the uncertainty of the origin of the profunda femoris, which, if it arise high up, would be too close to the ligature for the formation of a firm coagulum. The profunda sometimes arises higher than the point above mentioned, and rarely between two or three inches (in one case four) below Poupart's ligament. It would appear, then, that the most favorable situation for the application of a ligature to the femoral is on the superficial femoral at the apex of Scarpa's triangle. In order to expose the artery in this situation, an incision between three and four inches long should be made in the course of the vessel, the patient lying in the recumbent position, with the limb slightly flexed and abducted, and rotated outward. A large vein is frequently met with, passing in the course of the artery to join the internal saphenous vein; this must be avoided, and the fascia lata having been cautiously divided and the Sartorius exposed, that muscle must be drawn outward in order to expose fully the sheath of the vessels. The finger being introduced into the wound and the pulsation of the artery felt, the sheath should be opened on the outer side of the vessel to a sufficient extent to allow of the

[1] Ligation of the femoral artery has been also recommended and performed for elephantiasis of the leg and acute inflammation of the knee-joint (Maunder, Clin. Soc. Trans., vol. ii. p. 37).—Ed. of 15th English edition.

introduction of the ligature, but no farther; otherwise the nutrition of the coats of the vessel may be interfered with, or muscular branches which arise from the vessel at irregular intervals may be divided. In this part of the operation the long saphenous nerve and the nerve to the Vastus internus, which is in close relation with the sheath, should be avoided. The aneurism needle must be carefully introduced and kept close to the artery, to avoid the femoral vein, which lies behind the vessel in this part of its course.

To expose the artery in Hunter's canal, an incision should be made between three and four inches in length, a finger's breadth internal to the line of the artery, in the middle of the thigh *i. e.*, midway between the groin and the knee. The integument is first divided. The fascia lata having been divided, and the outer border of the Sartorius muscle exposed, it should be drawn inward, when the strong fascia which is stretched across from the Adductors to the Vastus internus will be exposed, and must be freely divided; the sheath of the vessels is now seen, and must be opened, and the artery secured by passing the aneurism needle between the vein and artery in the direction from without inward. The femoral vein in this situation lies on the outer side of the artery and the long saphenous nerve on the anterior and outer side of the artery.

It has been seen that the femoral artery occasionally divides into two trunks below the origin of the profunda. If in the operation for tying the femoral two vessels are met with, the surgeon should alternately compress each, in order to ascertain which vessel is connected with the aneurismal tumor or with the bleeding from the wound, and that one only should be tied which controls the pulsation or hemorrhage. If, however, it is necessary to compress both vessels before the circulation in the tumor is controlled, both should be tied, as it would be probable that they became reunited, as in the instances referred to above.

In wounds of the femoral artery the question of the mode of treatment is of considerable importance. If the wound in the superficial structures is a large one, the injured vessel must be exposed and tied; but if the wound is a punctured one and the bleeding has ceased, the question will arise whether to cut down upon the artery or to trust to pressure. Mr. Cripps[1] advises that if the wound is in the "upper part of the thigh—that is to say, in a position where the femoral artery is comparatively superficial—the surgeon may enlarge the opening with a good prospect of finding the wounded vessel without an extensive or prolonged operation. If the wound be in the lower half of the thigh, owing to the greater depth of the artery and the possibility of its being the popliteal that is wounded, the search is rendered a far more severe and hazardous operation, and it should not be undertaken until a thorough trial of pressure has proved ineffectual."

Great care and attention are necessary for the successful application of pressure. The limb should be carefully bandaged from the foot upward to the wound, which is not covered, and then onward to the groin. The wound is then dusted with iodoform or boracic powder and a conical pad applied over the wound. Rollers the thickness of the index finger are then placed along the course of the vessel above and below the wound, and the whole carefully bandaged to a back splint with a foot-piece.

Collateral Circulation.—When the common femoral is tied the main channels for carrying on the circulation are the anastomoses of the gluteal and circumflex iliac arteries above with the external circumflex below; of the obturator and sciatic above with the internal circumflex below; and of the comes nervi ischiadici with the arteries in the ham.

The principal agents in carrying on the collateral circulation after ligature of the superficial femoral artery are, according to Sir A. Cooper, as follows:

"The arteria profunda formed the new channel for the blood. The first artery sent off passed down close to the back of the thigh-bone, and entered the two superior articular branches of the popliteal artery.

"The second new large vessel, arising from the profunda at the same part with the former, passed down by the inner side of the Biceps muscle to a branch of the popliteal which was distributed to the Gastrocnemius muscle; whilst a third artery, dividing into several branches, passed down with the sciatic nerve behind the knee-joint, and some of its branches united themselves with the inferior articular arteries of the popliteal, with some recurrent branches of those arteries, with arteries passing to the Gastrocnemii, and, lastly, with the origin of the anterior and posterior tibial arteries.

"It appears, then, that it is those branches of the profunda which accompany the sciatic nerve that are the principal supporters of the new circulation."[2]

In Porta's work[3] (tab. xii., xiii.) is a good representation of the collateral circulation after the ligature of the femoral artery. The patient had survived the operation three years. The lower part of the artery is at least as large as the upper; about two inches of the vessel appear to have been obliterated. The external and internal circumflex arteries are seen anastomosing by a great number of branches with the lower branches of the femoral (muscular and anasto-

[1] Heath's Dictionary of Practical Surgery, vol. i. p. 525.
[2] Med.-Chir. Trans., vol. ii., 1811.
[3] Alterazioni patologiche delle Arterie.

motica magna) and with the articular branches of the popliteal. The branches from the external circumflex are extremely large and numerous. One very distinct anastomosis can be traced between this artery on the outside and the anastomotica magna on the inside through the intervention of the superior external articular artery, with which they both anastomose; and blood reaches even the anterior tibial recurrent from the external circumflex by means of anastomosis with the same external articular artery. The perforating branches of the profunda are also seen bringing blood round the obliterated portion of the artery into long branches (muscular)

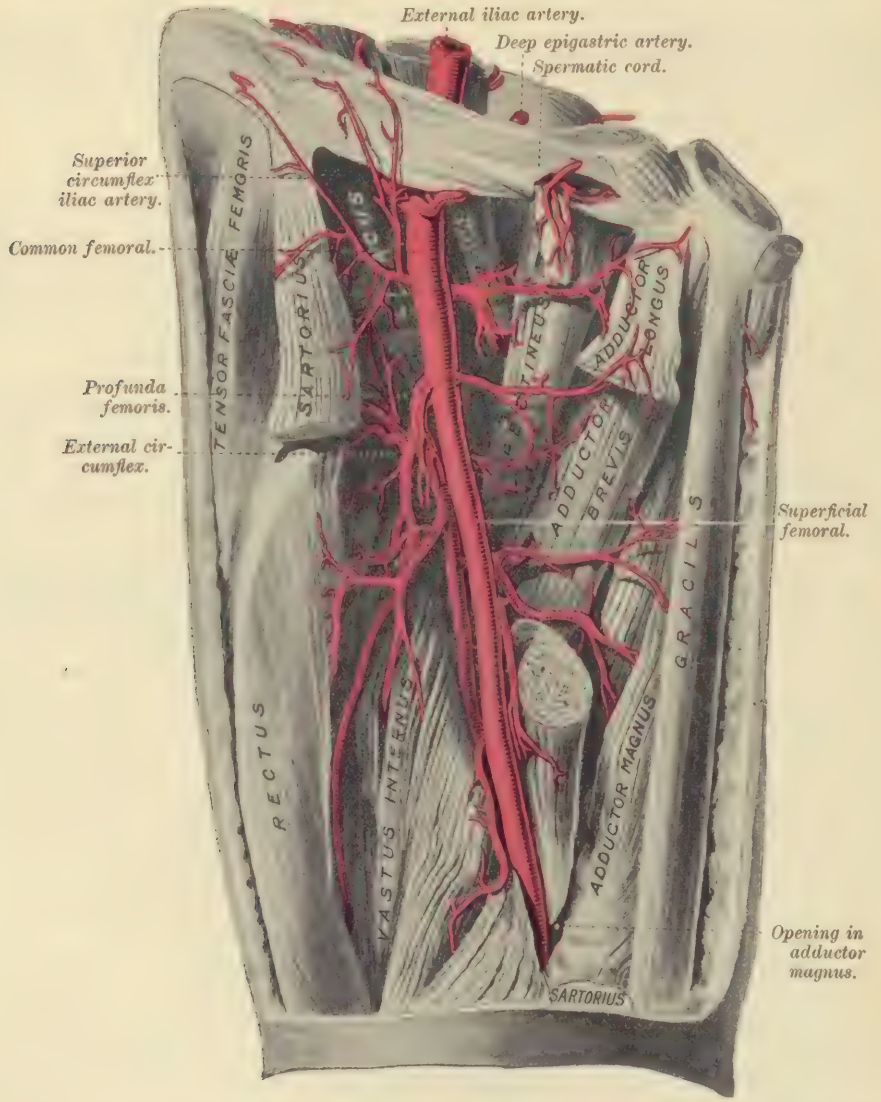

FIG. 432.—Femoral artery and its branches. (From a preparation in the Museum of the Royal College of Surgeons of England.)

which have been given off just below that portion. The termination of the profunda itself anastomoses most freely with the superior external articular. A long branch of anastomosis is also traced down from the internal iliac by means of the comes nervi ischiadici of the sciatic, which anastomoses on the popliteal nerves with branches from the popliteal and posterior tibial arteries. In this case the anastomosis had been too free, since the pulsation and growth of the aneurism recurred, and the patient died after ligature of the external iliac.

There is an interesting preparation in the Museum of the Royal College of Surgeons of a limb on which John Hunter had tied the femoral artery fifty years before the patient's death.

The whole of the superficial femoral and popliteal artery seems to have been obliterated. The anastomosis by means of the comes nervi ischiadici, which is shown in Porta's plate, is distinctly seen: the external circumflex and the termination of the profunda artery seem to have been the chief channels of anastomoses; but the injection has not been a very successful one.

Branches (Figs. 430, 431, and 432).—The branches of the femoral artery are—the

Superficial Epigastric.
Superficial Circumflex Iliac.
Superficial External Pudic.
Deep External Pudic.
Profunda Femoris { External Circumflex. Internal Circumflex. Three Perforating.
Muscular.
Anastomotica Magna.

The **Superficial Epigastric** (*a. epigastrica superficialis*) *arises* from the femoral about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric.

The **Superficial Circumflex Iliac** (*a. circumflexa ilium superficialis*), the smallest of the cutaneous branches, *arises* close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the integument of the groin, the superficial fascia, and the superficial inguinal lymphatic glands, anastomosing with the deep circumflex iliac and with the gluteal and external circumflex arteries.

The **Superficial External Pudic** or the **Superior Superficial External Pudic** (*a. pudenda externa superficialis*) *arises* from the inner side of the femoral artery, close to the preceding vessels, and, after passing through the saphenous opening, courses inward, across the spermatic cord or round ligament, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium in the female, anastomosing with branches of the internal pudic.

The **Deep External Pudic** or the **Deep Superficial External Pudic** (*a. pudenda externa profunda*), more deeply seated than the preceding, passes inward across the Pectineus and Adductor longus muscles, covered by the fascia lata, which it pierces at the inner border of the thigh, its branches being distributed, in the male, to the integument of the scrotum and perineum; and in the female to the labium, anastomosing with branches of the superficial perineal artery.

The **Deep Femoral** or the **Profunda Femoris** (*a. profunda femoris*) (Figs. 430, 431, and 432) nearly equals the size of the superficial femoral. It *arises* from the outer and back part of the femoral artery, from one to two inches below Poupart's ligament. It at first lies on the outer side of the superficial femoral, and then passes behind it and the femoral vein to the inner side of the femur, and, passing downward beneath the Adductor longus, terminates at the lower third of the thigh in a small branch which pierces the Adductor magnus (and from this circumstance is sometimes called the **fourth perforating artery**), and is distributed to the flexor muscles on the back of the thigh, anastomosing with branches of the popliteal and inferior perforating arteries.

Relations.—*Behind*, it lies first upon the Iliacus, and then on the Pectineus, Adductor brevis, and Adductor magnus muscles. *In front*, it is separated from the superficial femoral artery, above by the femoral and profunda veins, and below by the Adductor longus. On its *outer side* the origin of the Vastus internus separates it from the femur.

PLAN OF THE RELATIONS OF THE PROFUNDA ARTERY.

In front.

Branches.—The profunda gives off the following named branches:

Muscular.	Internal circumflex.
External circumflex.	Four perforating.

Muscular Branches are given off in Scarpa's triangle, and also from the vessel as it lies between the Adductor muscles.

The **External Circumflex Artery** (*a. circumflexa femoris lateralis*) supplies the muscles on the front of the thigh. It *arises* from the outer side of the profunda, passes horizontally outward, between the divisions of the anterior crural nerve and behind the Sartorius and Rectus muscles, and divides into three sets of **branches—ascending, transverse,** and **descending.**

The **ascending branch** (*ramus ascendens*) passes upward, beneath the Tensor fasciæ femoris muscle, to the outer side of the hip, anastomosing with the terminal branches of the gluteal and deep circumflex iliac arteries. It sends out muscular branches. The **descending branch** (*ramus descendens*) passes downward, behind the Rectus, upon the Vasti muscles, to which its branches are distributed, one or two passing beneath the Vastus externus as far as the knee, anastomosing with the superior articular branches of the popliteal artery. These are accompanied by the branch of the anterior crural nerve to the Vastus externus. The **transverse branch,** the smallest, passes outward over the Crureus, pierces the Vastus externus, and winds round the femur to its back part, just below the great trochanter, anastomosing at the back of the thigh with the internal circumflex, sciatic, and superior perforating arteries.

The **Internal Circumflex Artery** (*a. circumflexa femoris medialis*), smaller than the external, *arises* from the inner and back part of the profunda, and winds round the inner side of the femur, between the Pectineus and Psoas muscles. On reaching the upper border of the Adductor brevis it gives off two **muscular branches,** one of which passes inward to be distributed to the Adductor muscles, the Gracilis, and Obturator externus, anastomosing with the obturator artery; the other descends, and passes beneath the Adductor brevis, to supply it and the great Adductor; while the continuation of the vessel passes backward and divides into an ascending and a transverse branch (Fig. 348). The **ascending branch** (*ramus profundus*) passes obliquely upward upon the tendon of the Obturator externus and under cover of the Quadratus femoris toward the digital fossa, where it anastomoses with twigs from the gluteal and sciatic arteries. The **transverse branch** (*ramus superficialis*), larger than the ascending, appears between the Quadratus femoris and upper border of the Adductor magnus, anastomosing with the sciatic, external circumflex, and superior perforating arteries, the **crucial anas-**

tomosis. Opposite the hip-joint the artery gives off an **articular vessel** (*ramus acetabuli*), which enters the joint beneath the transverse ligament; and, after supplying the adipose tissue, passes along the round ligament to the head of the bone.

The **Perforating Arteries** (Figs. 429, 430, and 431), usually three in number, are so called from their perforating the tendon of the Adductor magnus muscle to

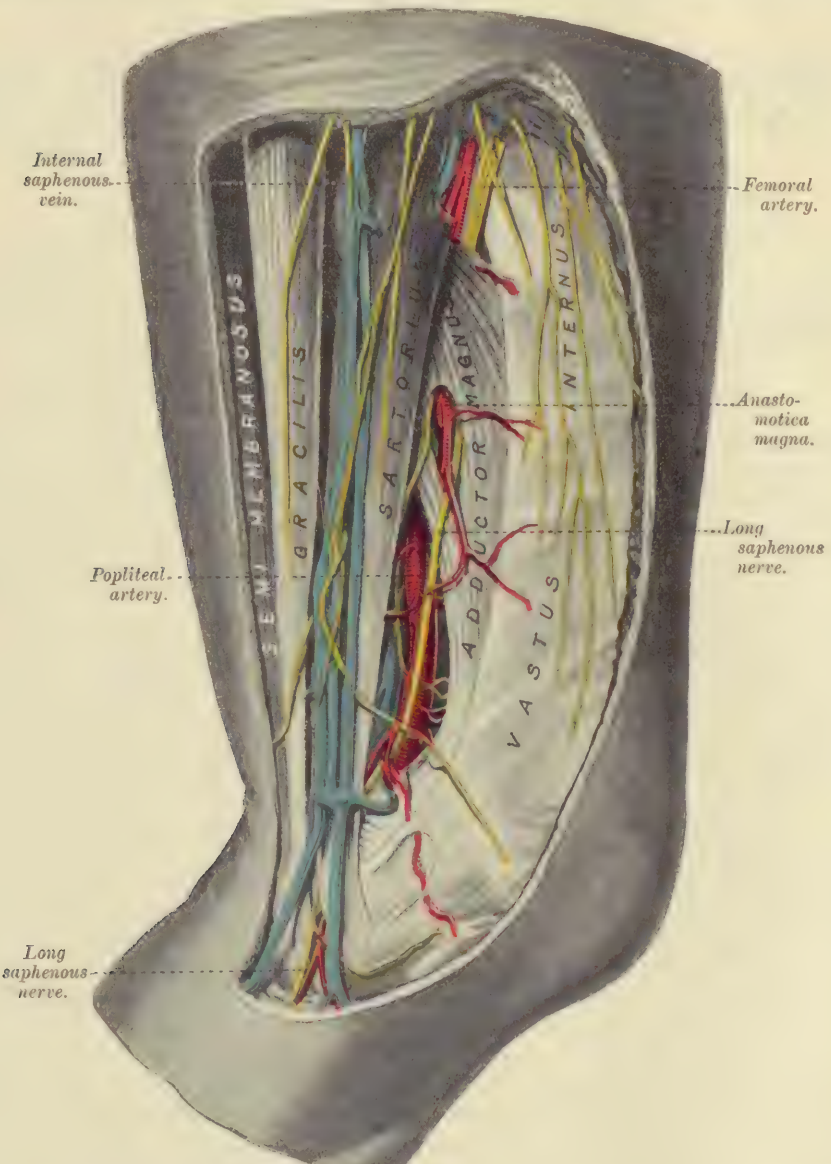

FIG. 433.—Side view of the popliteal artery. (From a preparation in the Museum of the Royal College of Surgeons of England.)

reach the back of the thigh. They pass backward close to the linea aspera of the femur, under cover of small tendinous arches in the Adductor magnus. The **first** is given off above the Adductor brevis, the **second** in front of that muscle, and the **third** immediately below it.

The **first perforating artery** (*a. perforans prima*) passes backward between the Pectineus and Adductor brevis (sometimes perforates the latter); it then pierces

the Adductor magnus close to the linea aspera. It gives off branches which supply the Adductor brevis, the Adductor magnus, the Biceps, and Gluteus maximus muscles, and anastomoses with the sciatic, internal and external circumflex, and middle perforating arteries. The **second perforating artery** (*a. perforans secunda*), larger than the first, pierces the tendons of the Adductor brevis and Adductor magnus muscles, and divides into ascending and descending branches, which supply the flexor muscles of the thigh, anastomosing with the first and third perforating arteries. The second artery frequently arises in common with the first. The **nutrient artery of the femur** is usually given off from this branch. The **third perforating artery** (*a. perforans tertia*) is given off below the Adductor brevis; it pierces the Adductor magnus, and divides into branches which supply the flexor muscles of the thigh; anastomosing above with the higher perforating arteries, and below with the terminal branches of the profunda and the muscular branches of the popliteal. A **fourth perforating artery** is represented by the termination of the profunda femoris artery.

The nutritive artery of the femur (*a. nutricia femoris*), if single, comes from the second perforating artery; if double, from the first and third perforating arteries. If double, one vessel is called **superior** and the other **inferior.**

Muscular Branches (*rami musculares*) are given off from the superficial femoral throughout its entire course. They vary from two to seven in number, and supply chiefly the Sartorius and Vastus internus.

The **Anastomotica Magna** (*a. genu suprema*) (Figs. 430, 431, and 433) arises from the femoral artery just before it passes through the tendinous opening in the Adductor magnus muscle, and immediately divides into a **superficial** and **deep branch.**

The **Superficial Branch** (*ramus saphenous*) pierces the aponeurotic covering of Hunter's canal, and accompanies the long saphenous nerve to the inner side of the thigh. It passes between the Sartorius and Gracilis muscles, and, piercing the fascia lata, is distributed to the integument of the upper and inner part of the leg, anastomosing with the inferior internal articular artery.

The **Deep Branch** (*ramus musculoarticularis*) descends in the substance of the Vastus internus, lying in front of the tendon of the Adductor magnus, to the inner side of the knee, where it anastomoses with the superior internal articular artery and the anterior recurrent branch of the anterior tibial. A branch from this vessel crosses outward above the articular surface of the femur, forming an anastomotic arch with the superior external articular artery, and supplies branches to the knee-joint.

THE POPLITEAL ARTERY (A. POPLITEA) (Figs. 429, 430, 433).

The popliteal artery commences at the termination of the femoral at the opening in the Adductor magnus, and, passing obliquely downward and outward behind the knee-joint to the lower border of the Popliteus muscle divides into the **anterior** and **posterior tibial arteries.** A portion of the artery lies in the popliteal space; but above and below, to a considerable extent, it is covered by the muscles which form the boundaries of the space, and is therefore beyond the confines of the hollow.

The Popliteal Space (Fig. 434).

Dissection. A vertical incision about eight inches in length should be made along the back part of the knee-joint, connected above and below by a transverse incision from the inner to the outer side of the limb. The flaps of integument included between these incisions should be reflected in the direction shown in Fig. 345, page 522.

Boundaries.—The popliteal space, or the **ham,** is a lozenge-shaped space, widest at the back part of the knee-joint, and deepest above the articular end of

the femur. It is bounded *externally, above the joint*, by the Biceps, and below the joint by the Plantaris and external head of the Gastrocnemius. *Internally, above the joint*, by the Semimembranosus, Semitendinosus, Gracilis, and Sartorius; below the joint, by the inner head of the Gastrocnemius.

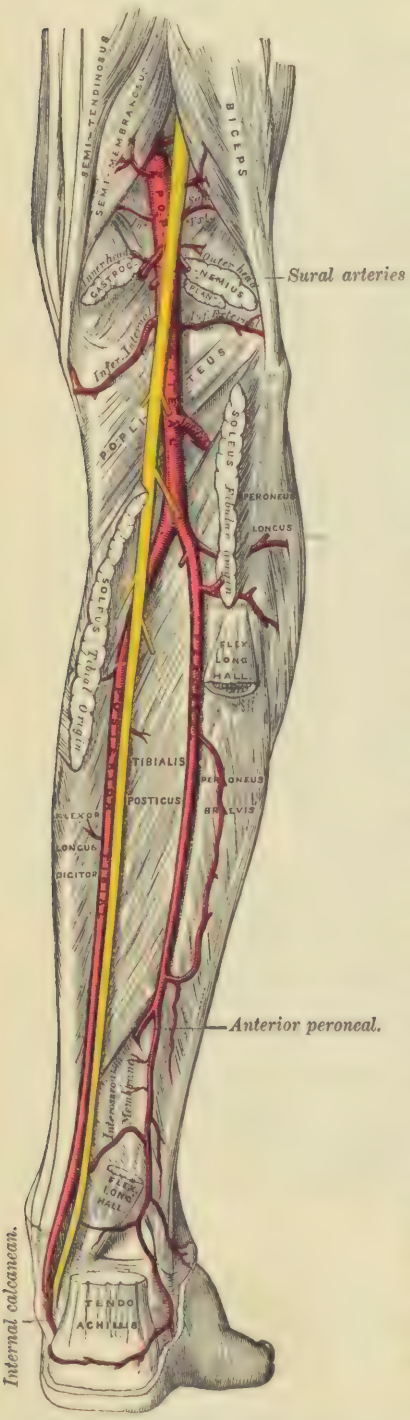

FIG. 434.—The popliteal, posterior tibial, and peroneal arteries.

Above, it is limited by the apposition of the inner and outer hamstring muscles; *below*, by the junction of the two heads of the Gastrocnemius. The floor is formed by the lower part of the posterior surface of the shaft of the femur, the posterior ligament of the knee-joint, the upper end of the tibia, and the fascia covering the Popliteus muscle, and the space is covered in by the fascia lata.

Contents.—It contains the popliteal vessels and their branches, together with the termination of the external saphenous vein, the internal and external popliteal nerves and some of their branches, the lower extremity of the small sciatic nerve, the articular branch from the obturator nerve, a few small lymphatic glands, and a considerable quantity of loose adipose tissue.

Position of Contained Parts.—The internal popliteal nerve descends in the middle line of the space lying superficial and crossing the artery from without inward. The external popliteal nerve descends on the outer side of the upper part of the space, lying close to the tendon of the Biceps muscle. More deeply at the bottom of the space are the popliteal vessels, the vein lying superficial to the artery, to which it is closely united by dense areolar tissue; it is a thick-walled vessel, and lies at first to the outer side of the artery, and then crosses it to gain the inner side below; sometimes the vein is double, the artery lying between the two venæ comites, which are usually connected by short transverse branches. More deeply and, at its upper part, close to the surface of the bone is the popliteal artery, and passing off from it at right angles are its articular branches. The articular branch from the obturator nerve descends upon the popliteal artery to supply the knee, and occasionally there is found deep in the space an articular filament from the great sciatic nerve.

The popliteal lymphatic glands, four or five in number, are found surrounding the artery; one usually lies superficial to the vessel; another is situated between it and the bone, and the rest are placed on either side of it.

The **Popliteal Artery**, in its course downward from the aperture in the Adductor magnus to the lower border of the Popliteus muscle, rests first on the inner surface of the femur, and is then separated by a little fat from the hollowed popliteal surface of the bone; in the middle of its course it rests on the posterior ligament of the knee-joint, and below on the fascia covering the Popliteus muscle. *Superficially*, it is covered above by the Semimembranosus; in the middle of its course, by a quantity of fat, which separates it from the deep fascia and integument; and below it is overlapped by the Gastrocnemius, Plantaris, and Soleus muscles, the popliteal vein, and the internal popliteal nerve. The popliteal vein, which is intimately attached to the artery, lies superficial and external to it above; it then crosses it and lies to its inner side. The internal popliteal nerve is still more superficial and external above, but below the joint it crosses the artery and lies on its inner side. *Laterally*, the artery is bounded by the muscles which are situated on either side of the popliteal space.

Peculiarities in Point of Division.—Occasionally the popliteal artery divides prematurely into its terminal branches: this unusual division occurs most frequently opposite the knee-joint. The anterior tibial under these circumstances may pass in front of the Popliteus muscle.

Unusual Branches.—The artery sometimes divides into the anterior tibial and peroneal, the posterior tibial being wanting or very small. Occasionally the popliteal is found to divide into three branches, the anterior and posterior tibial and peroneal.

Surface Marking.—The course of the upper part of the popliteal artery is indicated by a line drawn from the outer border of the Semimembranosus muscle at the junction of the middle and lower third of the thigh obliquely downward to the middle of the popliteal space, exactly behind the knee-joint. From this point it passes vertically downward to the level of a line drawn through the lower part of the tubercle of the tibia.

Surgical Anatomy.—The popliteal artery is not infrequently the seat of injury. It may be torn by direct violence, as by the passage of a cart-wheel over the knee or by hyper-extension of the knee; and in the dead body, at all events, the middle and internal coats may be ruptured by extreme flexion. It may also be lacerated by fracture of the lower part of the shaft of the femur or by antero-posterior dislocation of the knee-joint. It has been torn in breaking down adhesions in cases of fibrous ankylosis of the knee, and is in danger of being wounded, and in fact has been wounded, in performing Macewen's operation of osteotomy of the lower end of the femur for genu valgum. In addition, Spencer records a case in which the popliteal artery was wounded from in front by a stab just below the knee, the knife passing through the interosseous space. The popliteal artery is more frequently the seat of aneurism than is any other artery in the body, with the exception of the thoracic aorta. This is due no doubt, in a great measure, to the amount of movement to which it is subjected, and to the fact that it is supported by loose and lax tissue only, and not by muscles, as is the case with most arteries.

Ligature of the popliteal artery is required in cases of wound of that vessel, but for aneurism of the posterior tibial it is preferable to tie the superficial femoral. The popliteal may be tied in the upper or lower part of its course; but in the middle of the ham the operation is attended

with considerable difficulty, from the great depth of the artery and from the extreme degree of tension of the lateral boundaries of the space.

In order to expose the vessel in the upper part of its course, the patient should be placed in the supine position, with the knee flexed and the thigh rotated outward, so that it rests on its outer surface; an incision three inches in length, beginning at the junction of the middle and lower third of the thigh, is to be made parallel to and immediately behind the tendon of the Adductor magnus, and the skin, superficial and deep fascia divided. The tendon of the muscle is thus exposed, and is to be drawn forward and the hamstring tendons backward. A quantity of fatty tissue will now be opened up, in which the artery will be felt pulsating. This is to be separated with the point of a director until the artery is exposed. The vein and nerve will not be seen, as they lie to the outer side of the artery. The sheath is to be opened and the aneurism needle passed from before backward, keeping its point close to the artery for fear of injuring the vein. The only structure to avoid is the long saphenous vein in the superficial incision. The upper part of the popliteal artery may also be tied by an incision on the back of the limb, along the outer margin of the Semimembranosus, but the operation is a more difficult one, as the internal popliteal nerve and the popliteal vein are first exposed, and great care has to be exercised in separating them from the artery.

To expose the vessel in the lower part of its course, where the artery lies between the two heads of the Gastrocnemius, the patient should be placed in the prone position with the limb extended. An incision should then be made through the integument in the middle line, commencing opposite the bend of the knee-joint, care being taken to avoid the external saphenous vein and nerve. After dividing the deep fascia and separating some dense cellular membrane, the artery, vein, and nerve will be exposed, descending between the two heads of the Gastrocnemius. Some muscular branches of the popliteal should be avoided if possible, or, if divided, tied immediately. The leg being now flexed, in order the more effectually to separate the two heads of the Gastrocnemius, the nerve should be drawn inward and the vein outward, and the aneurism needle passed between the artery and vein from without inward.

Branches.—The branches of the popliteal artery are—the

Muscular { Superior. Inferior or Sural.	Superior External Articular.
Cutaneous.	Azygos Articular.
Superior Internal Articular.	Inferior Internal Articular.
	Inferior External Articular.

The **Superior Muscular Branches,** two or three in number, *arise* from the upper part of the popliteal artery, and are distributed to the lower part of the Adductor magnus and flexor muscles of the thigh, anastomosing with the fourth perforating branch of the profunda.

The **Inferior Muscular** (*aa. surales*) are two large branches which are distributed to the two heads of the Gastrocnemius and to the Plantaris muscle. They *arise* from the popliteal artery opposite the knee-joint.

The **Cutaneous Branches** *arise* separately from the popliteal artery or from some of its branches; they descend between the two heads of the Gastrocnemius muscle, and, piercing the deep fascia, are distributed to the integument of the calf. One branch usually accompanies the short, or external, saphenous vein, the **superficial sural artery.**

The **Superior Articular Arteries,** two in number, *arise* one on each side of the popliteal, and wind round the femur immediately above its condyles to the front of the knee-joint. The **internal branch** (*a. genu superior medialis*) winds inward beneath the hamstring muscles, to which it supplies branches, above the inner head of the Gastrocnemius, and, passing beneath the tendon of the Adductor magnus, divides into two branches, one of which supplies the Vastus internus, inosculating with the anastomotica magna and inferior internal articular; the other ramifies close to the surface of the femur, supplying it and the knee-joint, and anastomosing with the superior external articular artery. This branch is frequently of small size, a condition which is associated with an increase in the size of the anastomotica magna. The **external branch** (*a. genu superior lateralis*) passes above the outer condyle, beneath the tendon of the Biceps, and divides into a superficial and deep branch: the superficial branch supplies the Vastus externus, and anasto-

moses with the descending branch of the external circumflex and the inferior external articular arteries; the deep branch supplies the lower part of the femur and knee-joint, and forms an anastomotic arch across the bone with the anastomotica magna and the inferior internal articular arteries.

The **Azygos Articular** (*a. genu media*) is a small branch arising from the popliteal artery opposite the bend of the knee-joint. It pierces the posterior ligament, and supplies the ligaments and synovial membrane in the interior of the articulation.

The **Inferior Articular Arteries,** two in number, *arise* from the popliteal beneath the Gastrocnemius, and wind round the head of the tibia below the joint. The **internal branch** (*a. genu inferior medialis*) first descends along the upper margin of the Popliteus muscle, to which it gives branches; it then passes below the inner tuberosity, beneath the internal lateral ligament, at the anterior border of which it ascends to the front and inner side of the joint, to supply the head of the tibia and the articulation of the knee, anastomosing with the inferior external articular and superior internal articular arteries. The **external branch** (*a. genu inferior lateralis*) passes outward above the head of the fibula, to the front of the knee-joint, passing in its course beneath the outer head of the Gastrocnemius, the external lateral ligament, and the tendon of the Biceps muscle, and divides into branches which anastomose with the inferior internal articular artery, the superior external articular artery, and the anterior recurrent branch of the anterior tibial.

Circumpatellar Anastomosis.—Around and above the patella, and on the contiguous ends of the femur and tibia, is a large network of vessels, forming a superficial and a deep plexus. The superficial plexus is situated between the fascia and skin round about the patella; the deep plexus, which forms a close network of vessels, lies on the surface of the lower end of the femur and upper end of the tibia around their articular surfaces, and sends numerous offsets into the interior of the joint. The arteries from which this plexus is formed are the two internal and two external articular branches of the popliteal, the anastomotica magna, the terminal branch of the profunda, the descending branch from the external circumflex and the anterior recurrent branch of the anterior tibial.

The Anterior Tibial Artery (A. Tibialis Anterior) (Fig. 435).

The anterior tibial artery commences at the bifurcation of the popliteal at the lower border of the Popliteus muscle, passes forward between the two heads of the Tibialis posticus, and through the large oval aperture above the upper border of the interosseous membrane to the deep part of the front of the leg; it here lies close to the inner side of the neck of the fibula; it then descends on the anterior surface of the interosseous membrane, gradually approaching the tibia; and at the lower part of the leg lies on this bone, and then on the anterior ligament of the ankle to the bend of the ankle-joint, where it lies more superficially, and becomes the **dorsalis pedis.**

Relations.—In the upper two-thirds of its extent it rests upon the interosseous membrane, to which it is connected by delicate fibrous arches thrown across it; in the lower third, upon the front of the tibia and the anterior ligament of the ankle-joint. In the upper third of its course it lies between the Tibialis anticus and Extensor longus digitorum; in the middle third, between the Tibialis anticus and Extensor proprius hallucis. At the bend of the ankle it is crossed by the tendon of the Extensor proprius hallucis, and lies between it and the innermost tendon of the Extensor longus digitorum. It is covered, in the upper two-thirds of its course, by the muscles which lie on either side of it and by the deep fascia ; in the lower third, by the integument, anterior annular ligament, and fascia.

The anterior tibial artery is accompanied by two veins, **venæ comites,** which lie one on each side of the artery; the anterior tibial nerve, coursing round the outer side of the neck of the fibula, comes into relation with the outer side of the artery shortly after it has passed through the opening in the interosseous membrane; about the middle of the leg it is placed superficial to it; at the lower part of the artery the nerve is generally again on the outer side.

Anterior ligament of ankle-joint.

Peculiarities in Size.—This vessel may be very small, may be deficient to a greater or less extent, or may be entirely wanting, its place being supplied by perforating branches from the posterior tibial or by the anterior division of the peroneal artery.

Course.—The artery occasionally deviates in its course toward the fibular side of the leg, regaining its usual position beneath the annular ligament at the front of the ankle. In two instances the vessel has been found to approach the surface in the middle of the leg, being covered merely by the integument and fascia below that point.

Surface Marking.—Draw a line from the inner side of the head of the fibula to midway between the two malleoli. In this line take a point one inch and a quarter below the head of the fibula, and the portion of the line below this point will mark the course of the artery.

Surgical Anatomy.—The anterior tibial artery may be tied in the upper or lower part of the leg. In the upper part the operation is attended with great difficulty, on account of the depth of the vessel from the surface. An incision, about four inches in length, should be made through the integument, midway between the spine of the tibia and the outer margin of the fibula, and the deep fascia exposed. The wound must now be carefully dried, its edges retracted, and the white line separating the Tibialis anticus from the Extensor longus digitorum sought for. When this has been clearly defined, the deep fascia is to be divided in this line, and the Tibialis anticus separated from adjacent muscles with the handle of the scalpel or a director until the interosseous membrane is reached. The foot is to be flexed in order to relax the muscles, and upon drawing them apart the artery will be found lying on the interosseous membrane with the nerve on its outer side or on the top of the artery. The nerve should be drawn outward, and the venæ comites separated from the artery and the needle passed round it.

To tie the vessel in the lower third of the leg above the ankle-joint an incision about three inches in length should be made through the integument between the tendons of the Tibialis anticus and Extensor proprius hallucis muscles, the deep fascia being divided to the same extent. The tendon on either side should be held aside, when the vessel will be seen lying upon the tibia, with the nerve on the outer side and one of the venæ comites on either side.

Branches.—The branches of the anterior tibial artery are—the

Posterior Recurrent Tibial.	Muscular.
Superior Fibular.	Internal Malleolar.
Anterior Recurrent Tibial.	External Malleolar.

The **Posterior Recurrent Tibial** (*a. recurrens tibialis posterior*) is not a constant branch, and is given off from the anterior tibial before that vessel passes through the interosseous space. It ascends beneath the Popliteus muscle, which it supplies, and anastomoses with the lower articular branches of the popliteal artery, giving off an offset to the superior tibio-fibular joint.

The **Superior Fibular** is sometimes given off from the anterior tibial, sometimes from the posterior tibial. It passes outward, round the neck of the fibula, through the Soleus, which it supplies, and ends in the substance of the Peroneus longus muscle.

The **Anterior Recurrent Tibial** (*a. recurrens tibialis anterior*) *arises* from the anterior tibial as soon as that vessel has passed through the interosseous space; it ascends in the Tibialis anticus muscle, and ramifies on the front and sides of the knee-joint, anastomosing with the articular branches of the popliteal, with the anastomotica magna, and the external articular branches of the popliteal, assisting in the formation of the circumpatellar plexus.

The **Muscular Branches** are numerous; they are distributed to the muscles which lie on each side of the vessel, some **cutaneous branches** piercing the deep fascia to supply the integument, others passing through the interosseous membrane, and anastomosing with branches of the posterior tibial and peroneal arteries.

The **Malleolar Arteries** supply the ankle-joint. The **internal branch** (*a. malleolaris anterior medialis*) *arises* about two inches above the articulation, and passes beneath the tendons of the Extensor proprius hallucis and Tibialis anticus to the inner ankle, upon which it ramifies, anastomosing with branches of the posterior tibial and internal plantar arteries and with the internal calcanean from the posterior tibial. The **external branch** (*a. malleolaris anterior lateralis*) passes beneath the tendons of the Extensor longus digitorum and Peroneus

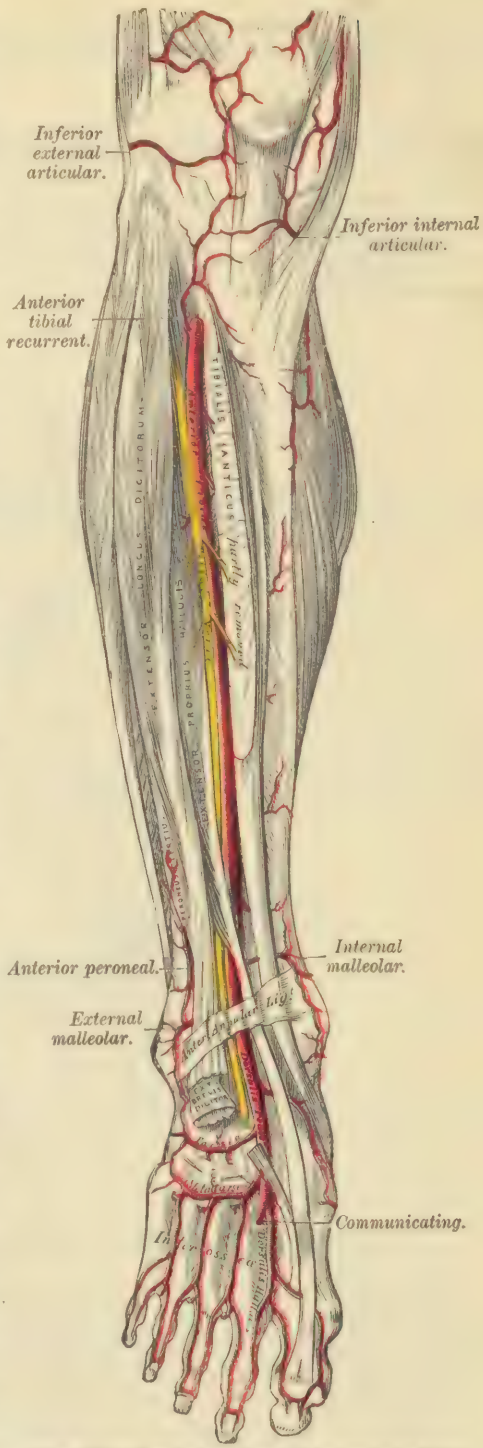

FIG. 435. Surgical anatomy of the anterior tibial and dorsalis pedis arteries.

tertius, and supplies the outer ankle, anastomosing with the anterior peroneal artery and with ascending branches from the tarsal branch of the dorsalis pedis.

The Dorsalis Pedis Artery (A. Dorsalis Pedis) (Figs. 435, 436).

The dorsalis pedis, the continuation of the anterior tibial, passes forward from the bend of the ankle along the tibial side of the foot to the back part of the first intermetatarsal space, where it divides into two branches, the **dorsalis hallucis** and **communicating.**

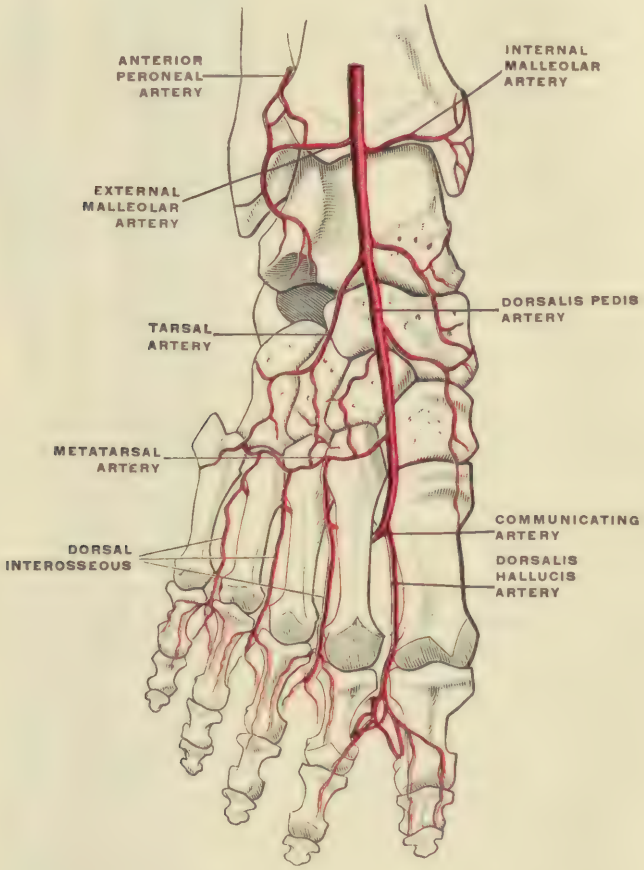

FIG. 436.—Diagram of the arteries of the dorsal surface of the foot. (Poirier and Charpy.)

Relations.—This vessel, in its course forward, rests upon the astragalus, navicular, and middle cuneiform bones and the ligaments connecting them, being covered by the integument and fascia, anterior annular ligament, and crossed near its termination by the innermost tendon of the Extensor brevis digitorum. On its *tibial side* is the tendon of the Extensor proprius hallucis; on its *fibular side*, the innermost tendon of the Extensor longus digitorum, and the termination of the anterior tibial nerve. It is accompanied by two veins.

And their ligaments.

Peculiarities in Size.—The dorsal artery of the foot may be larger than usual, to compensate for a deficient plantar artery; or it may be deficient in its terminal branches to the toes, which are then derived from the internal plantar; or its place may be supplied altogether by a large anterior peroneal artery.

Position. This artery frequently curves outward, lying external to the line between the middle of the ankle and the back part of the first interosseous space.

Surface Marking.—The dorsalis pedis artery is indicated on the surface of the dorsum of the foot by a line drawn from the centre of the space between the two malleoli to the back of the first intermetatarsal space.

Surgical Anatomy. This artery may be tied, by making an incision through the integument between two and three inches in length, on the fibular side of the tendon of the Extensor proprius hallucis, in the interval between it and the inner border of the short Extensor muscle. The incision should not extend farther forward than the back part of the first intermetatarsal space, as the artery divides in that situation. The deep fascia being divided to the same extent, the artery will be exposed, the nerve lying upon its outer side.

Branches.—The branches of the dorsalis pedis are—the

Cutaneous.	Metatarsal—Interosseous.
Tarsal.	Dorsalis Hallucis.
Communicating.	

Cutaneous Branches go to the skin of the dorsum and inner surface of the foot.

The **Tarsal Artery** (*a. tarsea lateralis*) *arises* from the dorsalis pedis, as that vessel crosses the navicular bone; it passes in an arched direction outward, lying upon the tarsal bones, and covered by the Extensor brevis digitorum; it supplies that muscle and the articulations of the tarsus, and anastomoses with branches from the metatarsal, external malleolar, peroneal, and external plantar arteries.

The **Metatarsal** (*a. arcuata*) *arises* a little anterior to the preceding; it passes outward to the outer part of the foot, over the bases of the metatarsal bones, beneath the tendons of the short Extensor, its direction being influenced by its point of origin; and it anastomoses with the tarsal and external plantar arteries. This vessel gives off three branches, the **dorsal interosseous arteries** (*aa. metatarseæ dorsales*), which pass forward upon the three outer Dorsal interossei muscles, and, in the clefts between the toes, divide into two dorsal collateral branches for the adjoining toes (*aa. digitales dorsales*). At the back part of each interosseous space these vessels receive the posterior perforating branches from the plantar arch, and at the forepart of each interosseous space they are joined by the anterior perforating branches from the digital arteries. The outermost interosseous artery gives off a branch which supplies the outer side of the little toe.

The **Dorsalis Hallucis** or the **First Dorsal Interosseous** (*a. dorsalis hallucis*) is one of the terminal branches of the dorsalis pedis. It runs forward along the outer border of the first metatarsal bone, and at the cleft between the first and second toes divides into two branches, one of which passes inward, beneath the tendon of the Extensor proprius hallucis, and is distributed to the inner border of the great toe; the outer branch bifurcates, to supply the adjoining sides of the great and second toes.

The **Communicating Artery** (*ramus plantaris profundus*), the other terminal branch of the dorsalis pedis, dips down into the sole of the foot, between the two heads of the First dorsal interosseous muscle, and inosculates with the termination of the external plantar artery, to complete the plantar arch. It here gives off its plantar digital branch, which is named the *arteria magna hallucis*, or the **princeps hallucis**. This artery passes forward along the first interosseous space, and, after sending a branch along the inner side of the great toe, bifurcates for the supply of the adjacent sides of the great and second toes.

The Posterior Tibial Artery (A. Tibialis Posterior) (Fig. 434).

The posterior tibial is an artery of large size, which extends obliquely downward from the lower border of the Popliteus muscle, along the tibial side of the leg, to the fossa between the inner ankle and the heel, where it divides beneath the origin of the Abductor hallucis, on a level with a line drawn from the point of the internal malleolus to the centre of the convexity of the heel, into the **internal** and **external plantar arteries**. At its origin it lies opposite the interval between the tibia and fibula; as it descends, it approaches the inner side of the leg, lying behind the tibia, and, in the lower part of its course, is situated midway between the inner malleolus and the tuberosity of the os calcis.

Relations.—It lies successively upon the Tibialis posticus, the Flexor longus digitorum, the tibia, and the back part of the ankle-joint. It is *covered* by the deep transverse fascia, which separates it above from the Gastrocnemius and Soleus muscles: at its termination it is covered by the Abductor hallucis muscle. In the lower third, where it is more superficial, it is covered only by the integument and fascia, and runs parallel with the inner border of the tendo Achillis. It is accompanied by two veins and by the posterior tibial nerve, which lies at first to the inner side of the artery, but soon crosses it, and is, in the greater part of its course, on its outer side.

Outer side.
Posterior tibial nerve, lower two-thirds.

Behind.
Integument and fascia.
Gastrocnemius.
Soleus.
Deep transverse fascia.
Posterior tibial nerve.
Abductor hallucis.

Behind the inner ankle the tendons and blood-vessels are arranged, under cover of the internal annular ligament, in the following order, from within out-

ward: First, the tendons of the Tibialis posticus and Flexor longus digitorum, lying in the same groove, behind the inner malleolus, the former being the most internal. External to these is the posterior tibial artery, having a vein on either side: and, still more externally, the posterior tibial nerve. About half an inch nearer the heel is the tendon of the Flexor longus hallucis.

Peculiarities in Size.—The posterior tibial is not unfrequently smaller than usual, or absent, its place being supplied by a large peroneal artery which passes inward at the lower end of the tibia, and either joins the small tibial artery or continues alone to the sole of the foot.

Surface Marking.—The course of the posterior tibial artery is indicated by a line drawn from a point one inch below the centre of the popliteal space to midway between the tip of the internal malleolus and the centre of the convexity of the heel.

Surgical Anatomy.—The *application of a ligature* to the posterior tibial may be required in cases of wound of the sole of the foot attended with great hemorrhage, when the vessel should be tied at the inner ankle. In cases of wound of the posterior tibial it will be necessary to enlarge the opening so as to expose the vessel at the wounded point, excepting where the vessel is injured by a punctured wound from the front of the leg. In cases of aneurism from wound of the artery low down, the vessel should be tied in the middle of the leg. But in aneurism of the posterior tibial high up it would be better to tie the femoral artery.

To tie the posterior tibial artery at the ankle, a semilunar incision, convex backward, should be made through the integument, about two inches and a half in length, midway between the heel and the inner ankle or a little nearer the latter. The subcutaneous cellular tissue having been divided, a strong and dense fascia, the internal annular ligament, is exposed. This ligament is continuous above with the deep fascia of the leg, covers the vessels and nerves, and is intimately adherent to the sheaths of the tendons. This having been cautiously divided upon a director, the sheath of the vessels is exposed, and, being opened, the artery is seen with one of the venæ comites on each side. The aneurism needle should be passed round the vessel from the heel toward the ankle, in order to avoid the posterior tibial nerve, care being at the same time taken not to include the venæ comites.

The vessel may also be tied in the lower third of the leg by making an incision, about three inches in length, parallel with the inner margin of the tendo Achillis. The internal saphenous vein being carefully avoided, the lwo layers of fascia must be divided upon a director, when the artery is exposed along the outer margin of the Flexor longus digitorum, with one of its venæ comites on either side and the nerve lying external to it.

To tie the posterior tibial in the middle of the leg is a very difficult operation, on account of the great depth of the vessel from the surface. The patient being placed in the recumbent position, the injured limb should rest on its outer side, the knee being partially bent and the foot extended, so as to relax the muscles of the calf. An incision about four inches in length should then be made through the integument a finger's breadth behind the inner margin of the tibia, taking care to avoid the internal saphenous vein. The deep fascia having been divided, the margin of the Gastrocnemius is exposed, and must be drawn aside, and the tibial attachment of the Soleus divided, a director being previously passed beneath it. The artery may now be felt pulsating beneath the deep fascia about an inch from the margin of the tibia. The fascia having been divided, and the limb placed in such a position as to relax the muscles of the calf as much as possible, the veins should be separated from the artery, and the aneurism needle passed round the vessel from without inward, so as to avoid wounding the posterior tibial nerve.

Branches.—The branches of the posterior tibial artery are—the

Peroneal.	Cutaneous.
Nutrient.	Communicating.
Muscular.	Internal Calcanean.

Malleolar cutaneous.

The **Peroneal Artery** (*a. peronæa*) (Fig. 434) lies, deeply seated, along the back part of the fibular side of the leg. It arises from the posterior tibial about an inch below the lower border of the Popliteus muscle, passes obliquely outward to the fibula, and then descends along the inner border of that bone, contained in a fibrous canal between the Tibialis posticus and the Flexor longus hallucis, or in the substance of the latter muscle to the lower third of the leg, where it gives off the **anterior peroneal.** It then passes across the articulation between the tibia and fibula to the outer side of the os calcis, where it gives off its terminal branches, the **external calcanean.**

Relations.—This vessel rests at first upon the Tibialis posticus, and then, for the greater part of its course, in a fibrous canal between the origins of the Flexor longus hallucis and Tibialis posticus, covered or surrounded by the fibres of the Flexor longus hallucis. It is *covered*, in the upper part of its course, by the Soleus and deep transverse fascia; *below*, by the Flexor longus hallucis.

PLAN OF THE RELATIONS OF THE PERONEAL ARTERY.

In front.
Tibialis posticus.
Flexor longus hallucis.

Outer side.
Fibula.
Flexor longus hallucis.

Peroneal Artery.

Inner side.
Flexor longus hallucis.

Behind.
Soleus.
Deep transverse fascia.
Flexor longus hallucis.

Peculiarities in Origin.—The peroneal artery may arise three inches below the Popliteus, or from the posterior tibial high up, or even from the popliteal.

Its size is more frequently increased than diminished; and then it either reinforces the posterior tibial by its junction with it, or altogether takes the place of the posterior tibial in the lower part of the leg and foot, the latter vessel only existing as a short muscular branch. In those rare cases where the peroneal artery is smaller than usual a branch from the posterior tibial supplies its place, and a branch from the anterior tibial compensates for the diminished anterior peroneal artery. In one case the peroneal artery has been found entirely wanting.

The anterior peroneal is sometimes enlarged, and takes the place of the dorsal artery of the foot.

Branches.—The branches of the peroneal are—the

Muscular.	Communicating.
Nutrient.	Posterior Peroneal.
Anterior Peroneal.	External Calcanean.

Muscular Branches.—The peroneal artery in its course gives off branches to the Soleus, Tibialis posticus, Flexor longus hallucis, and Peronei muscles.

The **Nutrient Artery** (*a. nutritia fibulæ*) supplies the fibula.

The **Anterior Peroneal** (*ramus perforans*) (Fig. 436) pierces the interosseous membrane, about two inches above the outer malleolus, to reach the forepart of the leg, and, passing down beneath the Peroneus tertius to the outer ankle, ramifies on the front and outer side of the tarsus, anastomosing with the external malleolar and tarsal arteries.

The **Communicating** (*ramus communicans*) is given off from the peroneal about an inch from its lower end, and, passing inward, joins the communicating branch of the posterior tibial.

The **Posterior Peroneal** passes down behind the outer ankle to the back of the external malleolus, to terminate in branches which ramify on the outer surface and back of the os calcis.

External Calcanean (*ramus calcaneus lateralis*) are the terminal branches of the peroneal artery; they pass to the outer side of the heel, and communicate with the external malleolar, and, on the back of the heel, with the internal calcanean arteries.

Cutaneous Branches come from the posterior tibial and supply the skin of the inner side and back of the leg.

The **Nutrient Artery** of the tibia (*a. nutricia tibiæ*) *arises* from the posterior tibial near its origin, and, after supplying a few muscular branches, enters the nutrient canal of that bone, which it traverses obliquely from above downward. This is the largest nutrient artery of bone in the body.

The **Muscular Branches** of the posterior tibial are distributed to the Soleus and deep muscles along the back of the leg.

The **Communicating Branch** (*ramus communicans*), to join a similar branch of the peroneal, runs transversely across the back of the tibia, about two inches above its lower end, passing beneath the Flexor longus hallucis.

The **Malleolar** or **Internal Malleolar** (*a. malleolaris posterior medialis*) lies upon the tibia, sends branches over the inner ankle, and anastomoses with the inner malleolar branch of the anterior tibial.

The **Internal Calcanean** (*rami calcanei mediales*) are several large arteries which *arise* from the posterior tibial just before its division: they are distributed

FIG. 437.—The plantar arteries. Superficial view.

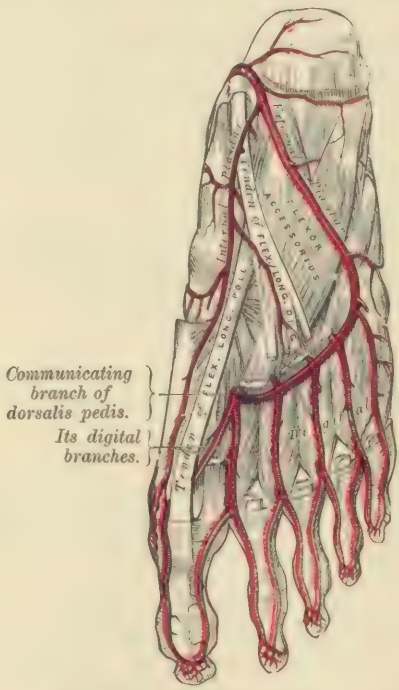

FIG. 438.—The plantar arteries. Deep view.

to the fat and integument behind the tendo Achillis and about the heel, and to the muscles on the inner side of the sole, anastomosing with the peroneal and internal malleolar, and, on the back of the heel, with the external calcanean arteries.

The **Internal Plantar Artery** (*a. plantaris medialis*) (Figs. 437 and 438), much smaller than the external, passes forward along the inner side of the foot. It is at first situated above[1] the Abductor hallucis, and then between it and the Flexor brevis digitorum, both of which it supplies. At the base of the first metatarsal bone, where it has become much diminished in size, it passes along the inner border of the great toe, inosculating with its digital branch. Small superficial digital branches accompany the digital branches of the internal plantar nerve and join the plantar digital arteries of the three inner spaces. In addition, this vessel gives off numerous cutaneous branches.

[1] This refers to the erect position of the body. In the ordinary position for dissection the artery is deeper than the muscle.

The **External Plantar Artery** (*a. plantaris lateralis*) (Figs. 437 and 438), much larger than the internal, passes obliquely outward and forward to the base of the fifth metatarsal bone. It then turns obliquely inward to the interval between the bases of the first and second metatarsal bones, where it anastomoses with the communicating branch from the dorsalis pedis artery, thus completing the **plantar arch** (*arcus plantaris*) (Fig. 438). As this artery passes outward, it is first placed between the os calcis and Abductor hallucis, and then between the Flexor brevis digitorum and Flexor accessorius, and as it passes forward to the base of the little toe it lies more superficially between the Flexor brevis digitorum and Abductor minimi digiti, covered by the deep fascia and integument. The remaining portion of the vessel is deeply situated: it extends from the base of the metatarsal bone of the little toe to the back part of the first interosseous space, and forms the plantar arch; it is convex forward, lies upon the Interossei muscles opposite the tarsal ends of the metatarsal bones, and is covered by the Adductor obliquus hallucis, the flexor tendons of the toes, and the Lumbricales.

Surface Marking.—The course of the internal plantar artery is represented by a line drawn from the mid-point between the tip of the internal malleolus and the centre of the convexity of the heel to the middle of the under surface of the great toe; the external plantar by a line from the same point to within a finger's breadth of the tuberosity of the fifth metatarsal bone. The plantar arch is indicated by a line drawn from this point—*i. e.*, a finger's breadth internal to the tuberosity of the fifth metatarsal bone transversely across the foot to the back of the first interosseous space.

Surgical Anatomy.—Wounds of the plantar arch are always serious, on account of the depth of the vessel and the important structures which must be interfered with in an attempt to ligate it. They must be treated on similar lines to those of wounds of the palmar arches (see page 665). Delorme has shown that the plantar arch may be ligated from the dorsum of the foot in almost any part of its course by removing a portion of one of the three middle metatarsal bones.

Branches.—The plantar arch, besides distributing numerous branches to the muscles, integument, and fasciæ in the sole, gives off the following branches:

Posterior Perforating. Digital.

The **Posterior Perforating** (*rami perforantes posteriores*) are three small branches which ascend through the back part of the three outer interosseous spaces, between the heads of the Dorsal interossei muscles, and anastomoses with the interosseous branches from the metatarsal artery.

The **Digital Branches** (*aa. metatarseæ plantares*) are four in number, and supply the three outer toes and half the second toe. It will be remembered that the arteria princeps hallucis is the plantar digital branch of the communicating arms in the first interosseous space and supplies the adjacent sides of the great and little toes. The *first digital branch* of the plantar arch passes outward from the outer side of the plantar arch, and is distributed to the outer side of the little toe, passing in its course beneath the Abductor and short Flexor muscles. The *second*, *third*, and *fourth* run forward along the interosseous spaces, and on arriving at the clefts between the toes divides into **collateral digital branches** (*aa. digitales plantares*), which supply the adjacent sides of the three outer toes and the outer side of the second. At the bifurcation of the toes each digital artery sends upward, through the forepart of the corresponding interosseous space, a small branch which inosculates with the interosseous branches of the metatarsal artery. These are the **anterior perforating branches** (*rami perforantes anteriores*).

From the arrangement already described of the distribution of the vessels to the toes it will be seen that both sides of the three outer toes and the outer side of the second toe are supplied by branches from the plantar arch; both sides of the great toe and the inner side of the second are supplied by the communicating branch of the dorsalis pedis.

THE VEINS.

THE Veins are the vessels which serve to return the blood from the capillaries of the different parts of the body to the heart. They consist of two distinct sets of vessels, the **pulmonary** and **systemic veins**, and an appendage to the systemic, the **portal system.**

The **Pulmonary Veins** are concerned in the circulation in the lungs. Unlike other vessels of this kind, they contain arterial blood, which they return from the lungs to the left auricle of the heart. The pulmonary veins are four in number.

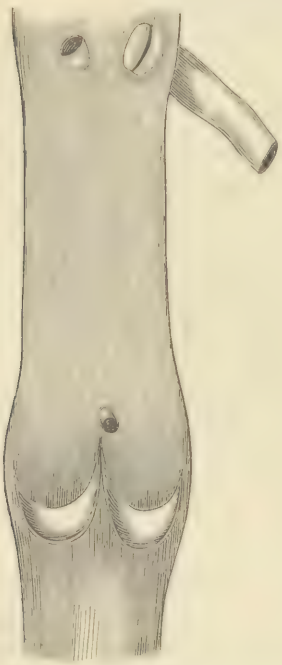

FIG. 439.—Valves of a vein. In the lower part of the figure is seen the parietal valves; the upper part shows the mouth of a vein guarded by a valve. (Poirier and Charpy.)

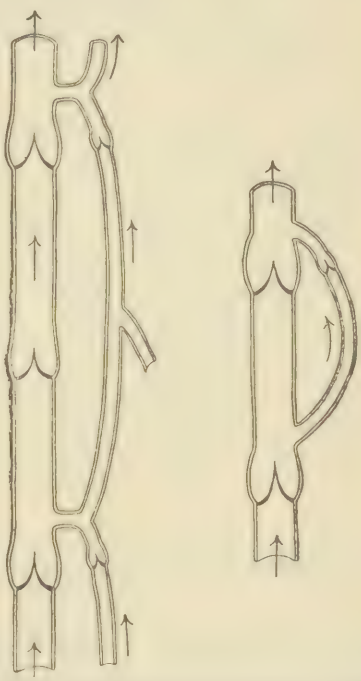

FIG. 440.—Collateral anastomosis of veins. The arrows indicate the direction of the flow of blood (schematic). (Poirier and Charpy.)

The **Systemic Veins** are concerned in the general circulation; they return the venous blood from the body generally to the right auricle of the heart. The systemic veins are the **superior vena cava**, the **inferior vena cava**, and the **coronary sinus.**

The **Portal Vein** constitutes the portal system. The portal system is in reality an appendage to the systemic venous system. It is confined to the abdominal cavity, returning the venous blood from the viscera of digestion, and carrying it to the liver by a single trunk of large size, the **portal vein** or **vena portæ.** This vessel ramifies in the substance of the liver and breaks up into a minute network

of capillaries. These capillaries then re-collect to form the **hepatic veins**, by which the blood is conveyed to the inferior vena cava.

The veins, like the arteries, are found in nearly every tissue of the body. They commence by minute plexuses which receive the blood from the capillaries. The branches which have their commencement in these plexuses unite together into trunks, and these, in their passage toward the heart, constantly increase in size as they receive tributaries or join other veins. The veins are larger and altogether more numerous than the arteries; hence the entire capacity of the venous system is much greater than that of the arterial, the pulmonary veins excepted, which only slightly exceed in capacity the pulmonary arteries. From the combined area of the smaller venous branches being greater than the main trunks, it results that the venous system represents a cone, the summit of which corresponds to the heart, its base to the circumference of the body. In form the veins are perfectly cylindrical, like the arteries, their walls being collapsed when empty, and the uniformity of their surface being interrupted at intervals by slight constrictions, which indicate the existence of valves in their interior (Fig. 439). They usually retain, however, about the same calibre as long as they receive no branches, but not so uniformly as do the arteries.

The veins communicate very freely with one another (Fig. 441), especially in certain regions of the body, and this communication exists between the larger trunks as well as between the smaller branches. Thus, in the cavity of the cranium and between the veins of the neck, where obstruction would be attended with imminent danger to the cerebral venous system, we find that the sinuses and larger veins have large and very frequent anastomoses (Fig. 440). The same free communication exists between the veins throughout the whole extent of the spinal canal, and between the veins composing the various venous plexuses in the abdomen and pelvis, as the spermatic, uterine, vesical, and prostatic.

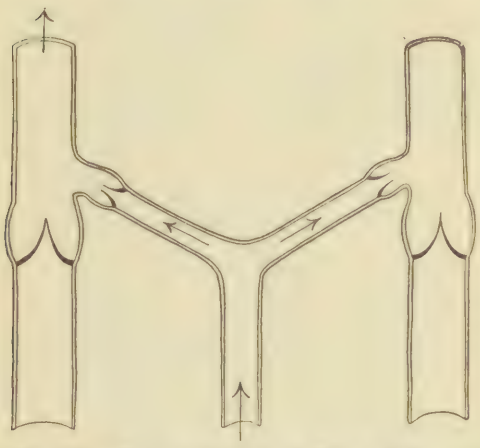

Fig. 441.—The venous circle of Braune (schematic). The arrows indicate the direction of the blood current. (Poirier and Charpy.)

Veins have thinner walls than arteries, the difference in thickness being due to the small amount of elastic and muscular tissues which the veins contain. The superficial veins usually have thicker coats than the deep veins, and the veins of the lower limb are thicker than those of the upper.

Histology of the Veins.—As previously stated, capillaries enter into **venules** or **precapillary veins.** The venules empty into larger veins. Vein walls are much thinner than arterial walls. A vein has a much thinner **media** and much less elastic tissue than an artery, and a very strongly developed **adventitia.** The **intima** is a connective-tissue layer containing a small number of elastic fibres and lined with endothelium. The media contains some circular muscle fibres and some fine elastic fibres. In some veins the media is thoroughly well developed (veins of the lower extremities), in others it is practically absent (veins of the retina, of the pia mater, of bone, the superior vena cava). The adventitia is dense and strong, and is composed of connective-tissue elastic fibres and non-striated muscle fibres placed longitudinally. Fig. 442 shows a transverse section of part of the wall of a vein. The vein valves (Fig. 439) are composed of intima and contain elastic fibres. The large veins and the veins of medium

size possess vasa vasorum, in the adventitia and to some extent in the media. The walls of veins contain vasomotor nerves. "Small blood-vessels are often surrounded by lymph capillaries and sometimes by endothelium-lined spaces which are in communication with the lymphatic system. These are called perivascular lymph spaces."[1]

The systemic veins are subdivided into three sets: **superficial, deep,** and **sinuses.**

The **Superficial** or **Cutaneous Veins** are found between the layers of the superficial fascia, immediately beneath the integument; they return the blood from these structures, and communicate with the deep veins by perforating the deep fascia.

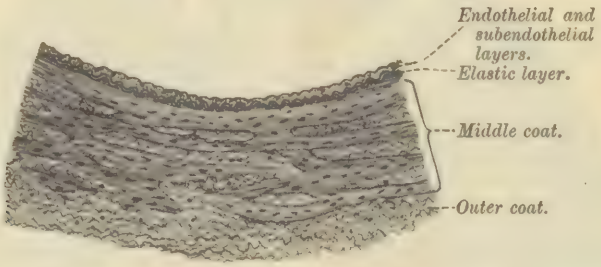

FIG. 442.—Transverse section of part of the wall of one of the posterior tibial veins. (After Schäfer.)

The **Deep Veins** accompany the arteries, and are usually enclosed in the same sheath with those vessels. With the smaller arteries—as the radial, ulnar, brachial, tibial, and peroneal—they exist generally in pairs, one lying on each side of the vessel, and are called **venæ comites.** The larger arteries—as the axillary, subclavian, popliteal, and femoral—have usually only one accompanying vein. In certain organs of the body, however, the deep veins do not accompany the arteries; for instance, the veins in the skull and spinal canal, the hepatic veins in the liver, and the larger veins returning blood from the osseous tissue.

Sinuses are venous channels which, in their structure and mode of distribution, differ altogether from the veins. They are found only in the interior of the skull, and consist of channels formed by a separation of the two layers of the dura mater, their outer coat consisting of fibrous tissue, their inner of an endothelial layer continuous with the lining membrane of the veins.

THE PULMONARY VEINS (V. PULMONALES) (Fig. 443).

The pulmonary veins return the arterial blood from the lungs to the left auricle of the heart. They are four in number, two for each lung. The pulmonary veins differ from other veins in several respects: 1. They carry arterial instead of venous blood. 2. They are destitute of valves. 3. They are only slightly larger than the arteries they accompany. 4. They accompany those vessels singly. They commence in a capillary network upon the walls of the air-cells, where they are continuous with the capillary ramifications of the pulmonary artery, and, uniting together, form one vessel for each lobule. These vessels, uniting successively, form a single trunk for each lobe, three for the right and two for the left lung. The vein from the middle lobe of the right lung generally unites with that from the upper lobe, forming two trunks on each side, which open separately into the left auricle. Occasionally they remain separate; there are then three

[1] Histology and Microscopic Anatomy. By Szymonowicz and MacCallum.

veins on the right side. Not unfrequently the two left pulmonary veins terminate by a common opening.

Within the lung, the branches of the pulmonary artery are *in front*, the veins *behind*, and the bronchi *between* the two.

At the root of the lung, the veins are *in front*, the artery *in the middle*, and the bronchus *behind*.

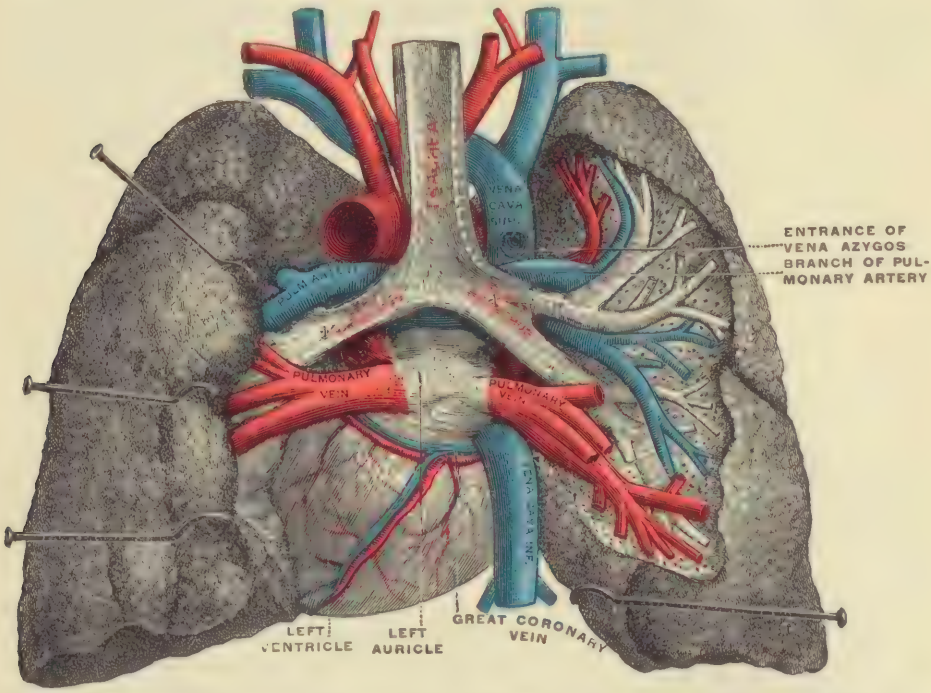

FIG. 443.—Pulmonary veins, seen in a dorsal view of the heart and lungs. The left lung is pulled to the left, and the right lung has been partly cut away to show the ramifications of the air-tubes and blood-vessels. (Testut.)

Within the pericardium, their anterior surface is invested by the serous layer of this membrane. The right pulmonary veins pass behind the right auricle and ascending aorta and superior vena cava; the left pass in front of the thoracic aorta with the left pulmonary artery.

THE SYSTEMIC VEINS.

The systemic veins may be arranged into three groups: 1. Those of the **head** and **neck, upper extremity,** and **thorax,** which terminate in the superior vena cava. 2. Those of the **lower extremity, abdomen,** and **pelvis,** which terminate in the inferior vena cava. 3. The **cardiac veins,** which open directly into the right auricle of the heart.

VEINS OF THE HEAD AND NECK.

The veins of the head and neck may be subdivided into three groups: 1. The veins of the **exterior of the head** and **face.** 2. The veins of the **neck.** 3. The veins of the **diploë** and **interior of the cranium.**

Veins of the Exterior of the Head and Face (Fig. 444).

The veins of the exterior of the head and face are—the

Frontal.	Temporal.
Supraorbital.	Internal Maxillary.
Angular.	Temporo-maxillary.
Facial.	Posterior Auricular.

Occipital.

The **Frontal Vein** (*v. frontalis*) *commences* on the anterior part of the skull by a venous plexus which communicates with the anterior tributaries of the temporal vein. The veins converge to form a single trunk, which runs downward near the

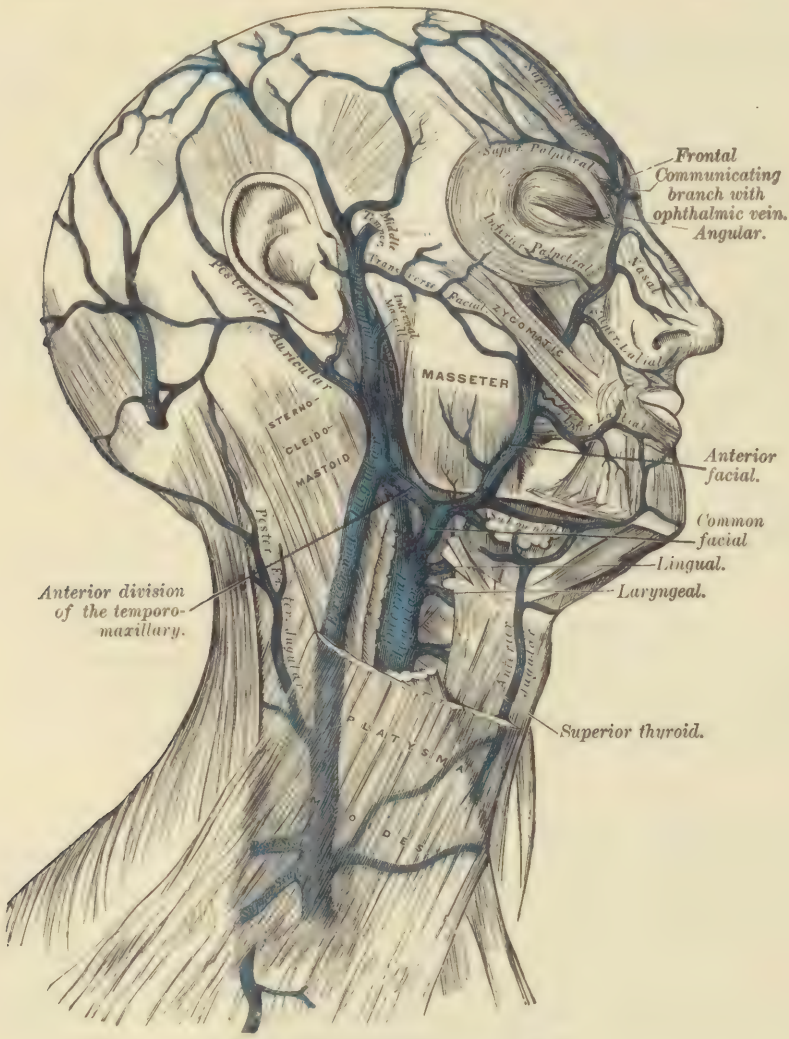

FIG. 444.—Veins of the head and neck.

middle line of the forehead parallel with the vein of the opposite side, and unites with it at the root of the nose by a transverse branch called the **nasal arch** (*v. naso-frontalis*). Occasionally the frontal veins join to form a single trunk, which

bifurcates at the root of the nose into the two angular veins. At the root of the nose the veins diverge and join the supraorbital vein, at the inner angle of the orbit, to form the angular vein.

The **Supraorbital Vein** (*v. supraorbitalis*) *commences* on the forehead, communicating with the anterior temporal vein, and runs downward and inward, superficial to the Occipito-frontalis muscle, receiving tributaries from the neighboring structures, and from the frontal vein of the diploë, and joins the frontal vein at the inner angle of the orbit to form the angular vein.

The **Angular Vein** (*v. angularis*), formed by the junction of the frontal and supraorbital veins, runs obliquely downward and outward on the side of the root of the nose, and receives the veins of the ala nasi on its inner side and the superior palpebral veins on its outer side; it moreover communicates with the ophthalmic vein, thus establishing an important anastomosis between this vessel and the cavernous sinus. Some small veins from the dorsum of the nose terminate in the nasal arch.

The **Anterior Facial Vein** (*v. facialis anterior*) commences at the side of the root of the nose, being a direct continuation of the angular vein, which is itself formed by the union of the frontal vein and the supraorbital vein. It lies behind and follows a less tortuous course than the facial artery. It passes obliquely downward and outward, beneath the Zygomaticus major and minor muscles, descends along the anterior border of the Masseter, crosses over the body of the lower jaw, with the facial artery to beneath the angle, and unites with the anterior division of the temporo-maxillary vein (*v. facialis posterior*) to form the common facial vein.

The **Common Facial Vein** (*v. facialis communis*) is formed by the union of the anterior facial and the anterior division of the temporo-maxillary vein, just beneath the angle of the mandible. The vein is covered by the Platysma myoid muscle, runs downward and backward beneath the Sterno-cleido-mastoid muscle, crosses the external carotid artery, and empties into the internal jugular vein at the level of the hyoid line. It receives a large branch at the anterior border of the Sterno-cleido-mastoid muscle, which comes from the anterior jugular vein in the supra-sternal fossa.

Tributaries of the Anterior and Common Facial Veins.—The anterior facial vein receives, near the angle of the mouth, communicating tributaries of considerable size, the deep facial or anterior internal maxillary vein, from the pterygoid plexus. It is also joined by the inferior palpebral, the superior and inferior labial veins, the buccal veins from the cheek, and the masseteric veins. The common facial vein receives the submental; the inferior palatine, which returns the blood from the plexus round the tonsil and soft palate; the submaxillary vein, which commences in the submaxillary gland; and, generally, the ranine vein.

Surgical Anatomy.—There are some points about the facial vein which render it of great importance in surgery. It is not so flaccid as are most superficial veins, and, in consequence of this, remains more patent when divided. It has, moreover, no valves. It communicates freely with the intracranial circulation, not only at its commencement by its tributaries, the angular and supraorbital veins, communicating with the ophthalmic vein, a tributary of the cavernous sinus, but also by its deep branch, which communicates through the pterygoid plexus with the cavernous sinus by branches which pass through the foramen ovale and foramen lacerum medium. These facts have an important bearing upon the surgery of some diseases of the face, for on account of its patency the facial vein favors septic absorption, and therefore any phlegmonous inflammation of the face following a poisoned wound is liable to set up thrombosis in the facial vein, and detached portions of the clot may give rise to purulent foci in other parts of the body. And on account of its communications with the cerebral sinuses these thrombi are apt to extend upward into them and so induce a fatal issue.

The **Superficial Temporal Vein** (*vv. temporales superficiales*) *commences* by a minute plexus on the side and vertex of the skull, which communicates with the frontal and supraorbital veins in front, the corresponding vein of the opposite side, and the posterior auricular and occipital veins behind. From this network anterior and posterior branches are formed which unite above the zygoma, forming the trunk of the vein. The trunk is joined in this situation by a large vein, the **middle temporal** (*v. temporalis media*), which receives blood from the substance of the Temporal muscle and pierces the fascia at the upper border of the zygoma. The junction of the superficial temporal and the middle temporal veins forms the **common temporal vein** (*v. temporalis communis*), which descends between the external auditory meatus and the condyle of the jaw, enters the substance of the parotid gland, and unites with the internal maxillary vein to form the **temporo-maxillary vein.**

Tributaries.—The common temporal vein receives in its course some parotid veins, an articular branch from the articulation of the jaw, anterior auricular veins from the external ear, and a vein of large size, the **transverse facial** (*v. transversa faciei*), from the side of the face. The middle temporal vein, previous to its junction with the temporal vein, receives a branch, the **orbital vein** (*v. orbitalis*), which is formed by some external palpebral branches, and passes backward between the layers of the temporal fascia.

The Pterygoid Plexus (*plexus pterygoideus*) **and the Internal Maxillary Vein.**—The internal maxillary vein is a vessel of considerable size, receiving branches which correspond with those of the internal maxillary artery. Thus it receives the two middle meningeal veins, the deep temporal, the pterygoid, masseteric, buccal, and alveolar veins, some palatine veins, the spheno-palatine and the inferior dental veins. The **deep temporal veins** (*vv. temporales profundæ*) come to the pterygoid plexus from the temporal muscle. These branches form a large plexus, the **pterygoid plexus,** which is placed between the Temporal and External pterygoid and partly between the Pterygoid muscles. This plexus is a tributary of the internal maxillary vein, and communicates very freely with the facial vein and with the cavernous sinus by branches through the foramen Vesalii, foramen ovale, and foramen lacerum medium, at the base of the skull. The trunk of the internal maxillary vein comes from the plexus, then passes backward behind the neck of the lower jaw, and unites with the temporal vein, forming the temporo-maxillary vein.

The **Temporo-maxillary Vein** (*v. facialis posterior*), formed by the union of the superficial temporal and internal maxillary veins, descends in the substance of the parotid gland on the outer surface of the external carotid artery, between the ramus of the jaw and the Sterno-mastoid muscle, and divides into two branches, an anterior, which passes inward to join the facial vein, and a posterior, which is joined by the posterior auricular vein and becomes the external jugular.

The **Posterior Auricular Vein** (*v. auricularis posterior*) *commences* upon the side of the head by a plexus which communicates with the tributaries of the temporal and occipital veins. The vein descends behind the external ear and joins the posterior division of the temporo-maxillary vein, forming the external jugular. This vessel receives the stylo-mastoid vein and some tributaries from the back part of the external ear.

The **Occipital Vein** (*v. occipitalis*) commences at the back part of the vertex of the skull by a plexus in a similar manner to the other veins. From the plexus comes one or two veins, which follow the course of the occipital artery, passing deeply beneath the muscles of the back part of the neck, and terminating in the suboccipital triangle by becoming continuous with the posterior vertebral vein. Sometimes they are more superficial, and in this case they are tributaries of the

external jugular vein. As the outermost occipital vein passes across the mastoid portion of the temporal bone, it receives the mastoid vein, which thus establishes a communication with the lateral sinus.

The Veins of the Neck (Fig. 444).

The veins of the neck, which return the blood from the head and face, are—the

External Jugular.	Anterior Jugular.
Posterior External Jugular.	Internal Jugular.
Vertebral.	

The **External Jugular Vein** (*v. jugularis externa*) receives the greater part of the blood from the exterior of the cranium and deep parts of the face, being formed by the junction of the posterior division of the temporo-maxillary and the posterior auricular veins. It commences in the substance of the parotid gland, on a level with the angle of the lower jaw, and runs perpendicularly down the neck in the direction of a line drawn from the angle of the jaw to the middle of the clavicle. In its course it crosses the Sterno-mastoid muscle, and runs parallel with its posterior border as far as its attachment to the clavicle, where it perforates the deep fascia, and terminates in the subclavian vein, on the outer side of, or in front of, the Scalenus anticus muscle. In the neck it is separated from the Sterno-mastoid by the investing layer of the deep cervical fascia, and is covered by the Platysma, the superficial fascia, and the integument. This vein is crossed about its middle by the superficialis colli nerve, and throughout the upper half of its course is accompanied by the auricularis magnus nerve. The external jugular vein varies in size, bearing an inverse proportion to that of the other veins of the neck; it is occasionally double. It is provided with two pairs of valves, the lower pair being placed at its entrance into the subclavian vein, the upper pair in most cases about an inch and a half above the clavicle. The portion of vein between the two sets of valves is often dilated, and is termed the **sinus**. These valves do not prevent the regurgitation of the blood or the passage of injection from below upward.[1]

Tributaries.—This vein receives the occipital occasionally, the posterior external jugular, and, near its termination, the suprascapular and transverse cervical veins. It communicates with the anterior jugular, and, in the substance of the parotid, receives a large branch of communication from the internal jugular.

The **Posterior External Jugular Vein** (*v. jugularis posterior*) commences in the occipital region, and returns the blood from the integument and superficial muscles in the upper and back part of the neck, lying between the Splenius and Trapezius muscles. It runs down the back part of the neck, and opens into the external jugular just below the middle of its course.

The **Anterior Jugular Vein** (*v. jugularis anterior*) commences near the hyoid bone from the convergence of the inferior coronary, the submental and the mental veins, and communicating branches. It passes down between the median line and the anterior border of the Sterno-mastoid, and at the lower part of the neck passes beneath that muscle to open into the termination of the external jugular or into the subclavian vein (Fig. 465). This vein varies considerably in size, bearing almost always an inverse proportion to the external jugular. Most frequently there are two anterior jugulars, a right and left, but occasionally only one. This vein receives some laryngeal veins, and occasionally a small thyroid vein. Just above the sternum the two anterior jugular veins communicate by a

[1] The student may refer to an interesting paper by Dr. Struthers, "On Jugular Venesection in Asphyxia, Anatomically and Experimentally Considered, including the Demonstration of Valves in the Veins of the Neck," in the Edinburgh Medical Journal for November, 1856. Ed. of 15th English edition.

transverse trunk, which receives tributaries from the inferior thyroid veins. It also communicates with the internal jugular. There are no valves in this vein.

The **Internal Jugular Vein** (*v. jugularis interna*) collects the blood from the interior of the cranium, from the superficial parts of the face, and from the neck. It *commences* just external to the jugular foramen, at the base of the skull, being formed by the coalescence of the lateral and inferior petrosal sinuses (Fig. 458). At its origin it is somewhat dilated, and this dilatation is called the **sinus** or **gulf of the internal jugular vein** (*bulbus v. jugularis superior*). It runs down the side of the neck in a vertical direction, lying at first on the outer side of the internal carotid artery, and then on the outer side of the common carotid artery, and at the root of the neck unites with the subclavian vein to form the innominate vein. Just before its termination it is distinctly dilated (*bulbus v. jugularis inferior*). The

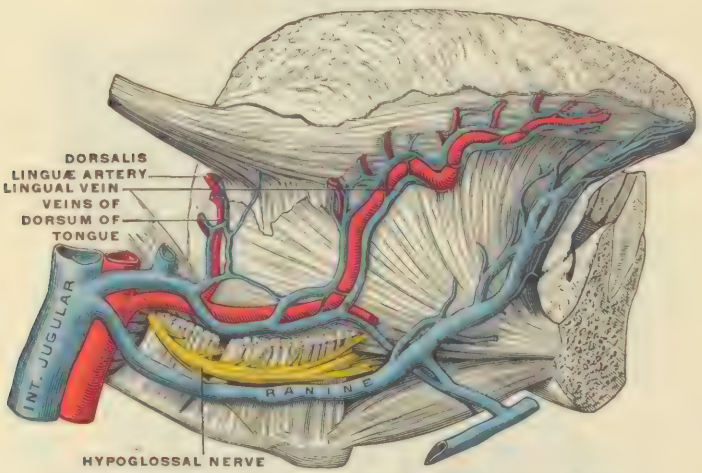

FIG. 445.—Veins of the tongue. (Testut, modified from Hirschfeld.)

internal jugular vein, at its *commencement*, lies upon the Rectus capitis lateralis, and behind the internal carotid artery and the nerves passing through the jugular foramen; lower down, the vein and artery lie upon the same plane, the glossopharyngeal and hypoglossal nerves passing forward between them; the pneumogastric descends between and behind them in the same sheath, and the spinal accessory passes obliquely outward, behind or in front of, the vein. At the root of the neck the vein of the right side is placed at a little distance from the artery; on the left side it usually lies over the artery at its lower part. The right internal jugular vein crosses the first part of the subclavian artery. The internal jugular vein is of considerable size, but varies in different individuals, the left one being usually the smaller. It is provided with a pair of valves, which are placed at its point of termination or from half to three-quarters of an inch above it.

Tributaries.—This vein receives in its course the facial, lingual, pharyngeal, superior, and middle thyroid veins. A branch from the cochlea opens into the sinus of the internal jugular vein. A venous plexus from the lateral sinus (*plexus venosus caroticus internus*) surrounds the internal carotid artery in the carotid canal and empties into the internal jugular vein. At its point of junction with the common facial vein it becomes increased in size. (See Facial Veins, p. 726.)

The **Lingual Veins** (*vv. linguale*) (Fig. 445) *commence* on the dorsum, sides, and under surface of the tongue, and, passing backward, following the course of the lingual artery and its branches, terminate in the internal jugular. Sometimes the **ranine vein**, which is a branch of considerable size commencing below the tip of the

tongue, joins the lingual. Generally, however, it passes backward, crosses the Hyo-glossus muscle in company with the hypoglossal nerve, and joins the internal jugular. The lingual vein receives the sublingual vein and the dorsalis linguæ veins.

The **Pharyngeal Veins** (*vv. pharyngeæ*) vary in number. They *commence* in a minute plexus, the **pharyngeal plexus** (*plexus pharyngeus*), at the back part and sides of the pharynx, and, after receiving meningeal tributaries, the **meningeal veins** (*vv. meningea*), the **Vidian veins** (*vv. canalis pterygoidei*), and the sphenopalatine veins, terminate in the internal jugular. They occasionally open into the facial, lingual, or superior thyroid vein.

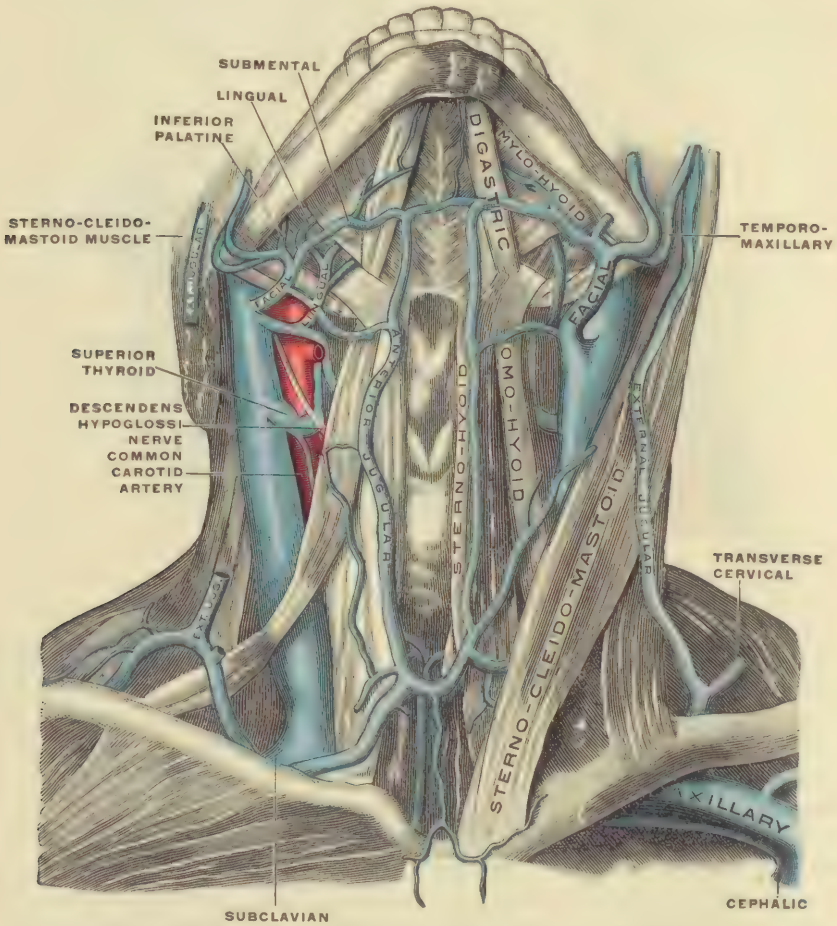

Fig. 446.—The veins of the neck, viewed from in front. (Spalteholz.)

The **Superior Thyroid Vein** (*v. thyreoidea superioris*) (Fig. 446) *commences* in the substance and on the surface of the thyroid gland by tributaries corresponding with the branches of the superior thyroid artery, and terminates in the upper part of the internal jugular vein. It receives the superior laryngeal and crico-thyroid veins. Some anatomists teach that there are two superior thyroid veins on each side, the upper vein being the one just considered, the lower vein being the one usually pointed out as the middle thyroid.

The **Middle Thyroid Vein** (Fig. 448) collects the blood from the lower part of the lateral lobe of the thyroid gland, and, being joined by some veins from the larynx and trachea, terminates in the lower part of the internal jugular vein. Often in

place of the middle thyroid vein there are two veins, the **superior** and **inferior accessory thyroid.** These veins pass into the internal jugular.

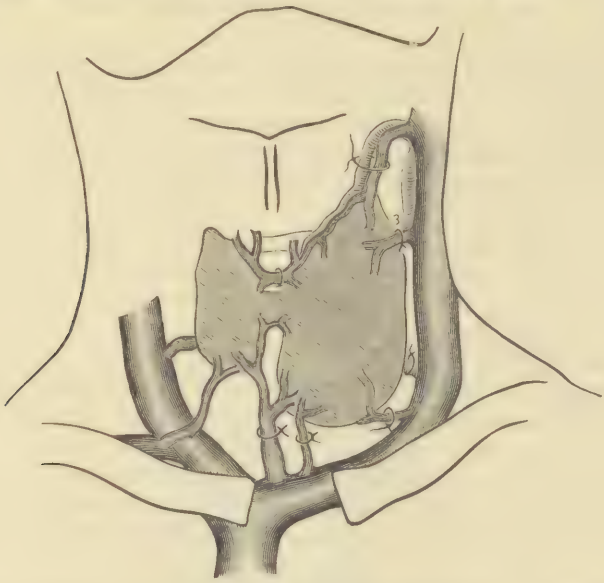

FIG. 447.—Diagram showing common arrangement of thyroid veins. (Kocher.)

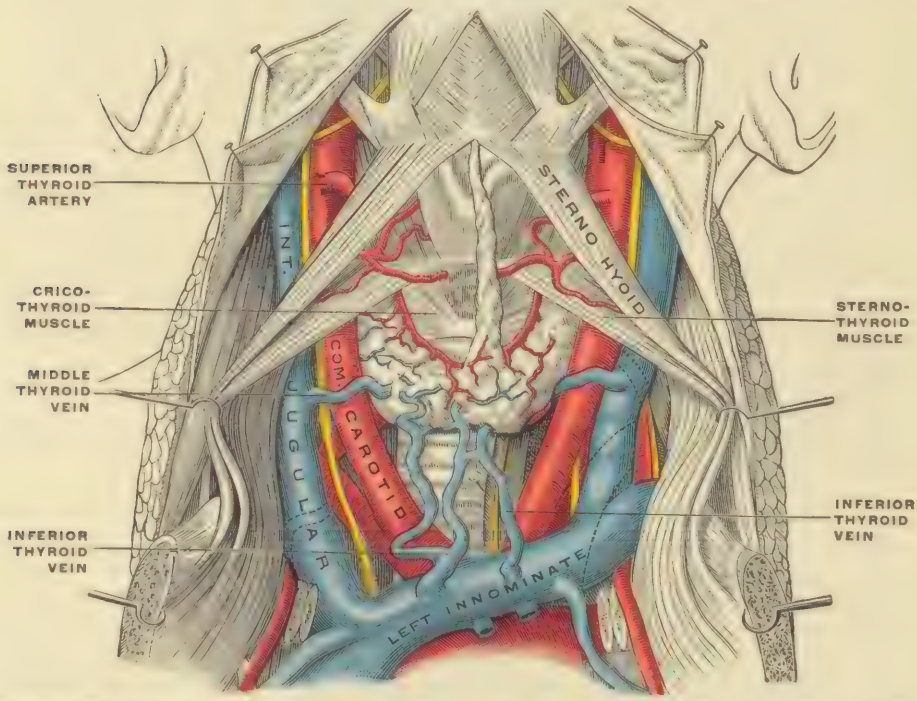

FIG. 448.—The fascia and middle thyroid veins. The veins here designated the inferior thyroid are called by Kocher the thyreoidea ima. (Poirier and Charpy.)

Veins of the Thyroid Gland[1] (Fig. 447).—On the surface of the thyroid glands the veins form a plexus between the capsule and the gland. A number of veins

[1] See Kocher's description in Langenbeck's Arch. f. klin. Chir., vol. xxix., and James Berry's description in his treatise on Diseases of the Thyroid Gland.

penetrate the capsule and pass into adjacent trunks. The most important veins coming from the gland are the **superior, middle,** and **inferior thyroids** (or instead of the middle thyroid the superior and inferior accessory thyroid) and the **thyreoidea ima.**

The **superior thyroid vein** emerges from the summit of the superior horn of the gland, runs along by the superior thyroid artery, and terminates in the internal jugular vein. A large branch which passes along the inner margin of the upper horn and across the upper surface of the isthmus joins the superior thyroid veins of each side. The **middle thyroid vein** when present emerges from the side of the gland and empties into the internal jugular. This single vein may be replaced by two veins, the superior and inferior accessory thyroid veins. The superior vein emerges from the outer surface of the upper horn somewhat below the apex. The inferior vein comes from the posterior and inferior portion of the gland. Both empty into the internal jugular. The lower surface of the isthmus and the inner side of each inferior horn is drained by two veins. Each vein is called the **thyreoidea ima** (Kocher). The left vein empties into the left innominate vein. The right vein empties into either the right or left innominate vein. These veins may be very small, may be absent, or may join and form one vein which empties into the left innominate. An inferior thyroid is often also present. It comes from the outer portion of the inferior horn of the gland and empties into the innominate vein.

The **facial** and **occipital veins** have been described on pages 726 and 727.

Surgical Anatomy.—The internal jugular vein occasionally requires ligature in cases of *septic thrombosis of the lateral sinus* from suppuration in the middle ear. This is done in order to prevent septic emboli being carried into the general circulation. This operation has been performed in a number of cases, with satisfactory results. The cases are generally those of chronic disease of the middle ear, with discharge of pus which perhaps has existed for many years. The patient is seized with acute septic inflammation, spreading to the mastoid cells, and, consequent on this, septic thrombosis of the lateral sinus extending to the internal jugular vein. Such cases are always extremely grave, for there is danger that a portion of the septic clot will be detached and cause septic embolism in the thoracic viscera. If thrombo-phlebitis of the sinus is suspected the mastoid should be opened and cleansed and the sinus should be at once exposed and explored. If the sinus is found to be thrombosed the surgeon should at once proceed to ligate the internal jugular vein, by an incision along the anterior border of the sterno-mastoid, the centre of which is on a level with the greater cornu of the hyoid bone. The vein should be ligated in two places and divided between. After the vessel has been secured and divided the lateral sinus is to be thoroughly cleared out, and, by removing the ligature from the upper end of the divided vein, all septic clots may be removed by syringing from the sinus through the vein. If hemorrhage occurs from the distal end of the sinus, it can be arrested by careful plugging with antiseptic gauze.

The thyroid veins are small vessels when the gland is of normal size, but become enormous when the gland is much enlarged.

In the operation of *thyroidectomy* the veins as well as the arteries are ligated before the gland, or rather before one lobe of it is extirpated.

The **Vertebral Vein** (*v. vertebralis*) (Fig. 449) *commences* by numerous small veins from the **intraspinal venous plexuses** (*plexus venosi vertebrales*); these pass outward and enter the foramen in the transverse process of the atlas, and descend, forming a dense plexus around the vertebral artery in the canal formed by the foramina in the transverse processes of the cervical vertebræ. The vessels of this plexus unite at the lower part of the neck into two main trunks, one of which emerges from the foramen in the transverse process of the sixth cervical vertebra, and the other through that of the seventh. Uniting, these two trunks form a single vessel which terminates at the root of the neck in the back part of the innominate vein near its origin, its mouth being guarded by a pair of valves. On the right side it crosses the first part of the subclavian artery.

Tributaries.—The vertebral vein receives in its course a vein from the inside of the skull through the posterior condyloid foramen. It anastomoses with the

occipital vein and receives muscular veins from the muscles in the prevertebral region; dorsi-spinal veins, from the back part of the cervical portion of the spine; meningo-rachidian veins, from the interior of the spinal canal; the anterior and posterior vertebral veins; and close to its termination it is joined by a small vein from the first intercostal space which accompanies the superior intercostal artery.

The **Anterior Vertebral** or **Anterior Deep Cervical Vein** *commences* in a plexus around the transverse processes of the upper cervical vertebræ, descends in company with the ascending cervical artery between the Scalenus anticus and Rectus capitis anticus major muscles, and opens into the vertebral vein just before its termination.

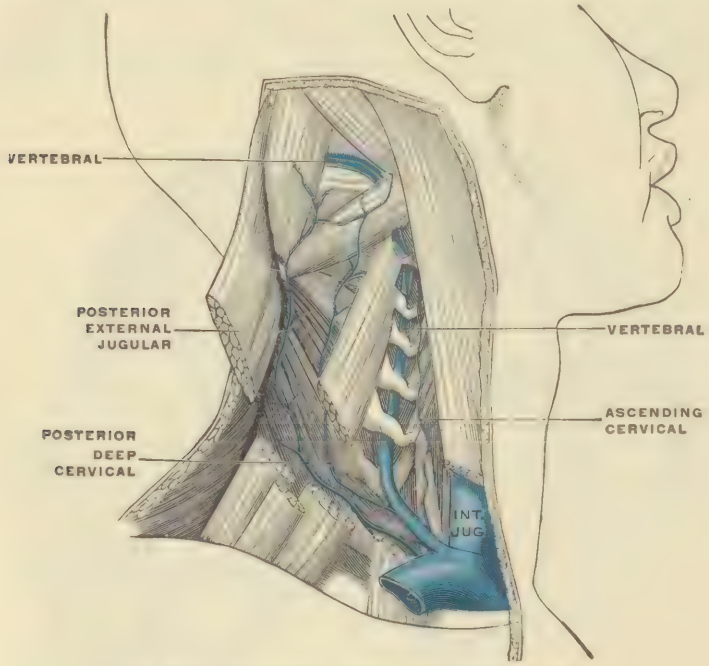

Fig. 449.—The vertebral vein. (Poirier and Charpy.)

The **Posterior Vertebral** or **Posterior Deep Cervical Vein** (*v. cervicalis profunda*) (Fig. 449) accompanies the profunda cervicis artery, lying between the Complexus and Semispinalis colli. It *commences* in the suboccipital region by communicating branches from the occipital vein and tributaries from the deep muscles at the back of the neck. It receives tributaries from the plexuses around the spinous processes of the cervical vertebræ, and terminates in the lower end of the vertebral vein.

The Veins of the Diploë (Venæ Diploicæ) (Fig. 450).

The diploë of the cranial bones is channelled in the adult by a number of tortuous canals, the **diploic canals** or **canals of Breschet** (*canales diploici* [*Breschetî*]), which are lined by a more or less complete layer of compact tissue. The veins they contain are large and capacious, their walls being thin, and formed only of endothelium resting upon a layer of elastic tissue, and they present at irregular intervals pouch-like dilatations, or *culs-de-sac*, which serve as reservoirs for the blood. These are the veins of the diploë; they can only be displayed by removing the outer table of the skull.

In adult life, as long as the cranial bones are distinct and separable, these veins are confined to the particular bones; but in old age, when the sutures are

united, they communicate with each other and increase in size. These vessels communicate, in the interior of the cranium, with the meningeal veins and with the sinuses of the dura mater, and on the exterior of the skull with the veins of the pericranium. They are divided into the **frontal diploic vein** (*v. diploica frontalis*), which opens into the supraorbital vein by an aperture in the supraorbital notch and into the superior longitudinal sinus; the **anterior temporal diploic vein** (*v. diploica temporalis anterior*), which is confined chiefly to the frontal bone, communicates with the spheno-parietal sinus and, after escaping by an aperture in the great wing of the sphenoid, opens into one of the deep temporal veins; the **posterior temporal,** or **external parietal diploic vein** (*v. diploica temporalis posterior*), is between the emissarium parietale and the emissarium mastoideum; and the **occipital diploic vein** (*v. diploica occipitalis*), the largest of the four, which is confined to the occipital bone, and opens into the emissarium occipitale.

FIG. 450.—Veins of the diploë as displayed by the removal of the outer table of the skull.

The **Emissary Veins** are considered on page 743.

The Meningeal Veins (*vv. meningeæ*).—They are numerous in the dura mater, are without valves, anastomose freely with each other, do not increase in size as they reach the sinus which receives them, and bear no regular relation to the meningeal arteries. The middle meningeal artery has two venæ comites. The other meningeal arteries usually have two apiece, but may have but one. The **middle meningeal veins** (*vv. meningeæ mediæ*) accompany the middle meningeal artery, are united to the spheno-parietal sinus, pass through the foramen spinosum, and join the pterygoid plexus. The other meningeal veins empty into the superior longitudinal sinus and communicate with the plexus of the foramen ovale.

The Cerebral Veins (Venæ Cerebri).

The cerebral veins are remarkable for the absence of valves and for the extreme thinness of their coats. The coats are thin because they contain no muscular tissue. The cerebral veins may be divided into two sets: the **superficial veins,** which are placed on the surface, and the **deep veins,** which occupy the interior of the organ. The veins of the brain do not accompany associated arteries.

The **Superficial** or **Cortical Cerebral Veins** (*venæ cerebri externæ*) (Fig. 546) ramify upon the surface of the brain, being lodged in the sulci between the convolutions, a few running across the convolutions. They receive branches from the substance of the brain and terminate in the sinuses. They are named, from the position they occupy, **superior, median,** and **inferior cerebral veins.**

The **Superior Cerebral Veins** (*vv. cerebri superiores*), eight to twelve in number on each side, return the blood from the convolutions on the superior surface of the hemisphere; they pass forward and inward toward the great longitudinal fissure, where they receive the median cerebral veins; near their termination they become invested with a tubular sheath of the arachnoid membrane, and open into the superior longitudinal sinus in the opposite direction to the course of the current of the blood.

The **Median Cerebral Veins** (*v. cerebri mediana*) return the blood from the convolutions of the mesial surface of the corresponding hemisphere; they open into the superior cerebral veins, or occasionally into the inferior longitudinal sinus.

The **Inferior Cerebral Veins** (*vv. cerebri inferiores*) ramify on the lower part of the outer surface and on the under surface of the cerebral hemisphere. Some, collecting tributaries from the under surface of the anterior lobes of the brain, terminate in the cavernous sinus. One vein of large size, the **middle cerebral** or **superficial Sylvian vein** (*v. cerebri media*), commences on the under surface of the temporal lobe, and, running along a portion of the fissure of Sylvius, opens into the cavernous sinus. The **great anastomotic vein of Trolard** or the **superficial communicating vein** establishes a union between the sinuses of the vertex and those of the base of the brain. It comes from one of the superior cerebral veins, passes downward into the fissure of Sylvius, and, by means of the middle cerebral vein, effects a communication with the cavernous sinus. The **posterior anastomotic vein** connects the middle cerebral vein with the lateral sinus. Other veins commence on the under surface of the base of the brain, and unite to form from three to five veins, which open into the superior petrosal and lateral sinuses from before backward.

The **Deep Cerebral, Central,** or **Ventricular Veins, Veins of Galen** (*venæ Galeni, vv. cerebri internæ*) (Fig. 548), are two in number. Each is formed by the union of two veins, the **vena corporis striati,** and the **choroid vein,** on either side. The deep cerebral veins run backward, parallel with one another, between the layers of the velum interpositum, and in the region of the pineal body unite to form one vein, the **vena magna Galeni** (*v. cerebri magna*), which passes out of the brain at the great transverse fissure, between the posterior extremity, or splenium, of the corpus callosum and the tubercula quadrigemina, to enter the straight sinus. The two deep cerebral veins receive branches from the callosal region, from a portion of the occipital lobe, and just before their union each vein receives the basilar vein. The vena magna Galeni receives the **vermian vein** from the superficial cerebellar veins.

The **Vena Corporis Striati** on each side *commences* in the groove between the corpus striatum and thalamus opticus, receives numerous veins from both of these parts, and unites behind the anterior pillar of the fornix with the choroid vein to form one of the deep cerebral veins.

The **Choroid Vein** (*v. choroidea*) originates in the extreme end of the middle cornu of the lateral ventricle and runs along the whole length of the outer border of the choroid plexus, receiving veins from the hippocampus major, the fornix, and corpus callosum, and unites, at the anterior extremity of the choroid plexus, with the vein of the corpus striatum to form the deep cerebral vein of that side.

The **Basilar Vein** (*v. basalis*) *commences* at the anterior perforated space at the base of the brain by the union of a small anterior cerebral vein, which courses backward between the anterior lobes of the cerebrum, with the deep Sylvian vein, which descends through the lower part of the Sylvian fissure and receives veins from

the island of Reil. It passes backward over the crus cerebri, receiving the inferior striate vein from the corpus striatum, interpeduncular veins from the interpeduncular space, ventricular veins from the middle cornu of the lateral ventricles, and tributaries from the uncinate convolution, and enters the vein of Galen just before its junction with the vein of the opposite side.

The **Superficial Cerebellar Veins** (Fig. 546) occupy the surface of the cerebellum, and are disposed in two sets, **superior** and **inferior.**

The **Superior Superficial Cerebellar Veins** (*vv. cerebelli superiores*) pass partly forward and inward, across the superior vermiform process, to terminate in lateral branches which pass partly to the straight sinus and partly outward to the lateral and superior petrosal sinuses.

The **Inferior Superficial Cerebellar Veins** (*vv. cerebelli inferiores*), of large size, terminate in the lateral, inferior petrosal, and occipital sinuses.

The **Deep Cerebellar Veins** bring blood from the interior of the cerebellum to the superficial veins.

Veins of the Pons Varolii.—Veins come from the depth of the pons, the **deep veins,** and empty into a plexus of **superficial veins.** From this superficial venous plexus a **superior vein** passes to the basilar vein, and an **inferior vein** either into a cerebellar vein or into the superior petrosal sinus.

Veins of the Medulla Oblongata.—Veins pass from the depth of the medulla and end in a plexus on the surface. From this plexus comes an **anterior median vein,** which is a prolongation of a like vein of the spinal cord—a **posterior median vein** corresponding to a like vein of the cord—and small branches which pass with the roots of the ninth, tenth, eleventh, and twelfth cranial nerves, and empty into the occipital and the inferior petrosal sinuses.

The perivascular lymph-spaces are especially found in connection with the vessels of the brain. These vessels are enclosed in a sheath, which acts as a lymphatic channel, through which the lymph is carried to the subarachnoid and subdural spaces, from which it is returned into the general circulation.

The Sinuses of the Dura Mater (Sinus Duræ Matris) (Figs. 451, 452, 453, 456, 457) Ophthalmic Veins and Emissary Veins.

The sinuses of the dura mater are venous channels, analogous to the veins. The outer coat of a sinus is formed by the dura mater; the inner coat, by a continuation of the lining membrane of the veins. The thick walls of a sinus resist intracranial pressure.[1] They are divided into two sets: (1) those situated at the upper and back part of the skull; (2) those at the base of the skull. The former are—the

Superior Longitudinal Sinus.	Straight Sinus.
Inferior Longitudinal Sinus.	Lateral Sinuses.
Occipital Sinus.	

The **Superior Longitudinal Sinus** (*sinus sagittalis superior*) (Figs. 451, 452, and 453) occupies the attached margin of the falx cerebri. *Commencing* at the foramen cæcum, through which, in the child, it constantly communicates by a small branch with the veins of the nasal fossæ, it runs from before backward, grooving the inner surface of the frontal, the adjacent margins of the two parietal, and the superior division of the crucial ridge of the occipital bone, and terminates by opening into the torcular Herophili. The sinus is triangular on transverse section, is narrow in front, and gradually increases in size as it passes backward. On examining its inner surface it presents the internal openings of the superior cerebral veins, which run, for the most part, from behind forward, and open

[1] A. W. Hughes.

chiefly at the back part of the sinus, their orifices being concealed by fibrous folds; numerous fibrous bands, **chordæ Willisii** (Fig. 453), are also seen extending transversely across the inferior angle of the sinus; and some small, white, projecting bodies, the **glandulæ Pacchioni** (*granulationes arachnoidales*). This sinus communicates by numerous small apertures with spaces in the dura mater known as **lacunæ laterales** or **parasinoidal spaces** (Fig. 453). The

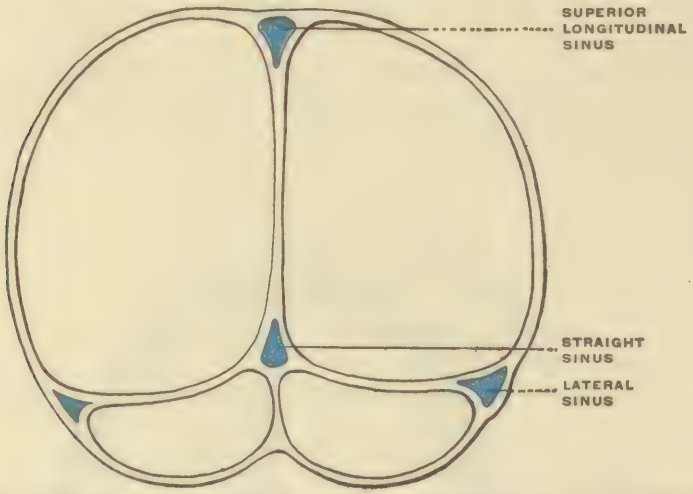

FIG. 451.—Coronal section of the skull to show the situations and shapes of the chief sinuses. (Poirier and Charpy.)

Pacchionian bodies project into these spaces. This sinus receives the superior cerebral veins, numerous veins from the diploë and dura mater, the outlets of the parasinoidal spaces, and, at the posterior extremity of the sagittal suture, veins from the pericranium, which pass through the parietal foramina. In children a twig from the longitudinal sinus passes through the foramen cæcum and into the nose.

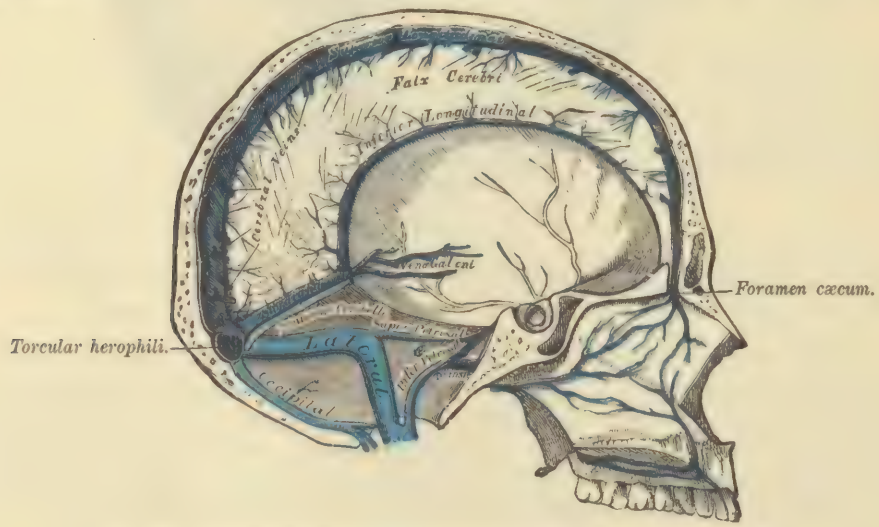

FIG. 452.—Vertical section of the skull, showing the sinuses of the dura mater.

The **Torcular Herophili** or the **confluence of the sinuses** (Figs. 452 and 456) is the dilated extremity of the superior longitudinal sinus. It is of irregular form, and

is lodged on one side (generally the right) of the internal occipital protuberance. From it the lateral sinus of the side to which it is deflected is derived. It receives also the blood from the occipital sinus.

The **Inferior Longitudinal Sinus** (*sinus sagittalis inferior*) (Fig. 452), more correctly described as the **inferior longitudinal vein**, is contained in the posterior part of the free margin of the falx cerebri. It is of a cylindrical form, increases in size as it passes backward, and terminates in the straight sinus. It receives several veins from the falx cerebri, and occasionally a few from the mesial surface of the hemispheres.

The **Straight Sinus** (*sinus rectus*) (Figs. 451 and 452) is situated at the line of junction of the falx cerebri with the tentorium. It is triangular in form, increases in size as it proceeds backward, and runs obliquely downward and backward from

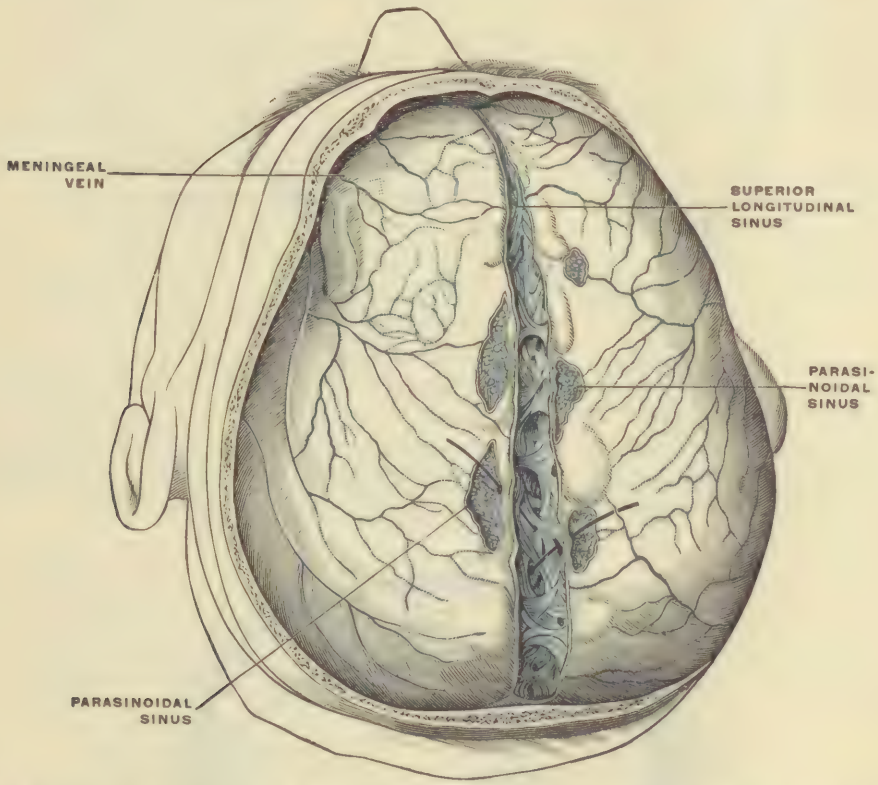

FIG. 453.—Superior longitudinal sinus seen from above after removal of the skull-cap. The chordæ Willisii are clearly visible. The para-sinoidal sinuses are also well shown. Probes passing from the latter to the longitudinal sinus show that they communicate. (Poirier and Charpy.)

the termination of the inferior longitudinal sinus to the lateral sinus of the opposite side to that into which the superior longitudinal sinus is prolonged. It communicates by a cross-branch with the torcular Herophili. Besides the inferior longitudinal sinus, it receives the vena magna Galeni and the superior cerebellar veins. A few transverse bands cross its interior. This sinus is usually considered to be formed by the union of the great vein of Galen and the inferior longitudinal sinus.

The **Lateral Sinus** (*sinus transversus*) (Figs. 451, 452, 456, and 457) is of large size. There are two lateral sinuses situated in the attached margin of the tentorium cerebelli throughout most of its extent. They commence at

the internal occipital protuberance, one, generally the right, being the direct continuation of the superior longitudinal sinus, the other of the straight sinus. Each passes outward and forward, describing a slight curve with its convexity upward, to the base of the petrous portion of the temporal bone, then, leaving the tentorium, curves downward and inward to reach the jugular foramen, where it terminates in the internal jugular vein. It rests, in its course, upon the inner surface of the occipital, the posterior inferior angle of the parietal, and the mastoid portion of the temporal bone, and on the occipital again, at the jugular process, just before its termination. The portion of the sinus resting on the mastoid process of the temporal and the jugular process of the occipital bone is not covered by the tentorium and is often called the **sigmoid sinus** because of its shape, which resembles the letter S. These sinuses are frequently of unequal size, that formed by the superior longitudinal sinus being the larger, and they increase in size as they proceed from behind forward. The horizontal portion is of a triangular form, the curved portion semicylindrical. Their inner surface is smooth, and not crossed by the fibrous bands found in the other sinuses. The lateral sinuses receive the blood from the superior petrosal sinuses at the base of the petrous portion of the temporal bone, and they unite with the inferior petrosal sinus, just external to the jugular foramen, to form the internal jugular vein (Fig. 457). They communicate with the veins of the pericranium by means of the mastoid and posterior condyloid veins, and they receive some of the inferior cerebral and inferior cerebellar veins, some veins from the diploë, and often veins from the internal ear (*vv. auditivæ internæ*), which come out of the internal auditory meatus. The **petro-squamous sinus**, when present, runs backward along the junction of the petrous and squamous portions of the temporal bone, and opens into the lateral sinus.

Surgical Anatomy.—The lateral sinus may, as a result of middle-ear disease, be attacked by suppurative inflammation, which leads to blocking (*septic thrombo-phlebitis*). In such a case the surgeon will be obliged to open the sinus to remove infected clot and tie the internal jugular vein to intercept thrombi. The lines overlying the sinus is as follows: Draw a line horizontally outward from the occipital protuberance to a point one inch posterior to a vertical line drawn through the external auditory meatus and from this point drop a second line to the mastoid process.

The **Occipital Sinus** (*sinus occipitalis*) (Fig. 452) is the smallest of the cranial sinuses. There is often but a single occipital sinus, but occasionally there are two. It is situated in the attached margin of the falx cerebelli. It commences by several small veins around the margin of the foramen magnum, one of which joins the termination of the lateral sinus; it communicates with the posterior spinal veins and terminates in the torcular Herophili.

The sinuses at the base of the skull are—the

Cavernous Sinuses.	Superior Petrosal Sinuses.
Spheno-parietal Sinuses.	Inferior Petrosal Sinuses.
Circular Sinus.	Transverse Sinus.

The **Cavernous Sinus** (*sinus cavernosus*) (Figs. 456 and 457) is named from presenting a reticulated structure, due to being traversed by numerous interlacing filaments (Fig. 454). There are two cavernous sinuses, of irregular form, larger behind than in front, and placed one on each side of the sella turcica, extending from the sphenoidal fissure to the apex of the petrous portion of the temporal bone. Each receives anteriorly the ophthalmic vein through the sphenoidal fissure, and opens behind into the petrosal sinuses. On the inner wall of each sinus is found the internal carotid artery, accompanied by filaments of the carotid plexus and by the sixth nerve; and on its outer wall, the third, fourth, and ophthalmic division

of the fifth nerve (Fig. 454). These parts are separated from the blood flowing along the sinus by the lining membrane, which is continuous with the inner coat of the veins. The cavernous sinuses receive some of the cerebral veins, and also the spheno-parietal sinuses. They communicate with the lateral sinuses by means of the superior and inferior petrosal sinuses, and with the facial veins through the ophthalmic veins. They also communicate with each other by means of the circular sinus.

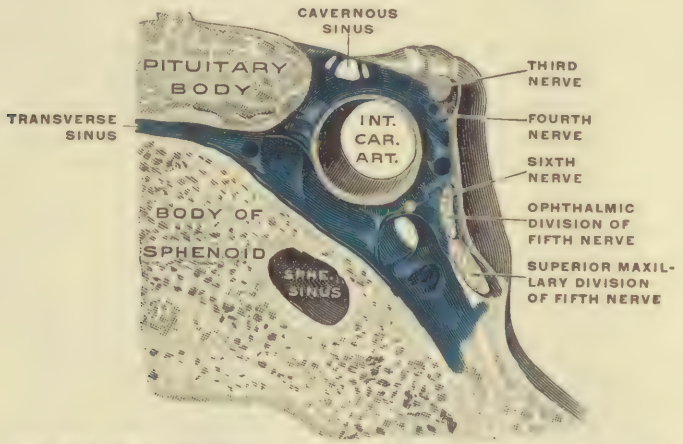

FIG. 454.—Frontal section through the right cavernous sinus. (Spalteholz.)

Surgical Anatomy.—An arterio-venous communication may be established between the cavernous sinus and the carotid artery, as it lies in it, giving rise to a *pulsating tumor* in the orbit. Such a communication may be the result of injury, such as a bullet wound, a stab, or a blow or fall sufficiently severe to cause a fracture of the base of the skull in this situation, or it may occur from the rupture of an aneurism or a diseased condition of the internal carotid artery. The disease begins with sudden noise and pain in the head, followed by exophthalmos, swelling and congestion of the lids and conjunctivæ. A pulsating tumor develops at the margin of the orbit, with thrill and the characteristic bruit; accompanying these symptoms there may be impairment of sight, paralysis of the iris and orbital muscles, and pain of varying intensity. In some cases the opposite orbit becomes affected by the passage of the arterial blood into the opposite sinus by means of the circular sinus. Or the arterial blood may find its way through the emissary veins into the pterygoid plexus, and thence into the veins of the face. Pulsating tumors of the orbit may also be due to traumatic aneurism of one of the orbital arteries, and symptoms resembling those of pulsating tumor may be produced by pressure on the ophthalmic vein, as it enters the sinus, by an aneurism of the internal carotid artery.

The Spheno-parietal Sinus or Sinus Alæ Parvæ (*sinus sphenoparietalis*).—Each of these sinuses is lodged in the dura mater on the under surface of the lesser wing of the sphenoid bone. It takes origin from one of the middle meningeal veins, usually receives blood from the diploë of the skull, passes inward, and ends in the anterior part of the cavernous sinus.

The **Ophthalmic Veins** are two in number, **superior** and **inferior.**

The **superior ophthalmic vein** (*v. ophthalmica superior*) (Fig. 455) begins as the **naso-frontal vein** (*v. nasofrontalis*), at the inner angle of the orbit, which communicates with the angular vein. It joins the angular vein with the cavernous sinus; it pursues the same course as the ophthalmic artery, and receives tributaries corresponding to the branches derived from that vessel. Forming a short single trunk, it passes through the inner extremity of the sphenoidal fissure, and terminates in the cavernous sinus. It anastomoses with the inferior ophthalmic vein and receives lachrymal, anterior, and posterior ethmoidal and muscular branches, and veins of the eyelids and of the bulbus oculi.

The **inferior ophthalmic vein** (*v. ophthalmica inferior*) (Fig. 455) *arises* in the veins of the eyelids and lachrymal sac, receives the veins from the floor of the orbit, and

FIG. 455.—Veins of the orbit. (Poirier and Charpy.)

from the portion of the nasal fossa supplied by the anterior and posterior ethmoidal arteries. It either passes out of the orbit through the spheno-maxillary fissure to join the pterygoid plexus of veins, or else, passing backward through the sphenoidal

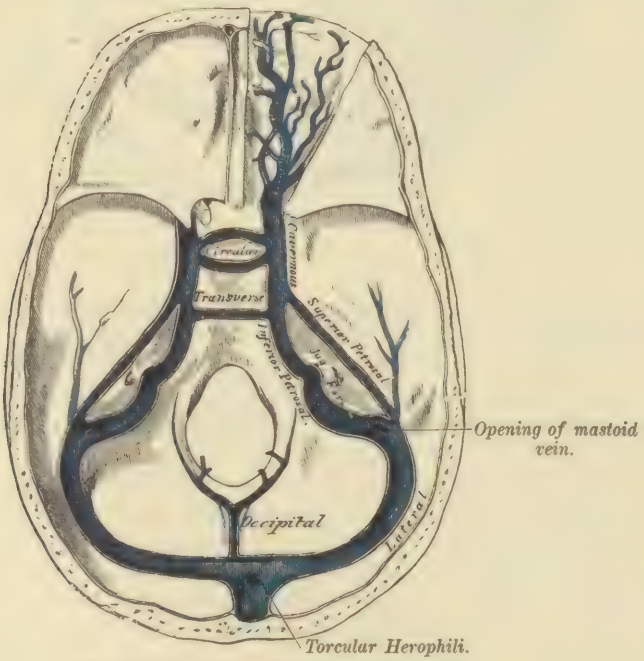

FIG. 456.—The sinuses at the base of the skull.

fissure, it enters the cavernous sinus, either by a separate opening, or, more frequently, in common with the superior ophthalmic vein. It receives muscular

branches and veins of the bulbus oculi, and anastomoses with the superior ophthalmic vein.

The **Circular Sinus** (*sinus circularis*) (Figs. 454 and 456) is formed by two transverse vessels, the **anterior** and **posterior intercavernous sinuses** (*sinus intercavernous anterior* and *sinus intercavernous posterior*), which connect together the two cavernous sinuses; the one passing in front and the other behind the pituitary body, and thus forming with the cavernous sinuses a venous circle around that body. The anterior one is usually the larger of the two, and one or other is occasionally found to be absent.

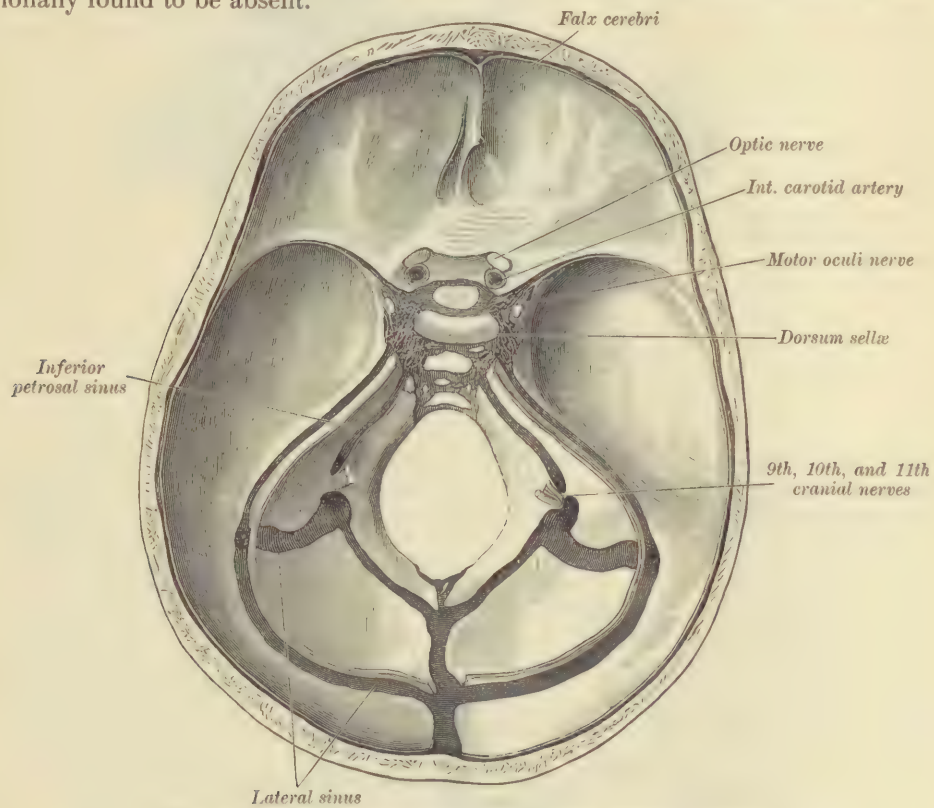

FIG. 457.—Relation of nerves to sinuses in jugular foramen. (Henle.)

The **Superior Petrosal Sinus** (*sinus petrosus superior*) (Figs. 452 and 456) is situated along the superior border of the petrous portion of the temporal bone, in the front part of the attached margin of the tentorium. It is small and narrow, and connects together the cavernous and lateral sinuses at each side. It receives some cerebellar and inferior cerebral veins, and usually veins from the tympanic cavity (*vv. auditivæ internæ*).

The **Inferior Petrosal Sinus** (*sinus petrosus inferior*) (Figs. 452 and 456) is situated in the groove formed by the junction of the posterior border of the petrous portion of the temporal with the basilar process of the occipital bone. It *commences* in front at the termination of the cavernous sinus, and behind joins the lateral sinus after it has passed through the jugular foramen; the junction of these two sinuses forming the commencement of the internal jugular vein. The inferior petrosal sinus receives a vein from the internal ear and also veins from the medulla, pons, and under surface of the cerebellum.

The junction of the two sinuses takes place at the lower border of, or just external to, the jugular foramen. The exact relation of the parts to one another

in the foramen is as follows: The inferior petrosal sinus is in front, with the meningeal branch of the ascending pharyngeal artery, and is directed obliquely downward and backward; the lateral sinus is situated at the back part of the foramen with a meningeal branch of the occipital artery, and between the two are the glosso-pharyngeal, pneumogastric, and spinal accessory nerves (Fig. 457). These three sets of structures are divided from each other by two processes of fibrous tissue. The junction of the sinuses takes place superficial to the nerves, so that these latter lie a little internal to the venous channels in the foramen (see Fig. 457). These sinuses are semicylindrical in form.

The **Transverse** or **Basilar Sinus** (*plexus basilaris*) (Figs. 456 and 457) consists of several interlacing veins between the layers of the dura mater over the basilar process of the occipital bone, which serve to connect the two inferior petrosal sinuses. With them the anterior spinal veins communicate.

Emissary Veins (*emissaria*).—The emissary veins are vessels which pass through apertures in the cranial wall and establish communications between the sinuses inside the skull and the diploic veins in the diploë, and the veins external to the skull. Some of these are always present, others only occasionally so. They vary much in size in different individuals. The principal emissary veins are the following: 1. A vein, almost always present, which passes through the mastoid foramen (*emissarium mastoideum*) and connects the lateral sinus with the posterior auricular or with an occipital vein. 2. A constant vein which passes through the parietal foramen (*emissarium parietale*) and connects the superior longitudinal sinus with the veins of the scalp. 3. A plexus of minute veins which pass through the anterior condyloid foramen (*emissarium condyloideum*) and connect the occipital sinus with the vertebral vein and deep veins of the neck. 4. An inconstant vein which passes through the posterior condyloid foramen and connects the lateral sinus with the deep veins of the neck. 5. One or two veins of considerable size which pass through the foramen ovale and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. 6. Two or three small veins which pass through the foramen lacerum medium and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. 7. There is sometimes a small vein connecting the same parts and passing through the inconstant foramen of Vesalius at the root of the pterygoid process of the sphenoid bone. 8. A plexus of veins passing through the carotid canal and connecting the cavernous sinus with the internal jugular vein. 9. A small vein (*emissarium occipitale*) usually connects the occipital vein with the lateral sinus or the torcular Herophili and the occipital diploic vein.

Surgical Anatomy.—These emissary veins are of great importance in surgery. In addition to them there are, however, other communications between the intra- and extra-cranial circulation, as, for instance, the communication of the angular and supra-orbital veins with the ophthalmic vein at the inner angle of the orbit, and the communication of the veins of the scalp with the diploic veins. Through these communications inflammatory processes commencing on the outside of the skull may travel inward, leading to osteo-phlebitis of the diploë and inflammation of the membranes of the brain. To this in former days was to be attributed one of the principal dangers of scalp wounds and other injuries of the scalp.

By means of these emissary veins blood may be abstracted almost directly from the intracranial circulation. For instance, leeches applied behind the ear abstract blood almost directly from the lateral sinus by means of the vein passing through the mastoid foramen. Again, epistaxis in children will frequently relieve severe headache, the blood which flows from the nose being derived from the longitudinal sinus by means of the vein which passes through the foramen cæcum, which is another communication between the intracranial and extracranial circulation constantly found in children.

VEINS OF THE UPPER EXTREMITY AND THORAX.

The veins of the Upper Extremity are divided into two sets, **superficial** and **deep.**

The **Superficial Veins** are placed immediately beneath the integument between the layers of superficial fascia.

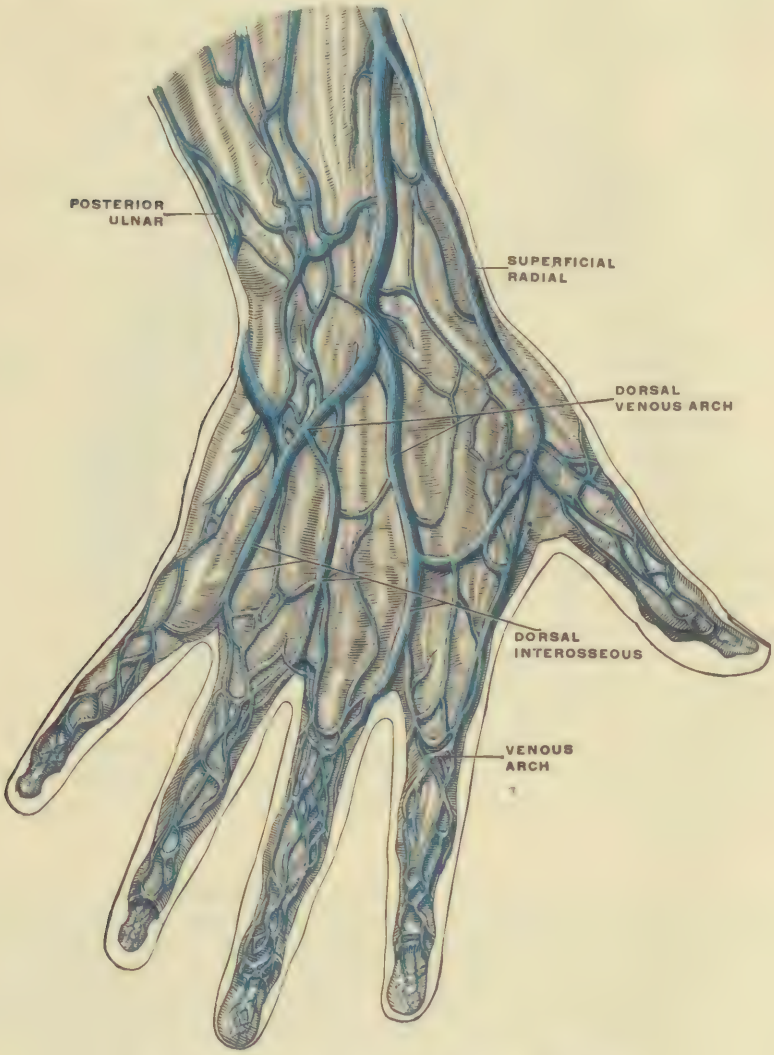

FIG. 458.—The veins on the dorsum of the hand. (Bourgery.)

The **Deep Veins** accompany the arteries, and constitute the venæ comites of those vessels.

Both sets of vessels are provided with valves, which are more numerous in the deep than in the superficial veins.

The Superficial Veins of the Upper Extremity (Fig. 459).

The superficial veins of the upper extremity are—the

Superficial Veins of the Hand.	Median.
Anterior Ulnar.	Median Cephalic.
Posterior Ulnar.	Median Basilic.
Common Ulnar.	Basilic.
Radial.	Cephalic.

The **Superficial Veins of the Hand and Fingers** (Figs. 458 and 459) are principally situated on the dorsal surface. These dorsal veins *begin* in each finger as a venous plexus, in which are distinct veins running in a longitudinal direction, and called **dorsal digital veins** (*vv. digitales dorsales propriæ*). The dorsal digital veins terminate over the first phalanges, in the **venous arches of the fingers** (*arcus venosi digitales*). From these arches take origin the four **dorsal interosseous** or the **interdigital veins** (*vv. metacarpeæ dorsales*). These veins form the **dorsal venous plexus of the hand** (*rete venosum dorsale manus*). This plexus lies in a line with the lower ends of the shafts of the metacarpal bones. It receives the dorsal interosseous veins, the radial digital vein of the index finger, and numerous superficial veins from the back of the hand. It gives origin to the superficial radial vein and the posterior ulnar vein. The superficial veins of the palmar surface are of less diameter than the dorsal veins. They arise from each of the phalanges by a plexus (*vv. digitales volares propriæ*). Vessels at the edges of the fingers take most of the blood to the dorsal veins. There are also veins in the finger webs (*vv. intercapitulares*), which take blood from the palm to the dorsum. A superficial plexus, the **palmar plexus**, lies upon the palmar fascia, the fascia of the thenar eminence, and the fascia of the hypothenar eminence.

The **Anterior Ulnar Vein** (*v. ulnaris anterior*) (Fig. 459) *commences* on the anterior surface of the ulnar side of the hand and wrist, and ascends along the anterior surface of the ulnar side of the forearm to the bend of the elbow, where it joins with the posterior ulnar vein to form the common ulnar. Occasionally it opens separately into the median basilic vein. It communicates with branches of the median vein in front and with the posterior ulnar behind.

The **Posterior** or **Dorsal Ulnar Vein** (*v. ulnaris posterior*) (Fig. 458) *commences* on the posterior surface of the ulnar side of the wrist. It runs on the posterior surface of the ulnar side of the forearm, and just below the elbow unites with the anterior ulnar vein to form the common ulnar, or else joins the median basilic and helps to form the basilic. It communicates with the deep veins of the palm by a branch which emerges from beneath the Abductor minimi digiti muscle.

The **Common Ulnar Vein** (*v. ulnaris communis*) (Fig. 459) is a short trunk which is not constant. When it exists it is *formed* by the junction of the two preceding veins, and, passing upward and outward, joins the median basilic to form the basilic vein. When it does not exist the anterior and posterior ulnar veins open separately into the median basilic vein.

The **Radial Vein** (*v. radialis*) (Figs. 459 and 460) *commences* upon the dorsal surface of the wrist, communicating with the deep veins of the palm by a branch which passes through the first interosseous space. The radial vein soon forms a large vessel, which ascends along the radial side of the forearm and receives numerous veins from both its surfaces. At the bend of the elbow it unites with the median cephalic to form the cephalic vein. Spalteholz considers the ulnar vein as a portion of the basilic and the radial vein a portion of the cephalic.

The **Median Vein** (*v. mediana cubiti*) (Fig. 459) ascends on the front of the forearm, and communicates with the anterior ulnar and radial veins. At the bend

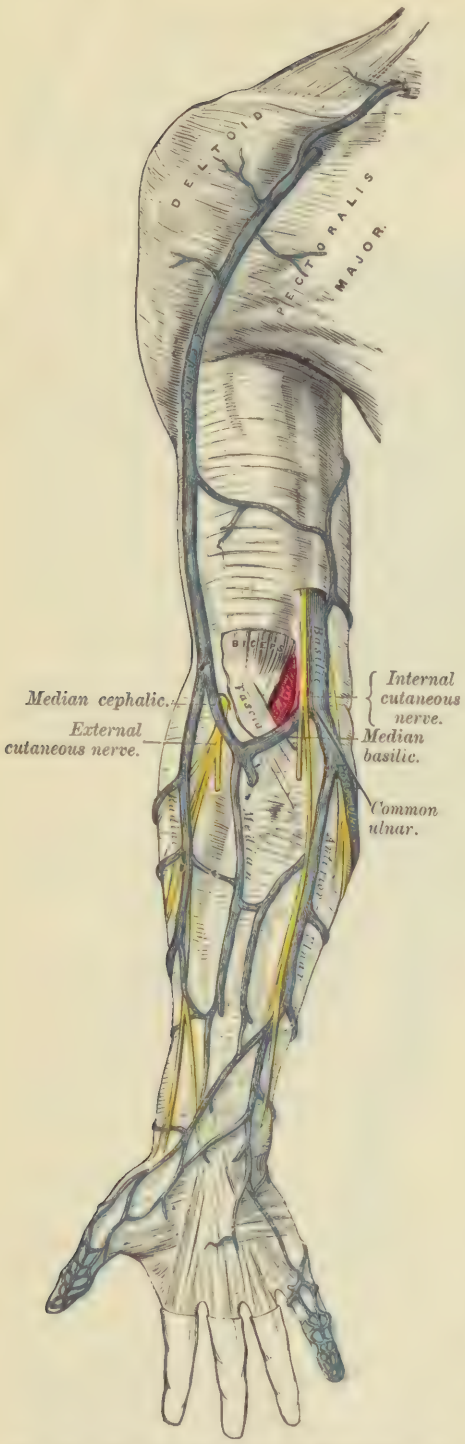

FIG. 459.—The superficial veins of the flexor aspect of the upper extremity.

of the elbow it receives a branch of communication from the deep veins, the **deep median vein**, and divides into two branches, the **median cephalic** and **median basilic**, which diverge from each other as they ascend.

The **Median Cephalic** (*v. mediana cephalica*) (Fig. 459), usually the smaller of the two, passes outward in the groove between the Supinator longus and Biceps muscles, and joins with the radial to form the cephalic vein. The branches of the external cutaneous nerve pass beneath this vessel.

The **Median Basilic Vein** (*v. mediana basilica*) (Fig. 459) passes obliquely inward, in the groove between the Biceps and Pronator radii teres muscles, and joins the common ulnar to form the basilic. This vein passes in front of the brachial artery, from which it is separated by a fibrous expansion, the **bicipital fascia**, which is given off from the tendon of the Biceps to the fascia covering the Flexor muscles of the forearm. Filaments of the internal cutaneous nerve pass in front as well as behind this vessel.[1]

Venesection is usually performed at the bend of the elbow, and as a matter of practice the largest vein in this situation is commonly selected. This is usually the median basilic, and there are anatomical advantages and disadvantages in selecting this vein. The advantages are, that in addition to its being the largest, and therefore yielding a greater supply of blood, it is the least movable and can be easily steadied on the bicipital fascia on which it rests. The disadvantages are, that it is in close relationship with the brachial artery, separated only by the bicipital fascia; and formerly, when venesection was frequently practised, arterio-venous aneurism was no uncommon result of this practice. Another disadvantage is, that the median basilic is crossed by some of the branches of the internal cutaneous nerve, and these may be divided in the operation, giving rise to "traumatic neuralgia of extreme intensity" (Tillaux).

The **Basilic Vein** (*v. basilica*) (Figs. 460 and 462) is of considerable size and is formed by the coalescence of the common ulnar vein with the median

[1] Cruveilhier says: "Numerous varieties are observed in the disposition of the veins of the elbow; sometimes the common median vein is wanting; but in those cases its two branches are furnished by the radial vein, and the cephalic is almost always in a rudimentary condition. In other cases only two veins are found at the bend of the elbow, the radial and ulnar, which are continuous, without any demarcation, with the cephalic and basilic."—ED. of 15th English edition.

basilic. It passes upward along the inner side of the Biceps muscle and pierces the deep fascia a little below the middle of the arm. The opening in the fascia is known as the **semilunar hiatus** (*hiatus semilunaris*). The vein ascends in the course of the brachial artery to the lower border of the tendons of the Latissimus dorsi and Teres major muscles, and is continued onward as the axillary vein.

The **Cephalic Vein** (*v. cephalica*) (Fig. 459) is formed by the union of the median cephalic and the radial veins. It courses along the outer border of the Biceps muscle, lying in the same groove with the upper external cutaneous branch of the musculo-spiral nerve, to the upper third of the arm; it then passes in the interval between the Pectoralis major and Deltoid muscles, lying in the same groove with the descending or humeral branch of the acromial-thoracic artery. It pierces the costo-coracoid membrane, and, crossing the axillary artery, terminates in the axillary vein just below the clavicle. This vein is occasionally connected with the external jugular or subclavian by a branch which passes from it upward in front of the clavicle.

The Deep Veins of the Upper Extremity (Fig. 460).

The deep veins of the upper extremity follow the course of the arteries, forming their **venæ comites** or **companion veins.** Usually there is one vein lying on each side of the corresponding artery, and they are connected at intervals by short transverse branches.

There are two **digital veins** accompanying each artery along the sides of the fingers: these, uniting at their base, pass along the interosseous spaces in the palm, and terminate in the two venæ comites which accompany the superficial palmar arch. Branches from these vessels on the radial side of the hand accompany the superficialis volæ, and on the ulnar side terminate in the **deep ulnar veins** (Fig. 460). The deep ulnar veins, as they pass in front of the wrist, communicate with the interosseous and superficial veins, and at the elbow unite with the deep radial veins to form the venæ comites of the brachial artery. The venæ comites of the brachial communicate by numerous transverse branches, which cross over or under the artery.

The **Interosseous Veins** (Fig. 460) accompany the anterior and posterior interosseous arteries. The anterior interosseous veins *commence* in front of the wrist, where they communicate with the deep radial and ulnar veins; at the upper part of the forearm they receive the posterior interosseous veins, and terminate in the venæ comites of the ulnar artery.

The **Deep Palmar Veins** accompany the deep palmar arch, being formed by tributaries which accompany the ramifications of that vessel. At the wrist they receive a dorsal and a palmar tributary from the thumb. The deep palmar veins communicate with the deep ulnar veins at the inner side of the hand, and on the outer side terminate in the **deep radial veins** (Fig. 460), which are the venæ comites of the radial artery. Accompanying the radial artery the deep radial veins terminate in the venæ comites of the brachial artery.

The **Brachial Veins** (*vv. brachiales*) (Fig. 460) are placed one on each side of the brachial artery, receiving tributaries corresponding with the branches given off from that vessel; at the lower margin of the Subscapularis muscle they join the axillary vein.

These deep veins have numerous anastomoses, not only with each other, but also with the superficial veins. One of the brachial veins empties into the axillary, the other, usually the smaller, generally unites with the basilic.

The **Axillary Vein** (*v. axillaris*) (Fig. 461) is of large size, and may be regarded as the continuation upward of the basilic vein, or as formed by the fusion of a brachial vein with the basilic vein. If the first view is accepted a brachial vein is described as one of the tributaries of the axillary vein. The axillary vein com-

mences at the lower border of the tendons of the Teres major and Latissimus dorsi muscles, increases in size as it ascends, by receiving tributaries corresponding with the branches of the axillary artery, and terminates immediately beneath the clavicle at the outer border of the first rib, where it becomes the subclavian vein. This vessel is covered in front by the Pectoral muscles and costocoracoid membrane, and lies on the thoracic side of the axillary artery, which it partially overlaps. It receives the brachial veins, the venæ comites of the axillary artery except the circumflex veins; and near its termination the cephalic vein. This vein is provided with a pair of valves opposite the lower border of the Subscapularis muscle; valves are also found at the termination of the cephalic and subscapular veins. The circumflex veins end in the subscapular or one of the brachial veins.

The **Long Thoracic Branch** (*v. thoracalis lateralis*) (Fig. 462) receives the **thoracico-epigastric vein** (*v. thoracoepigastrica*), which comes all the way from the superficial epigastric or from the femoral vein.

The **Costo-axillary Veins** (*vv. costoaxillares*) (Fig. 462) come from the first six intercostal spaces and bring blood from the intercostal veins to the axillary.

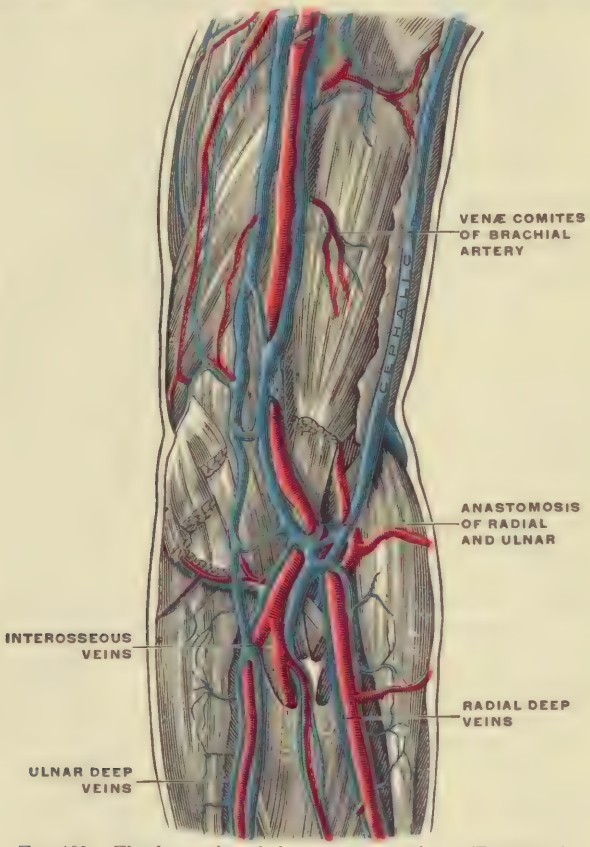

FIG. 460.—The deep veins of the upper extremity. (Bourgery.)

Surgical Anatomy.—There are several points of surgical interest in connection with the axillary vein. Being more superficial, larger, and slightly overlapping the axillary artery, it is more liable to be wounded in the operation of extirpation of the axillary glands, especially as these glands, when diseased, are apt to become adherent to the vessel. When wounded there is always danger of air being drawn into its interior, and death resulting. This is due not only to the fact that it is near the thorax, and therefore liable to be influenced by the respiratory movements, but also because it is adherent by its anterior surface to the costo-coracoid membrane, and therefore if wounded is likely to remain patulous and favor the chance of air being sucked in. This adhesion of the vein to the fascia prevents its collapsing, and therefore favors the furious bleeding which takes place in these cases.

To avoid wounding the axillary vein in the extirpation of glands from the axilla no undue force should be used in isolating the glands. If the vein is found to be so embedded in the malignant deposit that the latter cannot be removed without taking away a part of the vein, this must be done, the vessel having been first ligated above and below.

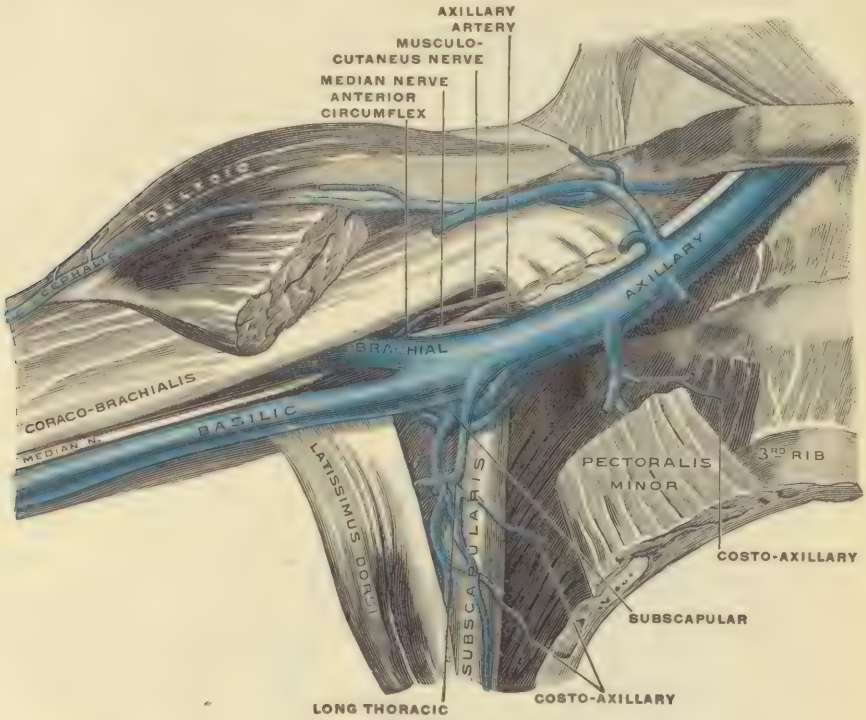

FIG. 461.—The veins of the right axilla, viewed from in front. (Spalteholz.)

The **Subclavian Vein** (*v. subclavia*) (Figs. 421 and 446), the continuation of the axillary, extends from the outer border of the first rib to the inner end of the clavicle, where it unites with the internal jugular to form the innominate vein. It is in relation, in *front*, with the clavicle and Subclavius muscle; *behind* and *above*, with the subclavian artery, from which it is separated internally by the Scalenus anticus muscle and phrenic nerve. *Below*, it rests in a depression on the first rib and upon the pleura. *Above*, it is covered by the cervical fascia and integument.

An expansion of the aponeurosis of the Subclavius muscle lies upon the vein (Fig. 462).

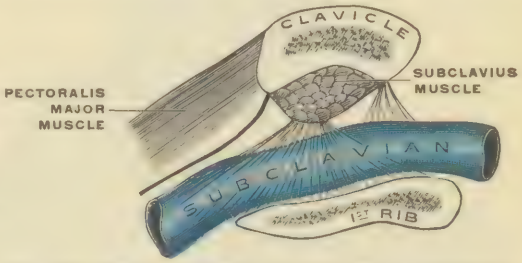

FIG. 462.—The aponeurotic expansion of the Subclavius muscle over the subclavian vein. (Poirier and Charpy.)

The subclavian vein occasionally rises in the neck to a level with the third part of the subclavian artery, and in two instances has been seen passing with this vessel behind the Scalenus anticus. This vessel is usually provided with valves about an inch from its termination in the innominate, just external to the entrance of the external jugular vein.

Tributaries.—It receives the external and anterior jugular veins and a small branch from the cephalic, outside the Scalenus, and on the inner side of that muscle the internal jugular vein. At the angle of junction with the internal

jugular the left subclavian vein receives the thoracic duct (Fig. 463), while the right subclavian vein receives the right lymphatic duct.

The **Innominate** or **Brachio-cephalic Veins** (*vv. anonymæ*) (Fig. 464) are two large trunks, placed one on each side of the root of the neck, and formed by the union of the internal jugular and subclavian veins of the corresponding side.

The **Right Innominate Vein** (*v. anonyma dextra*) is a short vessel, an inch in length, which *commences* at the inner end of the clavicle, and, passing almost vertically downward, joins with the left innominate vein just below the cartilage of the first rib, close to the right border of the sternum, to form the superior vena cava. It lies superficial and external to the innominate artery; on its right side is the phrenic nerve, and the pleura is here interposed between it and the apex of the lung. This vein, at the angle of junction of the internal jugular with the subclavian, receives the right vertebral vein, and, lower down, the right internal mammary, right inferior thyroid, and sometimes the right thyroidea ima and the right superior intercostal veins.

The **Left Innominate Vein** (*v. anonyma sinistra*), about two and a half inches in length, and larger than the right, passes from left to right across the upper and front part of the chest, at the same time inclining downward, and unites

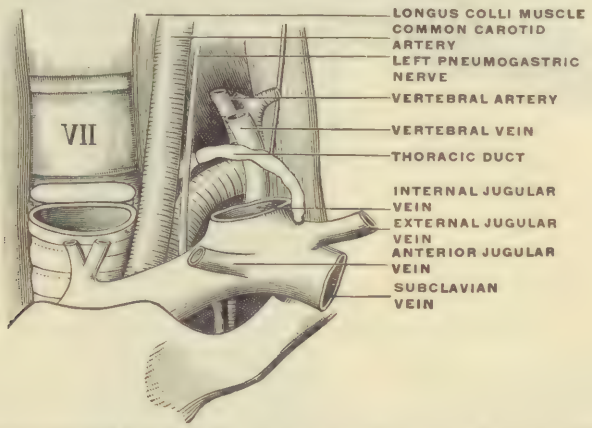

FIG. 463.—The bend of the thoracic duct at its termination in the subclavian vein. (Poirier and Charpy.)

with the right innominate vein to form the **superior vena cava.** It is in relation, in *front*, with the first piece of the sternum, from which it is separated by the Sterno-hyoid and Sterno-thyroid muscles, the thymus gland or its remains, and some loose areolar tissue. *Behind*, it lies across the roots of the three large arteries arising from the arch of the aorta. This vessel is joined by the left vertebral, left internal mammary, left inferior thyroid, left thyroidea ima, and the left superior intercostal veins, and occasionally some thymic and pericardiac veins, and the right thyroidea ima. There are no valves in the innominate veins.

Peculiarities.—Sometimes the innominate veins open *separately* into the right auricle; in such cases the right vein takes the ordinary course of the superior vena cava; but the left vein—the **left superior vena cava,** as it is termed—after communicating by a small branch with the right one, passes in front of the root of the left lung, and, turning to the back of the heart, receives the cardiac veins, and terminates in the back of the right auricle. This occasional condition in the adult is due to the persistence of the early fœtal condition, and is the normal state of things in birds and some mammalia.

The **Internal Mammary Vein** (*v. mammaria interna*) corresponds to the internal mammary artery, follows the course of that vessel, and receives branches corresponding with those derived from it. There are two internal mammary veins in the region of the Triangularis sterni muscle, but above this point the vein is single. The double vein is formed by the union of the venæ comites of the superior epigastric

artery (*vv. epigastricæ superiores*) and the venæ comites of the musculo-phrenic artery (*vv. musculophrenicæ*). It receives the twelve anterior intercostal veins from the upper six intercostal spaces of the corresponding side—six anterior perforating veins (*rami perforantes*)—veins from the surface of the sternum (*rami sternales*)—muscular veins, and vessels from the mediastinum and pleura. The two veins of each side unite into a single trunk, at the upper margin of the triangularis sterni muscle, which terminates in the innominate vein.

The Vertebral Vein (see p. 732).

The **Inferior Thyroid Veins** (*vv. thyreoideæ inferiores*) (Fig. 464), two, frequently three or four, in number, *arise* in the **venous plexus on the thyroid body** (*plexus thyreoideus impar*), communicating with the middle and superior thyroid veins. (See Kocher's views, pages 731 and 732.) Kocher states that two thyroidea ima veins are present, and that inferior thyroid veins may also be present. The veins from the lower portion of the gland form a plexus in front of the trachea, behind the Sterno-thyroid muscles. From this plexus a left vein descends and joins the left innominate trunk, and a right vein passes obliquely downward and outward across the innominate artery to open into the right innominate vein, just at its junction with the superior vena cava. The **thyroidea ima vein** (*v. thyreoidea ima*) passes downward in front of the trachea and terminates in the left innominate vein. These veins receive tributaries from the **tracheal veins** (*vv. tracheales*), from the **œsophageal veins** (*vv. œsophageæ*), from the **inferior laryngeal vein** (*v. laryngea inferior*).

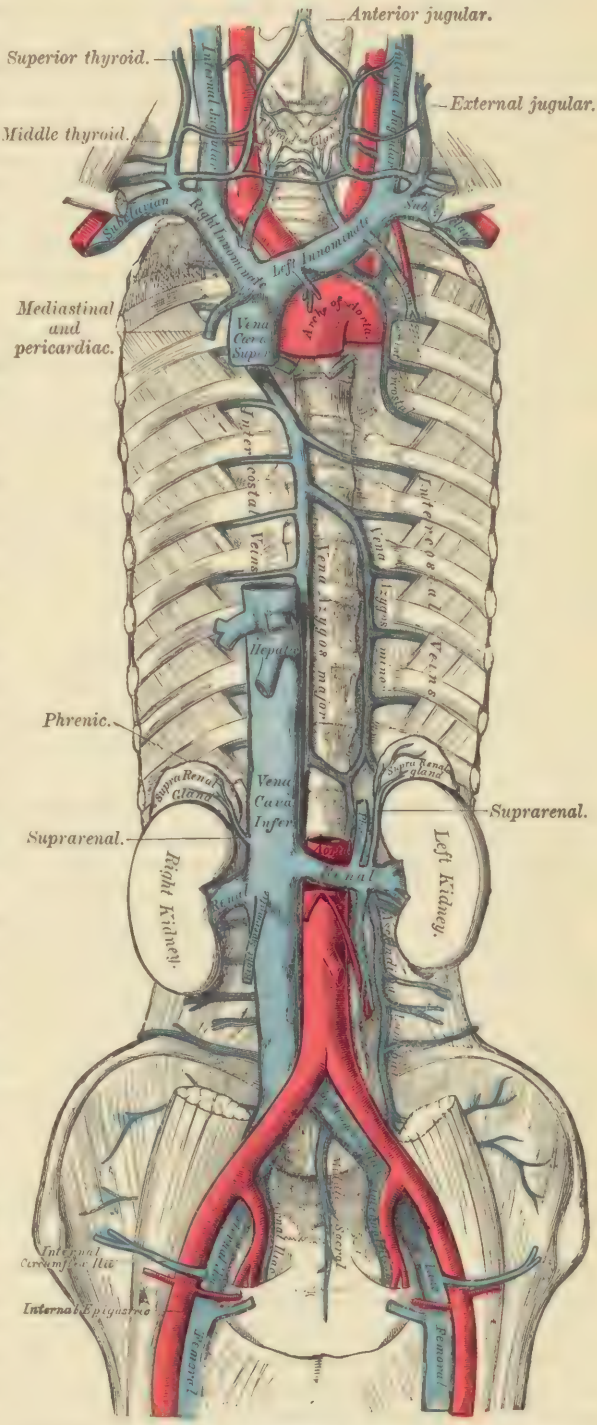

FIG. 464.—The venæ cavæ and azygos veins, with their formative branches.

The **Intercostal Veins** (*vv. intercostales*) are divided into anterior and posterior intercostals.

The **Anterior Intercostal Veins** are tributaries of the internal mammary or the musculo-phrenic veins (p. 731).

The **Posterior Intercostal Veins** (Fig. 464) number eleven on each side, there being one vein in each intercostal space. Each vein lies in the groove at the lower margin of the rib above the corresponding intercostal artery. On the right side the first posterior intercostal vein crosses the neck of the first rib anteriorly and opens into the vertebral vein or the innominate vein. The first posterior intercostal of the left side follows a like course, and empties into the vertebral or innominate vein. The posterior intercostals of the right side, from the fifth to the eleventh, inclusive, open individually into the vena azygos major. The left upper azygos vein receives the fifth, sixth, seventh, and eighth posterior intercostals of the left side. The left lower azygos vein receives the ninth, tenth, and eleventh left posterior intercostals.

The **Right Superior Intercostal Vein** (*v. intercostalis suprema dextra*) is formed by the union of the second, third, and fourth right posterior intercostals. It passes downward and inward and opens into the vena azygos major.

The **Left Superior Intercostal Vein** (*v. intercostalis suprema sinister*) runs across the transverse aorta and opens into the left innominate vein. It usually receives the left bronchial and left superior phrenic vein, and communicates below with the vena azygos minor superior. Each posterior intercostal vein obtains branches from the ribs and muscles and also a dorsal branch, which receives blood from the muscles of the back, from in front of the vertebral bodies, from back of the vertebral arches, and from the spinal canal by way of a vein which passes through the intervertebral foramen.

The **Superior Vena Cava** (*v. cava superior*) (Fig. 464) receives the blood which is conveyed to the heart from the whole of the upper half of the body. It is a short trunk, varying from two inches and a half to three inches in length, formed by the junction of the two innominate veins. It *commences* immediately below the cartilage of the first rib close to the sternum on the right side, and, descending vertically, enters the pericardium about an inch and a half above the heart, and terminates in the upper part of the right auricle opposite the upper border of the third right costal cartilage. In its course it describes a slight curve, the convexity of which is turned to the right side.

Relations.—*In front*, with the pericardium and process of cervical fascia which is continuous with it: this separates it from the thymus gland and from the sternum; *behind*, with the root of the right lung; on its *right side*, with the phrenic nerve and right pleura; on its *left side*, with the commencement of the innominate artery and ascending part of the aorta. The portion contained within the pericardium is covered by the serous layer of that membrane in its anterior three-fourths. It receives the vena azygos major just before it enters the pericardium, and several small veins from the pericardium and parts in the mediastinum. The superior vena cava has no valves.

The **Azygos Veins** connect together the superior and inferior venæ cavæ, taking the place of those vessels in that part of the chest occupied by the heart.

The **Larger** or **Right Azygos Vein** or the **Vena Azygos Major** (*v. azygos*) (Fig. 464) *commences* opposite the first or second lumbar vertebra by a branch from the right lumbar veins, called the **right ascending lumbar vein** (*v. lumbalis ascendens dextra*); sometimes by a branch from the right renal vein or from the inferior vena cava. It enters the thorax through the aortic opening in the Diaphragm, and passes along the right side of the vertebral column to the fourth dorsal vertebra, where it arches forward over the root of the right lung, and terminates in the superior vena cava just before that vessel enters the pericardium. Whilst passing through the

aortic opening of the Diaphragm it lies with the thoracic duct on the right side of the aorta, and in the thorax it lies upon the intercostal arteries on the right side of the aorta and thoracic duct, and is partly covered by pleura.

Tributaries.—It receives the lower ten posterior intercostal veins of the right side, the upper two or three of these opening first of all into the right superior intercostal vein. It receives the azygos minor veins, several œsophageal, mediastinal, and pericardial veins; near its termination, the right bronchial vein; and generally the right superior intercostal vein. A few imperfect valves are found in this vein; but its tributaries are provided with complete valves.

The intercostal veins on the left side, below the three upper intercostal spaces, usually form two trunks, named the **left lower** and the **left upper azygos veins.**

The **Left Lower** or **Smaller Azygos Vein** or the **Vena Azygos Minor** (*v. hemiazygos*) (Fig. 464) commences in the lumbar region by a branch from one of the lumbar veins, **ascending lumbar** (*v. lumbalis ascendens*), or from the left renal. It passes into the thorax through the left crus of the Diaphragm, and, descending on the left side of the spine as high as the ninth dorsal vertebra, passes across the column, behind the aorta and thoracic duct, to terminate in the right azygos vein. It receives the four or five lower intercostal veins of the left side, and some œsophageal and mediastinal veins.

The **Left Upper Azygos Vein** (*v. hemiazygos accessoria*) varies inversely with the size of the left superior intercostal. It receives veins from the intercostal spaces between the left superior intercostal vein and highest tributary of the left lower azygos. They are usually three or four in number, usually the fourth, fifth, sixth, and seventh left posterior intercostal veins. They join to form a trunk which ends in the right azygos vein or in the left lower azygos. It sometimes receives the left bronchial vein. When this vein is small or altogether wanting, the left superior intercostal vein will extend as low as the fifth or sixth intercostal space.

Surgical Anatomy.—In obstruction of the inferior vena cava the azygos veins are one of the principal means by which the venous circulation is carried on, connecting as they do the superior and inferior venæ cavæ, and communicating with the common iliac veins by the ascending lumbar veins, and with many of the tributaries of the inferior vena cava.

The **Bronchial Veins** (*vv. bronchiales*) return the blood from the substance of the lungs, except from the smaller bronchial tubes and alveola. The blood from them is received by the pulmonary veins. The bronchial vein of the right side opens into the vena azygos major near its termination. The bronchial vein of the left side opens into the left superior intercostal vein or the left upper azygos vein. The bronchial veins are joined by veins from the trachea and mediastinum.

The Spinal Veins.

The numerous venous plexuses placed upon and within the spine may be arranged into four sets:

1. Those placed on the exterior of the spinal column, the **dorsi-spinal veins.**
2. Those situated in the interior of the spinal canal, between the vertebræ and the theca vertebralis, **meningo-rachidian veins.**
3. The veins of the bodies of the vertebræ, **venæ basis vertebrarum.**
4. The veins of the spinal cord, **medulli-spinal veins.**

1. The **Dorsi-spinal Veins** (*plexus venosi vertebrales externi*) commence by small branches which receive their blood from the integument of the back of the spine and from the muscles in the vertebral grooves. They constitute two plexuses: an **anterior plexus** (*plexus venosi vertebrales anteriores*) upon the vertebral bodies and a **posterior plexus** (*plexus venosi vertebrales posteriores*), which surrounds the spinous processes, the laminæ, and the transverse and articular processes of

all the vertebræ. At the bases of the transverse processes they communicate, by means of ascending and descending branches, with the veins surrounding the contiguous vertebræ, and they join with the veins in the spinal canal by branches which perforate the ligamenta subflava. Other branches pass obliquely forward, between the transverse processes, and communicate with the intraspinal veins through the intervertebral foramina (*vv. intervertebrales*). The dorsi-spinal veins terminate by joining the vertebral veins in the neck, the intercostal veins in the thorax, and the lumbar and sacral veins in the loins and pelvis.

FIG. 465.—Transverse section of a dorsal vertebra, showing the spinal veins.

2. The **Meningo-rachidian Veins** (*plexus venosi vertebrales interni*).—The principal veins contained in the spinal canal are situated between the theca vertebralis and the vertebræ. They consist of two longitudinal plexuses, one of which runs along the posterior surface of the bodies of the vertebræ, **anterior longitudinal spinal veins.** The other plexus, **posterior longitudinal spinal veins,** is placed on the inner or anterior surface of the laminæ of the vertebræ.

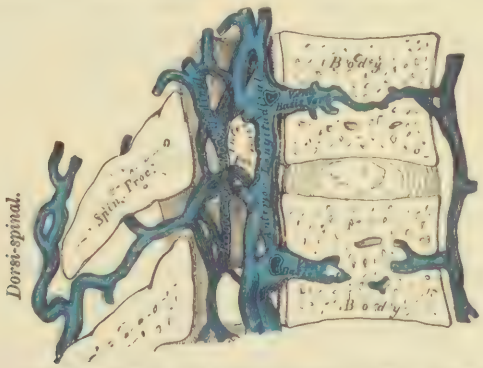

FIG. 466.—Vertical section of two dorsal vertebræ, showing the spinal veins.

The **Anterior Longitudinal Spinal Veins** (*sinus vertebrales longitudinales*) consist of two large, tortuous veins which extend along the whole length of the vertebral column, from the foramen magnum, where they communicate by a venous ring around that opening, to the base of the coccyx, being placed one on each side of the posterior surface of the bodies of the vertebræ along the margin of the posterior common ligament. These veins communicate together opposite each vertebra by

transverse trunks which pass beneath the ligament. Each transverse trunk receives the large **vena basis vertebræ** (*v. basivertebralis*) from the interior of the body of the vertebra. The anterior longitudinal spinal veins are least developed in the cervical and sacral regions. They are not of uniform size throughout, being alternately enlarged and constricted. At the intervertebral foramina they communicate with the dorsi-spinal veins, and with the vertebral veins in the neck, with the intercostal veins in the dorsal region, and with the lumbar and sacral veins in the corresponding regions.

The **Posterior Longitudinal Spinal Veins**, smaller than the anterior, are situated one on each side, between the inner surface of the laminæ and the theca vertebralis. They communicate (like the anterior) opposite each vertebra by transverse trunks, and with the anterior longitudinal veins by lateral transverse branches which pass from behind forward. The posterior longitudinal veins, by branches which perforate the ligamenta subflava, join with the dorsi-spinal veins. From them branches are given off which pass through the intervertebral foramina and join the vertebral, intercostal, lumbar, and sacral veins. The anterior and posterior longitudinal spinal veins join by numerous branches and really constitute one plexus, the plexus venosi vertebrales interni.

The **Intervertebral Veins** (*vv. intervertebrales*) accompany the spinal nerves in the intervertebral foramina, receive veins from the spinal cord, and join the meningo-rachidian and the dorsi-spinal veins.

3. The **Veins of the Bodies of the Vertebræ** or the **Venæ Basis Vertebrarum** (*vv. basivertebrales*) emerge from the foramen on the posterior surface of each vertebra and join the transverse trunk connecting the anterior longitudinal spinal veins. They are contained in large, tortuous channels in the substance of the bones, similar in every respect to those found in the diploë of the cranial bones. These canals lie parallel to the upper and lower surface of the bones. They *commence* by small openings on the front and sides of the bodies of the vertebræ, through which communicating branches from the veins external to the bone pass into its substance, and converge to the principal canal, which is sometimes double toward its posterior part. They open into the corresponding transverse branch uniting the anterior longitudinal veins. They become greatly developed in advanced age.

4. The **Veins of the Spinal Cord** or the **Medulli-spinal Veins** (*vv. spinales*) emerge from the cord substance and enter the pia mater plexus. The pia mater plexus is a minute, tortuous, venous plexus which covers the entire surface of the cord, being situated between the pia mater and arachnoid. "In this plexus there are six longitudinal channels—one antero-median, along the anterior fissure—two antero-lateral, immediately behind the anterior nerve roots—two postero-lateral, immediately behind the posterior nerve roots—and one postero-median, over the postero-septum."[1] These vessels are largest in the lumbar region. Near the base of the skull they unite and form two or three small trunks, which communicate with the vertebral veins, and terminate in the inferior cerebellar veins or in the inferior petrosal sinuses. Each of the spinal nerves is accompanied by a branch as far as the intervertebral foramina, where it joins the other veins from the spinal canal.

There are no valves in the spinal veins.

VEINS OF THE LOWER EXTREMITY, ABDOMEN, AND PELVIS

(Figs. 467, 468).

The Veins of the Lower Extremity are subdivided, like those of the upper, into two sets, **superficial** and **deep**, the superficial veins being placed beneath the

[1] D. J. Cunningham. A Text-book of Anatomy.

integument, between the two layers of superficial fascia, the deep veins accompanying the arteries, and forming the venæ comites of those vessels. Both sets of veins are provided with valves, which are more numerous in the deep than in the superficial set. These valves are also more numerous in the lower than in the upper limb.

The Superficial Veins of the Lower Extremity.

The Superficial Veins of the Foot.—On the sole of the foot there is a **subcutaneous venous plexus** (*rete venosum plantare cutaneum*), from which some branches go to the deep veins, but most of the branches pass around the margins to the dorsum of the foot. There is a transverse venous arch at the root of the toes which receives plantar vessels from the toes and sends branches between the toes (*vv. intercapitulares*) to the venous arch of the dorsum. On the dorsum of each toe the veins gather into two vessels, known as the **dorsal digital veins** (*vv. digitales pedis dorsales*). The dorsal digital veins from the opposed margins of two toes unite to form a dorsal interdigital vein. There are four **dorsal interdigital veins** (*vv. digitales communes pedis*), and they pass into the venous arch of the dorsum. The dorsal digital vein, from the inner surface of the great toe, passes directly into the internal saphenous vein, and the dorsal digital vein, from the outer surface of the little toe, passes directly into the external saphenous vein.

On the dorsum of the foot is a **venous arch** (*arcus venosus dorsalis pedis* [*cutaneus*]), situated in the superficial structures over the anterior extremities of the metatarsal bones. It has its convexity directed forward, and receives digital tributaries from the upper surface of the toes; at its concavity it is joined by numerous small veins which form a **plexus** on the dorsum of the foot (*rete venosum dorsale pedis cutaneum*). The arch terminates internally in the long saphenous, externally in the short saphenous vein.

The chief superficial veins of the lower extremity are the **internal** or **long saphenous** and the **external** or **short saphenous.**

The **Internal** or **Long Saphenous Vein** (*v. saphena magna*) (Figs. 467 and 470) *commences* at the inner side of the arch on the dorsum of the foot; it ascends in front of the inner malleolus and along the inner side of the leg, behind the inner margin of the tibia, accompanied by the internal saphenous nerve. At the knee it passes backward behind the inner condyle of the femur, ascends along the inside of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart's ligament. This vein receives in its course cutaneous tributaries from the leg and thigh, and at the saphenous opening receives the superficial epigastric, superficial circumflex iliac, and external pudic veins. The veins from the inner and back part of the thigh frequently unite to form a large vessel, which enters the main trunk near the saphenous opening; and sometimes those on the outer side of the thigh join to form another large vessel; so that occasionally three large veins are seen converging from different parts of the thigh toward the saphenous opening. The internal saphenous vein communicates in the foot with the internal plantar vein; in the leg, with the posterior tibial veins by branches which perforate the tibial origin of the Soleus muscle, and also with the anterior tibial veins; at the knee, with the articular veins; in the thigh, with the femoral vein by one or more branches. The valves in this vein vary from two to six in number; they are more numerous in the thigh than in the leg.

The **External** or **Short Saphenous Vein** (*v. saphena parva*) (Fig. 468) *commences* at the outer side of the arch on the dorsum of the foot; it ascends behind the outer malleolus, and along the outer border of the tendo Achillis, across which it passes at an acute angle to reach the middle line of the posterior aspect of the leg.

Passing directly upward, it perforates the deep fascia in the lower part of the popliteal space, and terminates in the popliteal vein, between the heads of the

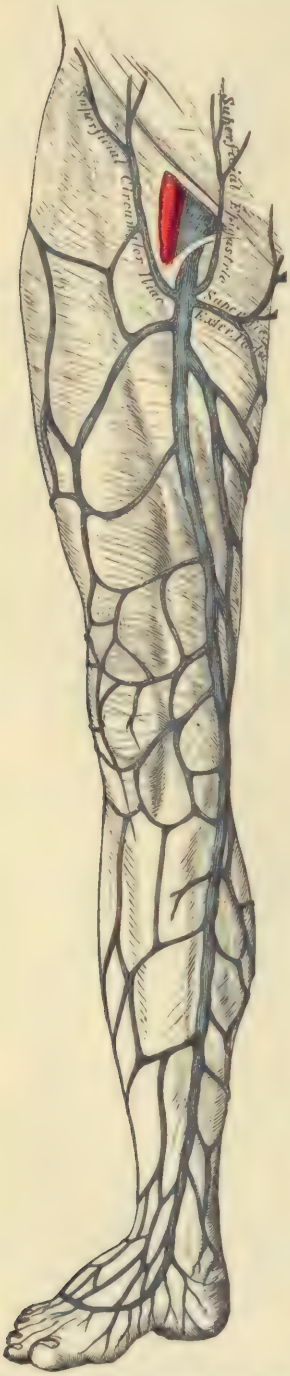

Fig. 467. — The internal or long saphenous vein and its branches.

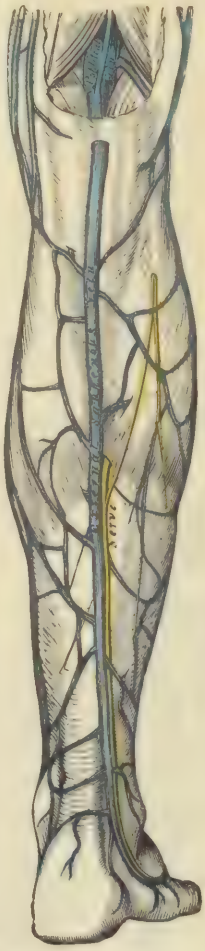

Fig. 468.—External or short saphenous vein.

Gastrocnemius muscle.[1] It receives numerous large tributaries from the back part of the leg, and communicates with the deep veins on the dorsum of the foot and behind the outer malleolus. Before it perforates the deep fascia it gives off a communicating branch, which passes upward and inward to join the internal saphenous vein. This vein has a variable number of valves, from three to nine (Gay), one of which is always found near its termination in the popliteal vein. The external saphenous nerve lies close beside this vein.

Surgical Anatomy.—The saphenous veins are of considerable surgical importance, since a *varicose* condition of these vessels is more frequently met with than of those in other parts

[1] Mr. Gay calls attention to the fact that the external saphenous vein often (he says invariably) penetrates the fascia at or about the point where the tendon of the Gastrocnemius commences, and runs below the fascia in the rest of its course, or sometimes among the muscular fibres, to join the popliteal vein. (See Gay on Varicose Disease of the Lower Extremities, p. 24, where there is also a careful and elaborate description of the branches of the saphena veins.)—Ed. of 15th English edition.

of the body, except perhaps the spermatic and hemorrhoidal veins. The course of the internal saphenous is in front of the tip of the inner malleolus, over the subcutaneous surface of the lower end of the tibia, and then along the internal border of this bone to the back part of the internal condyle of the femur, whence it follows the course of the Sartorius muscle, and is represented on the surface by a line drawn from the posterior border of the Sartorius on a level with the internal condyle to the saphenous opening. The external saphenous lies behind the external malleolus, and from this follows the middle line of the calf to just below the ham. It is not generally so apparent beneath the skin as the internal saphenous. Both these veins in the leg are accompanied by nerves, the internal saphenous being joined by its companion nerve just below the level of the knee-joint. No doubt much of the pain of varicose veins in the leg is due to this fact.

The Deep Veins of the Lower Extremity.

The deep veins of the lower extremity accompany the arteries and their branches and are called the **venæ comites** of those vessels. The venæ comites in the lower extremity pass into one trunk, the **popliteal vein**, whereas in the upper extremity the venæ comites continue with the artery to the axilla.

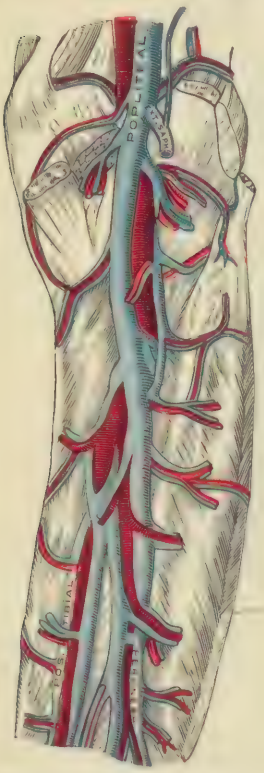

Fig. 469.—The popliteal vein. (Poirier and Charpy.)

The Deep Veins of the Foot.—The **plantar digital veins** (*vv. digitales plantares*) form the **plantar metatarsal veins** (*vv. metatarseæ plantares*), which communicate with the veins of the dorsum of the foot by perforating veins and also communicate with the deep venous arch of the sole of the foot (*arcus venosus plantaris profundus*). The plantar arch gives off **lateral** or **external plantar veins**, which unite with **median** or **internal plantar veins** to form the posterior tibial veins. On the dorsum of the foot the deep veins begin as the **dorsal metatarsal veins** (*vv. metatarseæ dorsales pedis*), which form the venæ comites of the dorsalis pedis artery.

The **Posterior Tibial Veins** (*vv. tibiales posteriores*) accompany the posterior tibial artery and are joined by the peroneal veins.

The **Anterior Tibial Veins** (*vv. tibiales anteriores*) are formed by a continuation upward of the venæ comites of the dorsalis pedis artery. They pass between the tibia and fibula, through the large oval aperture above the interosseous membrane, and form, by their junction with the posterior tibial, the popliteal vein.

The valves in the deep veins are very numerous.

The **Popliteal Vein** (*v. poplitea*) (Fig. 469) is formed by the junction of the anterior and posterior tibial veins; it ascends through the popliteal space to the aperture in the Adductor magnus, where it becomes the femoral vein. In the lower part of its course it is placed internal to the artery; between the heads of the Gastrocnemius it is superficial to that vessel; but above the knee-joint it is close to the outer side of the artery. It receives the **sural veins** from the Gastrocnemius muscle, the articular veins, and the external saphenous vein. The valves in this vein are usually four in number.

The **Femoral Vein** (*v. femoralis*) (Figs. 470 and 471) accompanies the femoral artery through the upper two-thirds of the thigh. In the lower part of its course it lies external to the artery; higher up it is behind it; and at Poupart's ligament it lies to its inner side and on the same plane. It receives numerous muscular tributaries, and about an inch and a half below Poupart's ligament it is joined by

the **profunda femoris** (*v. profunda femoris*); near its termination it is joined by the internal saphenous vein. The valves in this vein are four or five in number.

The **External Iliac Vein** (*v. iliaca externa*) (Figs. 464, 471, and 473) *commences* at the termination of the femoral, beneath the crural arch, and, passing upward along the brim of the pelvis, terminates opposite the sacro-iliac synchondrosis by uniting with the internal iliac to form the common iliac vein. On the right side it lies at first along the inner side of the external iliac artery, but as it passes upward gradually inclines behind it. On the left side it lies altogether on the inner side of the artery. It receives, immediately above Poupart's ligament, the deep epi-

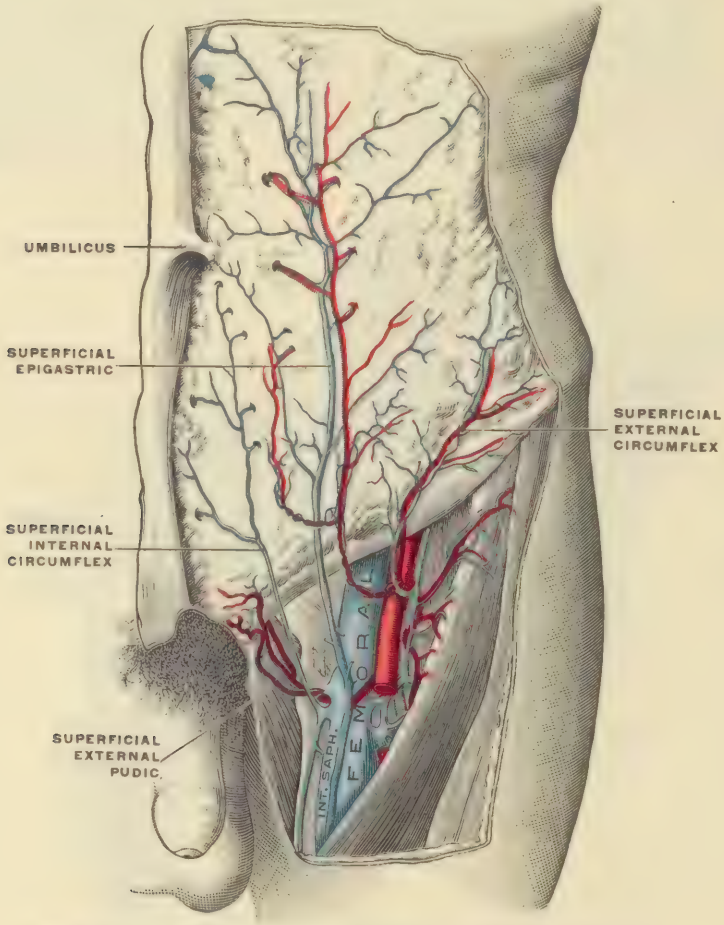

FIG. 470.—The femoral vein and its tributaries. (Poirier and Charpy.)

gastric and deep circumflex iliac veins and a small pubic vein, corresponding to the pubic branch of the obturator artery. According to Friedreich, it frequently contains one and sometimes two valves.

The **Deep Epigastric Vein** (*v. epigastrica inferior*) (Fig. 471).—Two veins accompany the deep epigastric artery; they usually unite into a single trunk before their termination in the external iliac vein.

The **Deep Circumflex Iliac Vein** (*v. circumflexa ilium profunda*) (Fig. 471).—Two veins accompany the deep circumflex iliac artery. These unite into a single trunk which crosses the external iliac artery just above Poupart's ligament and terminates in the external iliac vein.

The **Hypogastric** or **Internal Iliac Vein** (*v. iliaca interna* or *v. hypogastrica*) (Figs. 464, 471, and 473) is formed by the veins corresponding to all the branches of the internal iliac artery except the umbilical branch. It receives the blood from the exterior of the pelvis by the gluteal, sciatic, internal pudic, and obturator veins, and from the organs in the cavity of the pelvis by the middle hemorrhoidal veins, the superior vesical plexus and the prostatico-vesical plexus in the male, and the superior vesical, inferior vesical, uterine and vaginal plexuses in the female. The vessels forming these plexuses are remarkable for their large size, their frequent anastomoses, and the number of valves which they contain. The internal iliac vein lies at first on the inner side, and then behind the internal iliac artery, and terminates opposite the sacro-iliac articulation by uniting with the external iliac to form the common iliac vein. This vessel has no valves.

The **Internal Pudic Veins** (*vv. pudendæ internæ*) (Fig. 471) have the same course as the internal pudic artery. They receive tributaries corresponding to the branches of the artery, except the tributary corresponding to the dorsal artery of the penis; that is, the deep dorsal vein of the penis, which opens into the prostatico-vesical plexus.

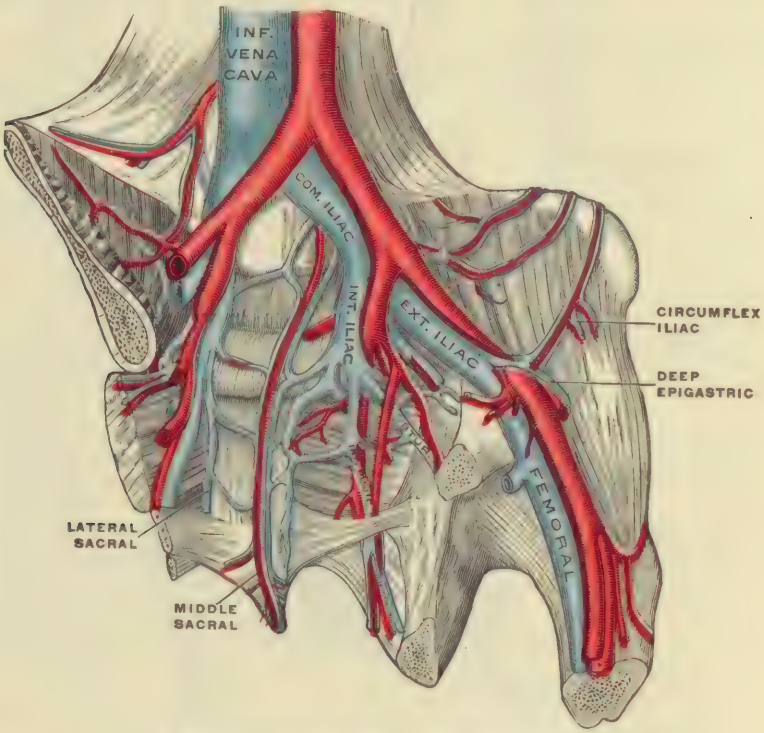

FIG. 471.—The iliac veins. (Poirier and Charpy.)

The **Inferior** or **External Hæmorrhoidal Veins** (Figs. 472 and 473) collect blood from the anus. They pass outward over the External sphincter muscle, unite with numerous subcutaneous veins, and form larger vessels which join the internal pudic veins.

The **Middle Hæmorrhoidal Veins** (Figs. 472 and 473) help to form the hemorrhoidal plexus, perforate the rectal wall, and empty into the internal iliac vein. These veins, by their anastomoses in the hemorrhoidal plexus, establish a communication between the portal and systemic venous systems.

The **Lateral Sacral Veins** (*vv. sacrales laterales*) (Fig. 471) accompany the lateral sacral arteries and terminate in the internal iliac vein.

Surgical Anatomy.—The veins of the hemorrhoidal plexus are apt to become dilated and varicose, and form piles, *hemorrhoids*. This is due to several anatomical reasons: the vessels are contained in very loose, or connective tissue, so that they obtain less support from surrounding structures than most other veins, and are less capable of resisting increased blood pressure: the condition is favored by gravitation, being influenced by the erect posture, either sitting or standing, and by the fact that the superior hemorrhoidal and portal veins have no valves. The veins pass through muscular tissue and are liable to be compressed by its contraction, especially during the act of defecation, and they are affected by every form of portal obstruction.

The **Obturator Vein** (*v. obturatoriæ*) (Figs. 471 and 473) follows the course of the obturator artery, lying below the artery as it passes over the side of the pelvis; this vein empties into the front part of the internal iliac vein.

The **Sciatic Veins** are two in number; they accompany the sciatic artery in the upper part of the back of the thigh, and just before their termination in the internal iliac the two veins unite.

The **Gluteal Veins** (*vv. glutea*) are usually two in number, and return to the internal iliac vein the blood that has been distributed by the gluteal artery and its branches.

FIG. 472.—Scheme of the anastomosis of the veins of the rectum. (Poirier and Charpy.)

The **Superior Vesical Plexus** (Fig. 473) is placed upon the fundus and lateral aspects of the bladder on the external aspect of the muscular coat. It receives vessels from the mucous membrane and from the muscular walls. It empties into the internal pudic vein: in the male it communicates with the prostatico-vesical plexus, and in the female with the inferior vesical plexus.

The **Prostatic** or the **Prostatico-vesical Plexus** (Fig. 473) surrounds the prostate gland and the neck of the bladder. It is contained between the recto-vesical fascia which surrounds the base and sides of the gland and the true capsule of the gland. It communicates with the superior vesical plexus behind and above, and receives the deep dorsal vein of the penis, which enters the pelvis between the subpubic and triangular ligaments. This plexus receives veins from the seminal vesicles and vasa deferentia. On each side one or more vessels pass

from the prostatico-vesical plexus to the internal iliac vein. The veins composing the prostatic plexus are very liable to become varicose, and often contain hard, earthy concretions called **phleboliths.**

The **Inferior Vesical Plexus** exists only in the female, and corresponds to the prostatico-vesical plexus in the male, and surrounds the neck of the bladder and the upper portion of the urethra. It receives the dorsal vein of the clitoris and sends efferents to the internal iliac vein.

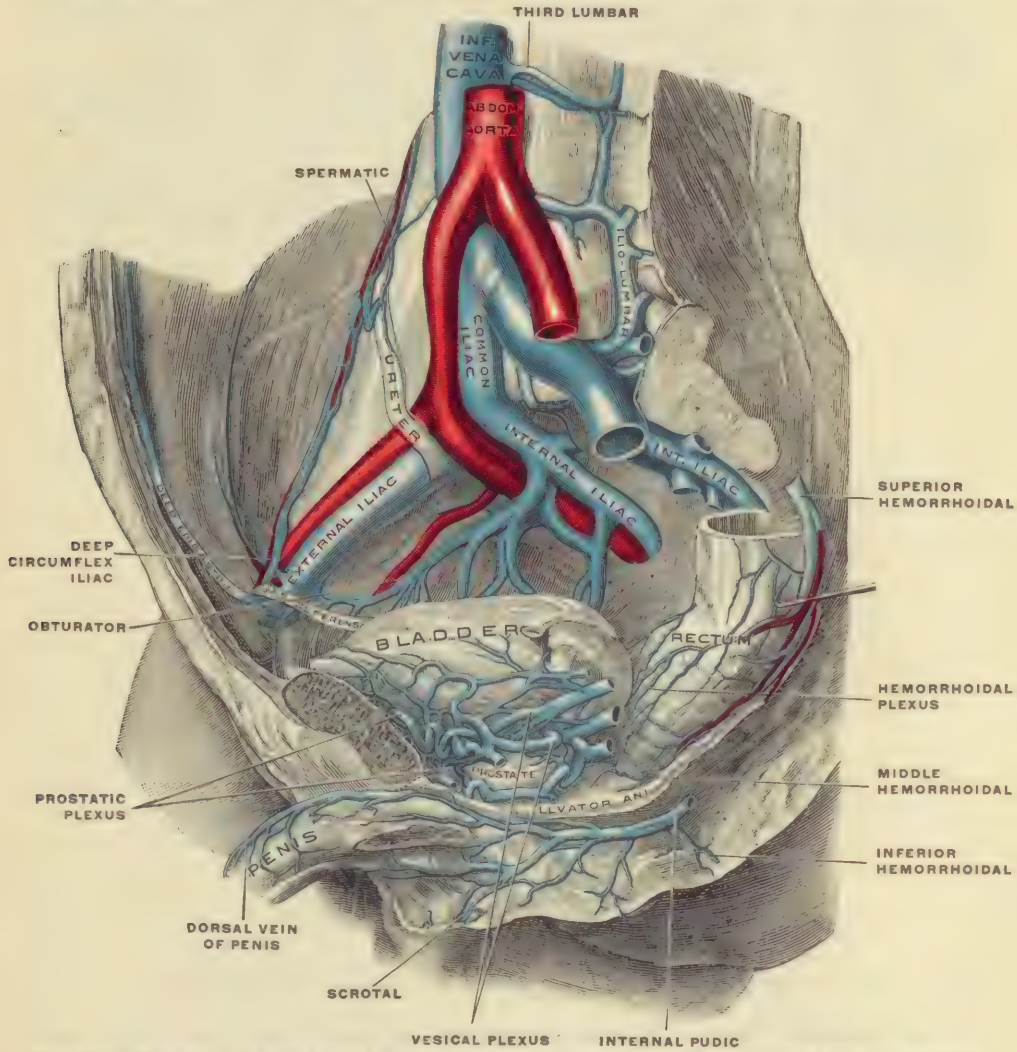

FIG. 473.—The veins of the male pelvis, right half, viewed from the left. The psoas muscle has been removed and the rectum drawn down somewhat to the side. (Spalteholz.)

Surgical Anatomy.—The prostatico-vesical plexus is wounded in the lateral operation of lithotomy, and it is through it that septic matter finds its way into the general circulation after this operation. In enucleating the prostate the gland is shelled out from its capsule of recto-vesical fascia. The veins of the plexus remain attached to the sheath.

The Dorsal Veins of the Penis.—The **Superficial Dorsal Vein of the Penis** (Fig. 474) receives blood from the prepuce and runs backward beneath the skin, and divides into two branches which terminate in the superficial external pudic vein.

The **Deep Dorsal Vein of the Penis** (*v. dorsalis penis*) (Figs. 473 and 474) is a vessel of large size which returns the blood from the body of that organ. At first it con-

sists of two branches, which are contained in the groove on the dorsum of the penis, and it receives numerous superficial veins and veins from the glans penis and the corpus spongiosum. These vessels unite into a single trunk, which passes between the two parts of the suspensory ligament of the penis, and through an aperture between the subpubic ligament and the apex of the triangular ligament, and divides into two branches, which enter the prostatico-vesical plexus. The dorsal vein of the clitoris corresponds in woman to the dorsal vein of the penis in man, and runs into the inferior vesical plexus.

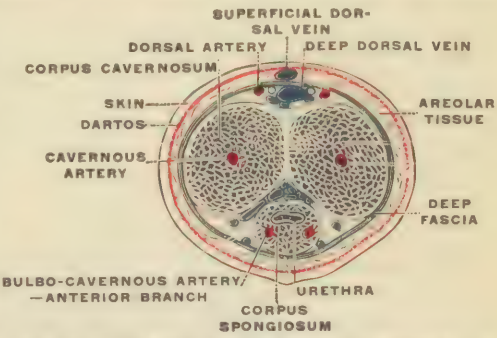

FIG. 474.—The penis in transverse section, showing the blood-vessels. (Testut.)

The Vaginal Plexuses and Veins (Fig. 475).—The vaginal plexuses are placed at the sides of the vagina, being especially developed at the orifice of the canal. They receive vessels from the vaginal walls. The plexuses communicate with the uterine plexus above, with the bulbar veins below, with the inferior vesical plexus in front and with the hemorrhoidal plexus behind. From the upper part of each vaginal plexus comes a **vaginal vein** which passes to the internal iliac.

The **Uterine Plexuses** (Fig. 475) are situated along the sides and superior angles of the uterus, between the layers of the broad ligament. They receive the veins from the uterus, which veins are without valves. During pregnancy these veins

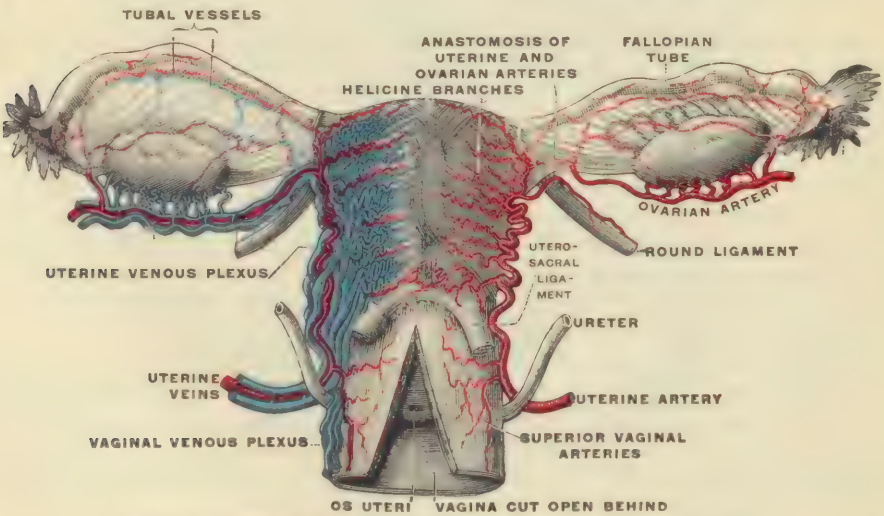

FIG. 475.—Vessels of the uterus and its appendages, rear view. (Testut.)

become large venous canals known as the **uterine sinuses**, and bring blood from the substance of the placenta. These veins join the ovarian above and the vaginal below, and anastomose with each other. They are not tortuous like the artery.

The **Uterine Veins** (*vv. uterinæ*) (Fig. 475) arise from the lower part of the plexus, and there are usually two veins on each side and they are without valves. These veins for the first portion of their course are placed in the base and inner portion of the broad ligament; they then pass back with the uterine artery in a peritoneal fold between the back of the broad ligament and the recto-uterine fold (Cunningham); they then pass upward and enter the internal iliac vein.

The **Common Iliac Vein** (*v. iliaca communis*) (Figs. 464, 471, and 473) on each side is formed by the union of the external and internal iliac veins in front of the sacro-iliac articulation: passing obliquely upward toward the right side, each vein terminates upon the intervertebral substance between the fourth and fifth lumbar vertebræ, where the veins of the two sides unite at an acute angle to form the inferior vena cava. The **right common iliac** (*v. iliaca communis dextra*) is shorter than the left, nearly vertical in its direction, and ascends behind and then to the outer side of its corresponding artery. The **left common iliac** (*v. iliaca communis sinistra*), longer and more oblique in its course, is at first situated on the inner side of the corresponding artery, and then behind the right common iliac. Each common iliac receives the ilio-lumbar, and sometimes the lateral sacral, veins. The left receives, in addition, the middle sacral vein. No valves are found in these veins.

The **Middle Sacral Veins** (Figs. 471 and 472) accompany the corresponding artery along the front of the sacrum, and join to form a single vein (*v. sacralis media*), which terminates in the left common iliac vein; occasionally in the angle of junction of the two iliac veins. The middle sacral veins communicate with the inferior hemorrhoidal.

The **Ilio-lumbar Veins** (*vv. iliolumbales*) receive branches from the iliac fossæ, spinal muscles, and spinal canal. One vein on each side runs with the artery, passes posterior to the psoas muscle, and joins the common iliac vein.

Peculiarities.—The left common iliac vein, instead of joining with the right in its usual position, occasionally ascends on the left side of the aorta as high as the kidney, where, after receiving the left renal vein, it crosses over the aorta, and then joins with the right vein to form the vena cava. In these cases the two common iliacs are connected by a small communicating branch at the spot where they are usually united.[1]

The **Ascending** or **Inferior Vena Cava** (*v. cava inferior*) (Figs. 464 and 471) returns to the heart the blood from all the parts below the Diaphragm. It is formed by the junction of the two common iliac veins on the right side of the intervertebral substance between the fourth and fifth lumbar vertebræ. It passes upward along the front of the spine on the right side of the aorta, and, having reached the under surface of the liver, is contained in a groove on its posterior surface. It then perforates the central tendon of the Diaphragm, enters the pericardium, where it is covered for a very short distance by the serous layer of the pericardium, and terminates in the lower and back part of the right auricle. At its termination in the auricle it is provided with a valve, the **Eustachian valve** (*valvula v. cavæ [inferioris Eustachii]*), which is of large size during fœtal life.

Relations.—*In front*, from below upward, with the mesentery, right spermatic artery, transverse portion of the duodenum, the pancreas, portal vein, and the posterior surface of the liver, which, in most cases, partly and occasionally completely surrounds it; *behind*, with the vertebral column, the right crus of the Diaphragm, the right renal and lumbar arteries, and the right semilunar ganglion; on the *left side*, with the aorta.

Peculiarities. *In Position.*—This vessel is sometimes placed on the left side of the aorta, as high as the left renal veins, after receiving which it crosses over to its usual position on the right side; or it may be placed altogether on the left side of the aorta, as far upward as its termination in the heart: in such cases the abdominal and thoracic viscera, together with the great vessels, are all transposed.

Point of Termination.—Occasionally the inferior vena cava joins the right azygos vein, which is then of large size. In such cases the superior cava receives the whole of the blood from the body before transmitting it to the right auricle, except the blood from the hepatic veins, which passes directly into the right auricle.

[1] See two cases which have been described by Mr. Walsham in the St. Bartholomew's Hospital Reports, vols. xvi. and xvii.—Ed. of 15th English edition.

Tributaries.—It receives in its course the following veins:

Lumbar.	Suprarenal.
Right Spermatic.	Phrenic.
Renal.	Hepatic.

The **Lumbar Veins** (*vv. lumbales*), four in number on each side, collect the blood by dorsal tributaries from the muscles and integument of the loins and by abdominal tributaries from the walls of the abdomen, where they communicate with the epigastric veins. At the spine they receive veins from the spinal plexuses, and then pass forward, round the sides of the bodies of the vertebræ beneath the

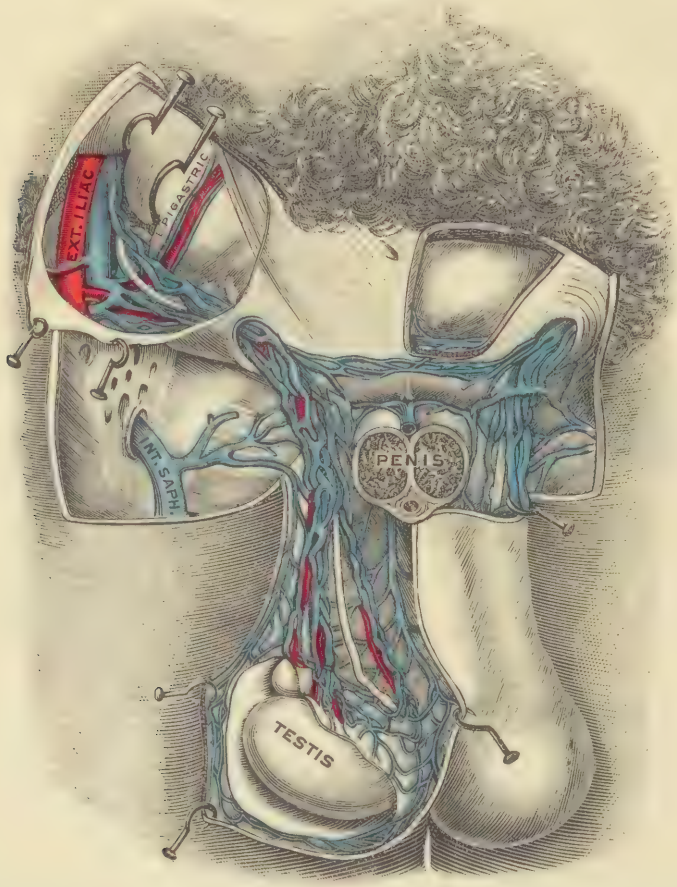

FIG. 476.—Spermatic veins. (Testut.)

Psoas magnus muscle, and terminate at the back part of the inferior cava. The left lumbar veins are longer than the right, and pass behind the aorta. The lumbar veins of a side are connected together by a longitudinal vein which passes in front of the transverse processes of the lumbar vertebræ, and is called the **ascending lumbar vein** (*v. lumbalis ascendens*) (Fig. 464). It forms the most frequent origin of the corresponding vena azygos, and serves to connect the common iliac, iliolumbar, lumbar, and azygos veins of the corresponding side of the body.

The **Spermatic Veins** (*vv. spermaticæ*) (Fig. 476) emerge from the back of the testis, and receive tributaries from the epididymis; they unite and form a convoluted plexus called the **spermatic plexus** (*plexus pampiniformis*), which forms the chief

mass of the cord: the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external abdominal ring they unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the internal abdominal ring, coalesce to form two veins, which ascend on the Psoas muscle behind the peritoneum, lying one on each side of the spermatic artery, and unite to form a single vein, which opens on the right side into the inferior vena cava at an acute angle; on the left side into the left renal vein at a right angle (Fig. 477). The termination of the left spermatic vein

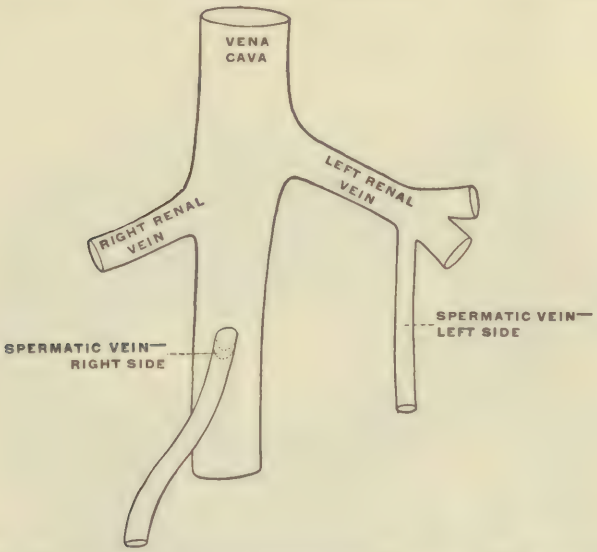

FIG. 477.—Terminations of the right and left spermatic veins. (Poirier and Charpy.)

is called the **emulgent vein**. Professor John H. Brinton pointed out that a valve is usually absent in the emulgent vein (Fig. 478), but regularly present in the right spermatic vein.[1] The left spermatic vein passes behind the sigmoid flexure of the colon, and is thus exposed to pressure from the contents of that bowel.

Surgical Anatomy.—The spermatic veins are very frequently *varicose*, constituting the disease known as *varicocele*. Though it is quite possible that the originating cause of this affection may be a congenital abnormality either in the size or number of the veins of the pampiniform plexus, still it must be admitted that there are many anatomical reasons why these veins should become varicose—viz., the imperfect support afforded to them by the loose tissue of the scrotum; their great length; their vertical course; their dependent position; their plexiform arrangement in the scrotum, with their termination in one small vein in the abdomen; their few and imperfect valves; and the fact that they may be subjected to pressure in their passage through the abdominal wall. The left veins more often become varicose than the right veins, probably, as Brinton suggests, because the right spermatic vein practically always has a valve and opens into the vena cava at an acute angle, whereas the left spermatic vein is not unusually destitute of a valve at its opening and passes into the left renal vein at a right angle.

The **Ovarian Veins** (*vv. ovaricæ*) (Fig. 475) are analogous to the spermatic in the male; they form a plexus near the ovary in the broad ligament and about the Fallopian tube, communicating with the uterine plexus. They terminate in the same way as the spermatic veins in the male. Valves are occasionally found in these veins. These vessels, like the uterine veins, become much enlarged during pregnancy.

[1] See John H. Brinton in the American Journal of the Medical Sciences, and also Handbuch der Topographischen Anatomie, von Joseph Hyrtl. Rivington maintains that a valve is usually found at the orifices of both the right and left spermatic veins. When no valves exist at the opening of the left spermatic vein into the left renal vein, valves are generally present in the left renal vein within a quarter of an inch from the orifice of the spermatic vein. (Journal of Anatomy and Physiology, vol. vii. p. 163).—ED. of 15th English edition.

The **Renal Veins** (*vv. renales*) (Fig. 465) are of large size, and are placed in front of the renal arteries.[1] The left is longer than the right, and passes in front of the aorta, just below the origin of the superior mesenteric artery. It receives the left spermatic, the left inferior, and, generally, the left suprarenal veins. It opens into the vena cava a little higher than the right. The *utero-venous triangle* of Byron Robinson is formed by the ureter, the renal veins, and the ovarian veins.

The **Suprarenal Veins** (*vv. suprarenales*) (Fig. 464) are two in number: that on the right side terminates in the vena cava; that on the left side, in the left renal or in the left phrenic vein.

The **Phrenic Veins** (*vv. phrenicæ*) follow the course of the phrenic arteries. The two **superior phrenic veins** (*vv. phrenicæ superiores*), of small size, accompany the phrenic nerve and comes nervi phrenici artery, and join the internal mammary vein. The two **inferior phrenic veins** (*vv. phrenicæ inferiores*) follow the course of the phrenic arteries, and terminate, the right in the inferior vena cava, the left in the left renal vein.

FIG. 478.—Dissection of the vena cava, emulgent and spermatic veins, showing the right spermatic valve and its accompanying sinus. *c*, vena cava; *e*, emulgent vein; *r*, right spermatic vein; *l*, left spermatic vein; *a*, aperture by which the right spermatic vein empties into the vena cava; *v*, right spermatic valve; *s*, sinus across which the valve is stretched; *f*, termination of the left spermatic vein in the emulgent vein. (John H. Brinton.)

The **Hepatic Veins** (*vv. hepaticæ*) *commence* in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery, **intralobular veins**: these tributaries, gradually uniting into **sublobular veins**; usually form three large hepatic veins, which converge toward the posterior surface of the liver and open into the inferior vena cava, whilst that vessel is situated in the groove at the back part of this organ. Of these three veins, one from the right and another from

[1] The student may observe that all veins above the Diaphragm, which do not lie on the same plane as the arteries which they accompany, lie in front of them, and that all veins below the Diaphragm, which do not lie on the same plane as the arteries which they accompany, lie behind them, except the renal and profunda femoris vein.—ED. of 15th English edition.

the left lobe open obliquely into the inferior vena cava, that from the middle of the organ and lobulus Spigelii having a straight course. The hepatic veins run singly, and are in direct contact with the hepatic tissue. They are destitute of valves.

The Portal System of Veins (Fig. 479).

The portal venous system is composed of four large veins which collect the venous blood from the viscera of digestion (stomach, intestine, and pancreas) and from the spleen. The trunk formed by their union, the **Portal Vein** (*vena portæ*), enters the liver and ramifies throughout its substance after the manner of an artery and ends in capillaries, from which the blood is collected into the hepatic veins, which terminate in the inferior vena cava. The branches of this vein are in all cases single, and destitute of valves.

The veins forming the portal system are—the

Superior Mesenteric. Inferior Mesenteric.
Splenic. Gastric.
Cystic.

The **Superior Mesenteric Vein** (*v. mesenterica superior*) (Fig. 479) returns the blood from the small intestines and from the cæcum and ascending and transverse portions of the colon, corresponding with the distribution of the branches of the superior mesenteric artery. The large trunk formed by the union of these branches ascends along the right side and in front of the corresponding artery, passes in front of the transverse portion of the duodenum, and unites, behind the upper border of the pancreas, with the splenic vein to form the vena portæ. It receives the right gastro-epiploic vein. The **appendicular vein** is a tributary of the superior mesenteric vein.

The **Splenic Vein** (*v. lienalis*) (Fig. 479) *commences* by five or six large branches which return the blood from the substance of the spleen. These, uniting, form a single vessel, which passes from left to right, grooving the upper and back part of the pancreas below the artery, and terminates at its greater end by uniting at a right angle with the superior mesenteric to form the vena portæ. The splenic vein is of large size, and not tortuous like the artery. It receives the vasa brevia from the left extremity of the stomach, the left gastro-epiploic vein, pancreatic branches from the pancreas, the pancreatico-duodenal vein, and the inferior mesenteric vein.

The **Inferior Mesenteric Vein** (*v. mesenterica inferior*) (Fig. 479) returns the blood from the rectum, sigmoid flexure, and descending colon, corresponding with the ramifications of the branches of the inferior mesenteric artery. It lies to the left of the artery, and ascends beneath the peritoneum in the lumbar region; it passes behind the transverse portion of the duodenum and pancreas, and terminates in the splenic vein. Its hemorrhoidal branches, the **superior hæmorrhoidal veins,** inosculate with the middle hemorrhoidal branches of the internal iliac, and thus establish a communication between the portal and the general venous system.[1]

The **Gastric Veins** (*vv. gastricæ*) (Fig. 479) are two in number: one, a small vein, corresponds to the pyloric branch of the hepatic artery; the other, considerably larger, corresponds to the gastric artery. The former, the **pyloric vein** (*v. pylorica*), runs along the lesser curvature of the stomach toward the pyloric end, receives branches from the pylorus and duodenum, and ends in the vena portæ. The latter, the **gastric** or **coronary vein** (*v. coronaria ventriculi*), begins near the pylorus,

[1] Besides this anastomosis between the portal vein and the branches of the vena cava, other anastomoses between the portal and systemic veins are formed by the communication between the gastric veins and the œsophageal veins, which empty themselves into the vena azygos minor; between the left renal vein and the veins of the intestines, especially of the colon and duodenum; between the veins of the round ligament of the liver and the portal veins; and between the superficial branches of the portal veins of the liver and the phrenic veins, as pointed out by Mr. Kiernan. (See Physiological Anatomy, by Todd and Bowman, 1859, vol. ii. p. 348).—Ed. of 15th English edition.

runs along the lesser curvature of the stomach toward the œsophageal opening in the diaphragm, and then passes across the front of the spine from left to right to end in the vena portæ, at a point a little above the junction of the pyloric vein.

The **Cystic Vein** (*v. cystica*) (Fig. 479).—The vena portæ generally receives the cystic vein, although that vessel sometimes terminates in the right branch of the vena portæ.

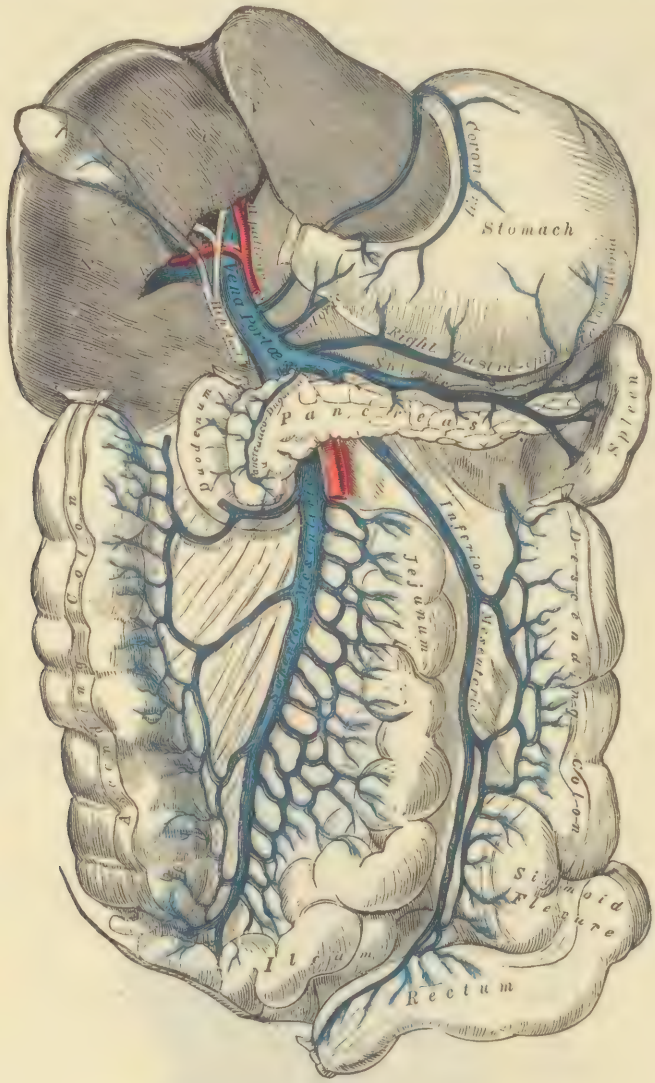

Fig. 479.—Portal vein and its branches.

Note.—In this diagram the right gastro-epiploic vein opens into the splenic vein; generally it empties itself into the superior mesenteric, close to its termination.

The **Portal Vein** (*vena portæ*) (Fig. 479) is formed by the junction of the superior mesenteric and splenic veins, their union taking place in front of the vena cava and behind the upper border of the head of the pancreas. Passing upward through the right border of the lesser omentum to the under surface of the liver, it enters the transverse fissure, where it is somewhat enlarged, forming the *sinus* of the portal vein, and divides into two branches which accompany the ramifications of the hepatic artery and hepatic duct throughout the substance of the liver. Of

these two branches, the right is the larger, but the shorter, of the two. The portal vein is about three or four inches in length, and, whilst contained in the lesser omentum, lies behind and between the common bile-duct and the hepatic artery, the former being to the right, the latter to the left. These structures are accompanied by filaments of the hepatic plexus of nerves and numerous lymphatics, and are surrounded by a quantity of loose areolar tissue, the **capsule of Glisson.**

The portal vein divides, in the substance of the liver, like an artery, and its minute ramifications end in capillaries, from which the blood is carried to the inferior vena cava by the hepatic veins; these veins also collect the blood which has been brought to the liver by the hepatic artery. It will therefore be seen that the blood which is carried to the liver by the portal vein passes through two sets of capillary vessels—viz.: (1) the capillaries in the stomach, intestine, pancreas, and spleen, and (2) the capillaries of the portal vein in the liver.

THE CARDIAC VEINS (Fig. 480).

The veins which return the blood from the substance of the heart are—the

Great Cardiac Vein.	Anterior Cardiac Veins.
Posterior Cardiac Vein.	Right or Small Coronary Vein.
Left Cardiac Veins.	Coronary Sinus.

Venæ Thebesii.

The **Great Cardiac** or **Left Coronary Vein** (*v. cordis magna*) is a vessel of considerable size, which *commences* at the apex of the heart, and ascends along the anterior interventricular groove to the base of the ventricles. It then curves

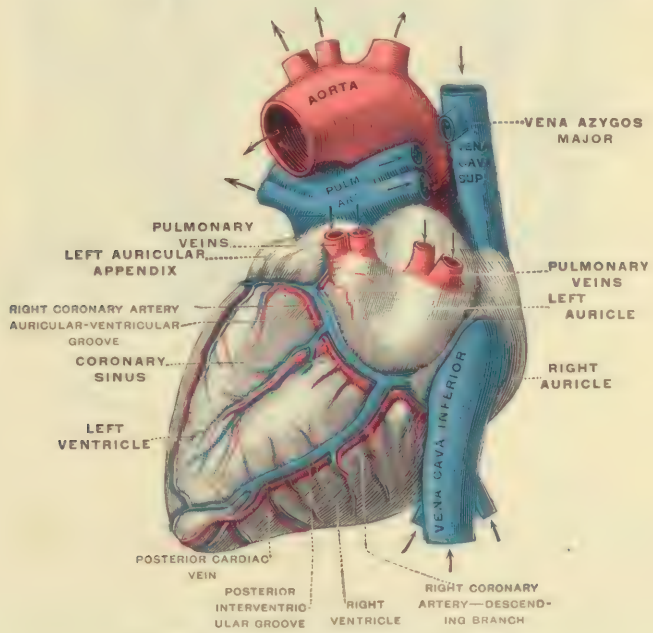

FIG. 480.—Cardiac veins, dorsal view. (Testut.)

to the left side, around the auriculo-ventricular groove, between the left auricle and ventricle, to the back part of the heart, and opens into the left extremity of the coronary sinus, its aperture being guarded by two valves. It receives, in

its course, tributaries from both ventricles, but especially from the left, and also from the left auricle; one of these ascending along the thick margin of the left ventricle is of considerable size, and is called the **left marginal vein**. The vessels joining the great cardiac vein are provided with valves.

The **Posterior** or **Middle Cardiac Vein** (*v. cordis media*) *commences* by small tributaries, at the apex of the heart, communicating with those of the preceding. It ascends along the posterior interventricular groove to the base of the heart, and terminates in the coronary sinus, its orifice being guarded by a valve. It receives veins from the posterior surface of both ventricles.

The **Left Cardiac Vein** (*v. posterior ventriculi sinistri*) receives three or four small vessels, which collect the blood from the posterior surface of the left ventricle. It opens into the lower border of the coronary sinus.

The **Anterior Cardiac Veins** (*vv. cordis anteriores*) are three or four small vessels, which collect the blood from the anterior surface of the right ventricle. One of these, the **vein of Galen**, larger than the rest, runs along the right border of the heart. They open separately into the lower part of the right auricle.

The **Right Cardiac** or **Small Coronary Vein** (*v. cordis parva*) runs along the groove between the right auricle and ventricle, to open into the right extremity of the coronary sinus. It receives blood from the back part of the right auricle and ventricle.

The **Coronary Sinus** (*sinus coronarius*) is that portion of the anterior or great cardiac vein which is situated in the posterior part of the left auriculo-ventricular groove. It is about an inch in length, presents a considerable dilatation, and is covered by the muscular fibres of the left auricle. It receives most of the veins of the heart. Besides those mentioned it receives the **oblique vein of Marshall** (*v. obliqua atrii sinistri*) from the back part of the left auricle, the remnant of the obliterated left Cuvierian duct of the fœtus, described by Mr. Marshall. The great coronary sinus terminates in the right auricle, between the inferior vena cava and the auriculo-ventricular aperture, its orifice being guarded by a semilunar fold of the lining membrane of the heart, the **Thebesian valve**. All the veins joining this vessel, excepting the oblique vein above mentioned, are provided with valves.

The **Venæ Thebesii** (*venæ cordis minimæ*) are numerous minute veins, which return the blood directly from the muscular substance, without entering the venous current. They open by minute orifices, **foramina Thebesii** (*foramina venarum minamarum*), chiefly on the inner surface of the right auricle.

THE LYMPHATIC SYSTEM.

Lymph is obtained from the blood-plasma. From lymph the body cells obtain food, into lymph they discharge their waste materials, and there is a distinct lymphatic circulation, the constituents of the plasma passing into the perivascular lymph-spaces and returning to the heart by way of the lymphatics and certain veins.

The lymphatic system consists of **lymphatic glands**—**large lymph-vessels, small lymph-vessels** (*lymphatic capillaries*), the **perivascular lymph-spaces,** the **lymph canalicular system,** and the **body cavities.** To this system also belong the **lacteal** or **chyliferous vessels.** The lacteals are the lymphatic vessels of the small intestine, and differ in no respect from the lymphatics generally, excepting that during the process of digestion they contain a milk-white fluid, the **chyle,** which passes into the blood through the thoracic duct.

The **lymph canalicular system** is the system of spaces in areolar connective tissue. The spaces are called **lymph-spaces.** In these spaces lie the cells of the tissue. The larger spaces are lined with endothelium, the smaller spaces are not lined with endothelium; they form connections with each other by anastomotic channels and constitute a system of spaces and channels which probably join the lymphatic capillaries.

The **perivascular lymph-spaces** are found around certain blood-vessels. Each space is lined with endothelium, and is joined to other spaces by trabeculæ of connective tissue. The spaces form a system which joins the lymphatic capillaries. Perivascular lymph-spaces have been demonstrated in the Haversian canals and in the subdural space of the pia mater.

The **pleural, pericardial, peritoneal,** and **synovial cavities** belong to the lymphatic system. These cavities are lined by endothelial cells. Beneath the layer of lining cells are lymph-spaces or lymph-vessels, which communicate with the body cavity by means of numerous openings in the lining membrane. These openings are called **stomata.**

Lymph-capillaries are larger than blood-capillaries, but the diameter of a lymph-capillary is different at different points, at some places being much larger than at others. Lymph-capillaries are formed of flattened endothelial cells. In some situations networks of lymphatic capillaries surround the blood-vessels. The lymph-vessels are called the **lymphatics.**

The **lymphatics** have derived their name from the appearance of the fluid contained in their interior (*lympha*, water). They are also called **absorbents,** from the property they possess of absorbing certain materials from the tissues and conveying them into the circulation. Larger lymphatics are called **trunks** and the largest are called **ducts.**

The lymphatics are exceedingly delicate vessels, the coats of which are so transparent that the fluid they contain is readily seen through them, and they appear milky-white; hence the name Asellius gave them of **lacteal veins.** They retain a nearly uniform size, and may be cylindrical in shape, but usually are interrupted at intervals by constrictions which give them a knotted, beaded, or sac-like appearance. These constrictions are due to the presence of valves in the interior of the vessel. Lymphatic vessels do not invariably contain valves. Valves

are absent at the starting points of lymphatics, are absent in lymphatic capillaries, are not numerous in the largest ducts (thoracic duct), and are seldom found in visceral lymphatics. The valves are not found in fixed situations and vary in number. Between the ends of the fingers and the axillary glands Sappey counted from sixty to eighty. "They are arranged in pairs and resemble the aortic semilunar valves."[1] The lymphatic capillaries are composed purely of endothelium, but the collecting trunks possess not only an endothelial inner coat, but an investing elasto-muscular coat. Vessels in the subcutaneous connective tissue are devoid of muscle. Lymphatics have been found in nearly every texture and organ of the body which contains blood-vessels. Such non-vascular structures as cartilage, the nails, cuticle, and hair have none, but with these exceptions it is probable that eventually all parts will be found to be permeated by these vessels.

A larger lymphatic vessel is composed of three coats. The inner coat is composed of elastic tissue lined with endothelium. The middle coat is composed of elastic and muscular fibres. The external coat is composed of connective tissue intermixed with smooth muscular fibres longitudinally or obliquely placed.

The thoracic duct possesses a subendothelial layer of connective tissue like that found in the arteries, and in the middle coat there is a longitudinal layer of connective tissue. The wall of a smaller lymphatic contains no elastic and no muscular tissue, and consists merely of connective tissue lined with endothelium.

The lymphatics are arranged in **superficial** and **deep sets**. The **superficial lymphatics,** on the surface of the body, are placed immediately beneath the integument, accompanying the superficial veins; they join the deep lymphatics in certain situations by perforating the deep fascia. In the interior of the body the lymphatics lie in the submucous areolar tissue throughout the whole length of the gastro-pulmonary and genito-urinary tracts, and in the subserous tissue of the thoracic and abdominal cavities. In the cranial cavity the perivascular sheaths are lymph-spaces. A plexiform network of minute, closed, capillary lymphatics may be found interspersed among the proper elements and blood-vessels of the several tissues, the vessels composing which, as well as the meshes between them, are much larger than those of the capillary blood-vessel plexus. From these networks small collecting vessels emerge, pass to a neighboring gland, and divide into a capillary network in the gland. Numerous small vessels emerge from the gland, which unite into one lymphatic vessel, which joins a larger lymphatic trunk, which empties into a branch of the superior vena cava. The **deep lymphatics,** fewer in number and larger than the superficial, accompany the deep blood-vessels. Their mode of origin is probably similar to that of the superficial vessels. The lymphatics of any part or organ exceed the veins in number and in capacity, but in size they are much smaller. Their anastomoses also, especially those of the large trunks, are more frequent, and are effected by vessels equal in diameter to those which they connect. The continuous trunks retain the same diameter throughout. As the lymphatic vessels approach their point of discharge their number diminishes, but the calibre of the remainder does not increase in proportion.

The gaps in the connective tissue, the larger of which are lined with endothelium, the smaller of which are devoid of endothelial lining, and all of which communicate with the lymphatic capillaries, are known as **lymphatic spaces**. It is asserted by some, but is not proved, that the spaces are continuous with the lymph-capillaries. Some hold that lymph gets from the spaces into the capillaries by means of openings in intervening tissue. The perivascular spaces, the serous cavities, and the ventricles of the brain resemble in function lymphatic structures.

[1] Treatise on Anatomy. By P. Poirier and A. Charpy. Article on the Lymphatics. By G. Delamare, P. Poirier, and B. Cunéo.

The **lymphatic** or **absorbent glands** (*lymphoglandulae*), named also **conglobate glands** and **lymph-nodes**, are small, solid, glandular bodies situated in the course of the lymphatic and lacteal vessels. They vary from microscopic dimensions to the size of an olive, and their color, on section, is of a pinkish-gray tint, excepting the bronchial glands, which in the adult are mottled with black, the hepatic glands, which are yellow, and the splenic glands, which are brown. Each gland has a layer or capsule of cellular tissue investing it, from which prolongations dip into its substance, forming partitions. The lymphatic and lacteal vessels pass through these glands in their passage to the lymphatic ducts. A lymphatic or lacteal vessel, previous to entering a gland, divides into several small branches, which are named **afferent vessels** (*vasa afferentia*). As they enter the gland, the external coat of each becomes continuous with the capsule of the gland, and the vessels becoming much thinned, and consisting only of their internal or endothelial coat, pass into the gland, and branch out upon and in the tissue of the capsule, these branches opening into the **lymph-sinuses** of the gland. There is an extensive sinus beneath the capsule; from this **subcapsular sinus** numerous branches run inward to a **central sinus**. From both sinuses fine branches proceed to form a plexus, the vessels of which unite to form a single **efferent vessel** (*vas efferens*), which, on emerging from the gland, is again invested with an external coat from the gland capsule. The lymph-glands are filters through which lymph and chyle flow. Carcinoma cells are caught in them, and the dissemination of the disease is retarded. In the glands are masses of newly formed leukocytes which attack any bacteria in the lymph or chyle.

FIG. 481. — A lymph-node with its afferent and efferent vessels. (Testut.)

The size of the lymphatic glands decreases as age advances, and in very old individuals many glands actually disappear. It is impossible to estimate the number of macroscopic glands. Sappey estimated the number to be from 600 to 700. Glands are embedded in fat and are distinctly movable. Some of them are **superficial** (above the deep fascia); others are **deep** (below the deep fascia). Occasionally a gland exists alone, but, as a rule, they are assembled in communities or chains of from eight to twelve, or even more. They are usually arranged around vessels, and often are upon vessels. The glands have a plentiful blood-supply, and contain not only vascular nerves, but definite nerve-plexuses. Besides the glands, the body contains numerous lymphoid areas, which, in structure and function, are allied to lymph-glands (tonsils, Peyer's patches, etc.).

Surgical Anatomy. —In an operation for *cancer* it is not sufficient to cut wide of the growth and remove it; it is imperatively necessary to remove the lymphatic glands which receive lymph from the diseased area, and also, when possible, the lymphatic vessels between the cancer and the glands. Glands are diseased very early in cancer, long before they are palpably enlarged, and are usually infected by emboli of cancer cells. The rule is in any cancer, however recent, to regard the associated glands as diseased, whether enlarged or not, and to thoroughly remove them, if possible, in one piece, with the intervening lymph-vessels and the area of primary malignant growth.

THE THORACIC DUCT AND THE RIGHT LYMPHATIC DUCT.

The thoracic duct or the *left lymphatic* duct (*ductus thoracicus*) (Figs. 482 and 483) conveys the great mass of lymph and chyle into the blood. It is the common trunk of all the lymphatic vessels of the body below the Diaphragm, and usually, but not always, also receives the lymph from the left side of the body above the Diaphragm. It does not drain the right side of the head and neck, the right upper extremity, the right lung, right side of the heart, and the convex surface of the liver. It partly drains the right chest wall. It varies in length from fifteen to eighteen inches in the adult, and extends from the second lumbar vertebra to the root of the neck. It commences in the abdomen by a triangular dilatation, the **receptaculum chyli** or the **reservoir** or **cistern of Pecquet** (*cisterna chyli*), which is situated upon the front of the bodies of the first and of the second lumbar vertebræ, to the right side and behind the aorta, by the side of the right crus of the Diaphragm. The receptaculum is absent in some individuals. The thoracic duct ascends into the thorax through the aortic opening in the Diaphragm, lying to the right of the aorta, and is placed in the posterior mediastinum in front of the vertebral column, lying between the aorta and vena azygos major. Opposite the fourth dorsal vertebra it inclines toward the left side, and ascends behind the arch of the aorta on the left side of the œsophagus, and behind the first portion of the left subclavian artery, to the upper orifice of the thorax. Opposite the seventh cervical vertebra it turns outward and then curves downward over the subclavian artery and in front of the Scalenus anticus muscle, so as to form an arch, and terminates in the left subclavian vein at its angle of junction with the left internal jugular vein. It usually opens at the apex of the angle in the superior and outer surface, but may open on the posterior surface. Sometimes it terminates by two branches. Figs. 482

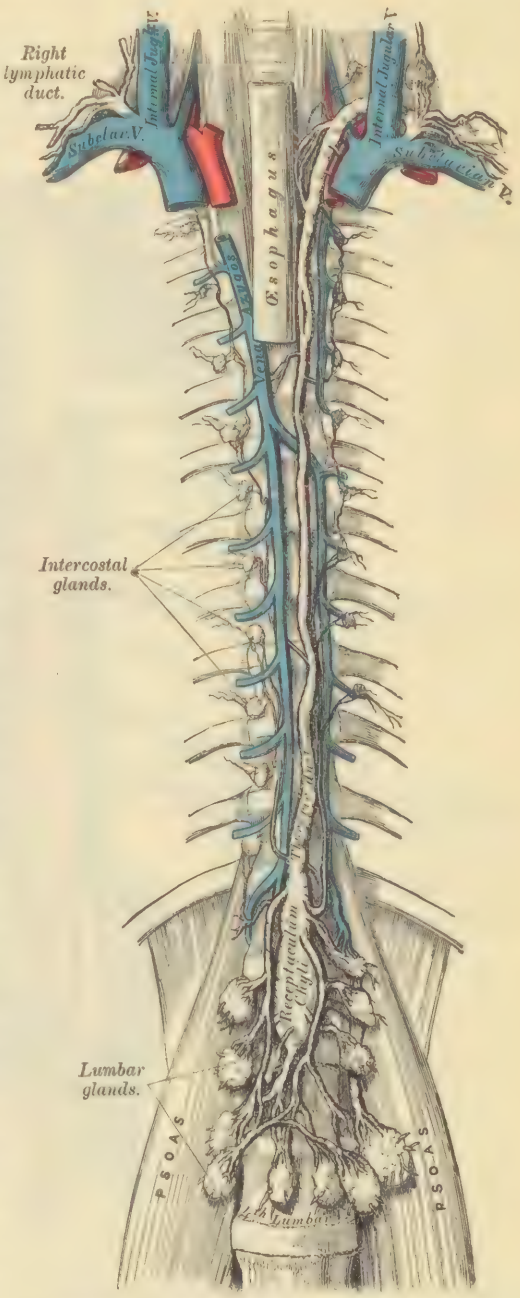

FIG. 482.—The thoracic and right lymphatic ducts.

and 485 show the termination of the thoracic duct. The thoracic duct, at its commencement, is about equal in diameter to that of a goose-quill, diminishes considerably in its calibre in the middle of the thorax, and is again dilated just before its termination, the **ampulla**. It is generally flexuous in its

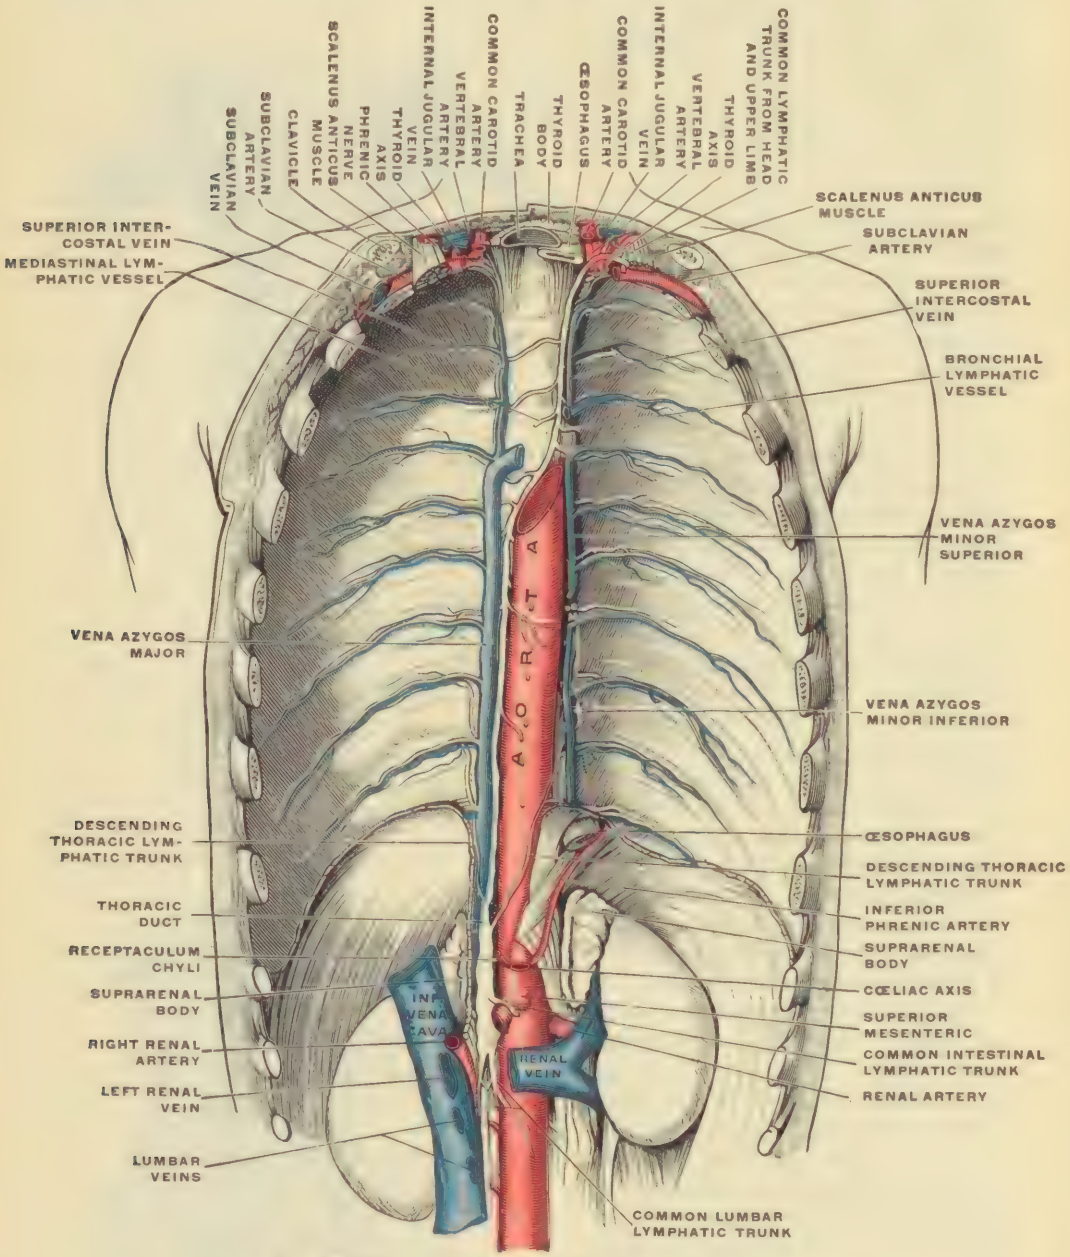

FIG. 483.—Thoracic duct and its tributaries. (Cunningham.)

course, the older the person the greater the flexuosity, and it is constricted at intervals so as to present a varicose appearance. The thoracic duct not infrequently divides in the middle of its course into two branches of unequal size, which soon reunite, or divides into several branches, which form a plexiform interlacement. It occasionally divides, at its upper part, into two branches, of which the

one on the left side terminates in the usual manner, while that on the right opens into the right subclavian vein, in connection with the right lymphatic duct. The thoracic duct has several valves throughout its whole course, but they are more numerous in the upper than in the lower part, and the lower valves are not competent; at its termination it is provided with a pair of competent valves, the free borders of which are turned toward the vein, so as to prevent the passage of venous blood into the duct.

The **common intestinal trunk** (*truncus intestinalis*) (Figs. 483, 484, and 511) empties into the receptaculum and brings lymph from the small intestine (lacteals), the stomach, the pancreas, and the spleen.

Radicals of Origin and Tributaries. In most individuals the **juxta-aortic glands** which are placed on each side of the aorta send a vessel upward and inward, which unite to form the thoracic duct. The right vessel is known as the **truncus lymphaticus lumbalis dextra.** The left vessel is known as the **truncus lymphaticus lumbalis sinistra.** A vessel from the glands in front of (*pre-aortic*) and back (*retro-aortic*) of the aorta empties into each of the above-named vessels. In some cases a large vessel forms from the glands in front of the aorta and helps form the duct. The receptaculum chyli receives the common intestinal lymphatic trunk, which conveys lymph from the small intestine, stomach, spleen, pancreas, and a portion of the liver.

FIG. 484.—Modes of origin of the thoracic duct. *a*, thoracic duct; *a'*, receptaculum chyli; *b*, common trunk of the efferents of the right juxta-aortic glands; *c*, common trunk of the efferents of the left juxta-aortic glands; *d*, one of these efferents passing through the left pillar of the diaphragm; *e*, right juxta-aortic gland; *f*, left juxta-aortic gland; *h*, retro-aortic gland; *i*, common trunk of the pre-aortic glands (truncus intestinalis); *j*, collecting trunks of the intercostal lymphatics, which reach the receptaculum chyli by taking the downward course. (Poirier and Charpy.)

The branches of the left lymphatic duct are (Fig. 483): 1. A descending trunk, which collects lymph from the posterior intercostal glands of the seven lower intercostal spaces. 2. A trunk is formed by vessels coming from the superior juxta-aortic glands beneath the Diaphragm. 3. The lymphatic vessels form the upper five intercostal spaces. 4. The lymphatic vessels form the posterior mediastinal glands and retrosternal glands. 5. The **left jugular trunk** (*truncus jugularis*), although this may open directly into the junction of the subclavian and internal jugular veins. 6. In rare cases the thoracic duct receives near its termination the **left subclavian trunk** (*truncus subclavius*) and a broncho-mediastinal trunk. As a rule, however, the two last-mentioned trunks empty into the jugulo-subclavian junction separately or as one duct.

The thoracic duct receives the lymph from the extremities, the deep portion of the abdominal wall and of the pelvic wall, the pelvic viscera, the kidneys and suprarenal capsules, the large intestine, the small intestine, the walls of the thoracic cavity, the under surface and anterior portion of the liver, the stomach,

the spleen, the pancreas, the sternal and intercostal glands, the left lung, left side of the heart, trachea, and œsophagus, and often, just before its termination, the lymphatics of the left side of the head and neck, and of the left upper extremity.

Structure.—The thoracic duct is composed of three coats, which differ in some respects from those of the lymphatic vessels. The **internal coat** consists of a single layer of flattened endothelial cells; of a subendothelial layer, similar to that found in the arteries; and an elastic fibrous coat, the fibres of which run in a longitudinal direction. Each endothelial cell is shaped like a lance-head and has serrated

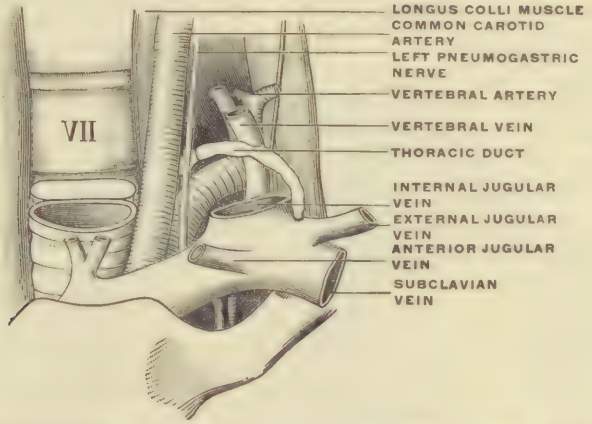

FIG. 485.—The bend of the thoracic duct at its termination in the subclavian vein. (Poirier and Charpy.)

borders. The **middle coat** consists of a longitudinal layer of white connective tissue with elastic fibres, external to which are several laminæ of muscular tissue, the fibres of which are for the most part disposed transversely, but some are oblique or longitudinal. The muscular fibres are intermixed with elastic fibres. The **external coat** is composed of areolar tissue, with elastic fibres and isolated fasciculi of muscular fibres.

The Right Lymphatic Duct (Ductus Lymphaticus Dexter)

(Figs. 482, 486, 487, 511).

A right lymphatic duct is frequently present. It is a short trunk, about half an inch in length and a line or a line and a half in diameter. It is formed by the union

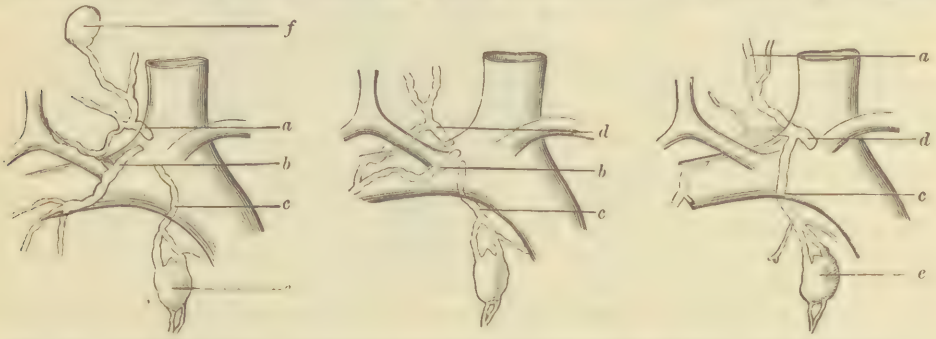

FIG. 486.—Terminal collecting trunks of the right half of the supra-diaphragmatic portion of the body. *a*, jugular trunk; *b*, subclavian trunk; *c*, broncho-mediastinal trunk; *d*, right lymphatic trunk; *e*, gland of the internal mammary chain; *f*, gland of the deep cervical chain. (Poirier and Charpy.)

of the right jugular, right broncho-mediastinal, and right subclavian trunks. Often on the right side the jugular, subclavian, and broncho-mediastinal trunks

are double. Usually they open into the junction of the internal jugular and subclavian veins separately. Sometimes they unite and open by one duct, and that is the right lymphatic duct. The orifice of the right lymphatic duct is guarded by two semilunar valves, which prevent the passage of venous blood into the duct.

Tributaries.—The right lymphatic duct, if present, receives lymph from the right side of the head and neck, the right upper extremity, the right side of the thorax, the right lung, and the right side of the heart, and from part of the convex surface of the liver.

LYMPHATICS OF THE CRANIAL REGION, FACE, AND NECK.

It is customary to divide the lymphatics of this region into **intracranial** and **extracranial lymphatics.** The statement is made by Poirier and Cunéo[1] that the

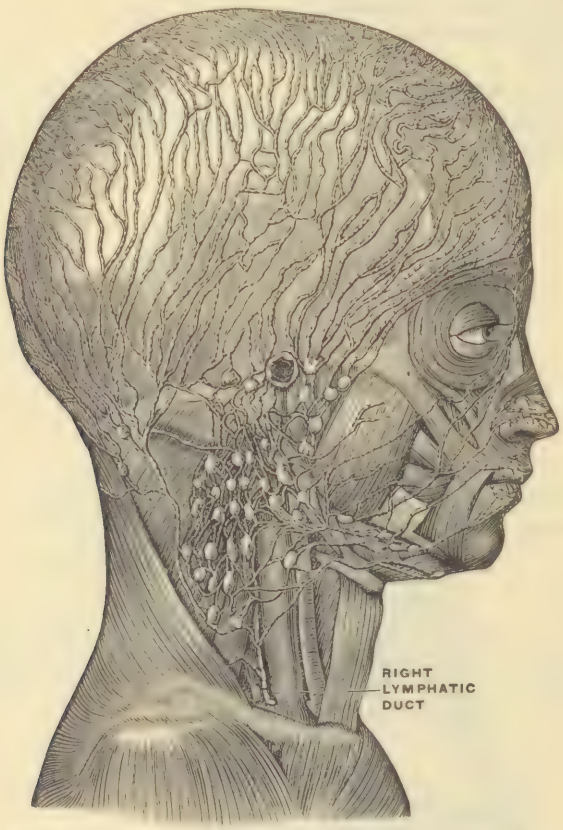

FIG. 487.—The lymphatics of the head and neck. (Sappey.)

brain and its membranes are without lymphatics. They state that there are spaces in the nervous centres comparable to lymphatic channels, but which are not truly lymphatic vessels and which are regarded by most as independent of the lymphatic system. Other writers[2] believe that there are **cerebral** and **meningeal lymphatic vessels.** It is highly probable that the perivascular spaces around the cerebral arteries are the beginning of a cerebral lymph system, and that these peri-

[1] Article on the Lymphatics in the Treatise on Human Anatomy. By Poirier and Charpy.
[2] Cunningham's Text-book of Anatomy.

vascular lymph-channels pass out of the cranium with the arteries and the internal jugular vein and terminate in the superior deep cervical glands. It is also probable that lymph-spaces surround the meningeal blood-vessels and terminate in the superior deep cervical and the internal maxillary glands.

The **extracranial lymphatics** are divided into **superficial** and **deep**, and the two systems freely communicate. All of these vessels run into glands about the head and neck. The superficial lymphatics take origin in the subcutaneous tissue and superficial muscles. The deep vessels arise in the orbit, mouth, nose, pharynx, œsophagus, tongue, larynx, and the muscular, ligamentous, and osseous structures.

The Lymphatic Glands of the Head and Face.

The lymphatic glands of the head and face are as follows:

1. The Occipital.
2. The Posterior Auricular.
3. The Parotid and Subparotid.
4. The Internal Maxillary.
5. The Facial.

The Occipital or Suboccipital Glands (*lymphoglandulae occipitales*) (Figs. 488 and 493).—There are only two or three of these glands on each side. They are situated beneath the deep fascia, a little in front of the anterior edge of the

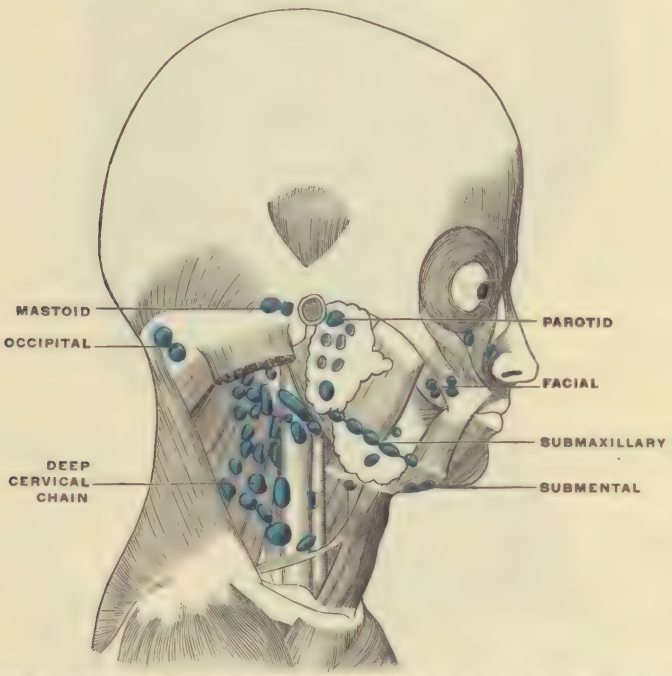

FIG. 488.—General arrangement of the lymphatic gland groups of the head and neck. (Poirier and Charpy.)

Trapezius muscle, near to but seldom upon the insertion of the Complexus muscle. They receive lymph from the occipital region of the scalp and from them it is sent to the upper deep cervical glands.

The Posterior Auricular Retro-auricular or Mastoid Glands (*lymphoglandulae auriculares posteriores*) (Figs. 488, 492, and 493).—There are two of these on each side. They are situated just beneath the lower margin of the Retrahens aurem muscle. They receive lymph from the parietal lymph-vessels, "from the internal

surface of the auricle, with the exception of the lobule, and from the posterior surface of the external auditory meatus."[1] The lymph-vessels from these glands empty into the upper deep cervical glands.

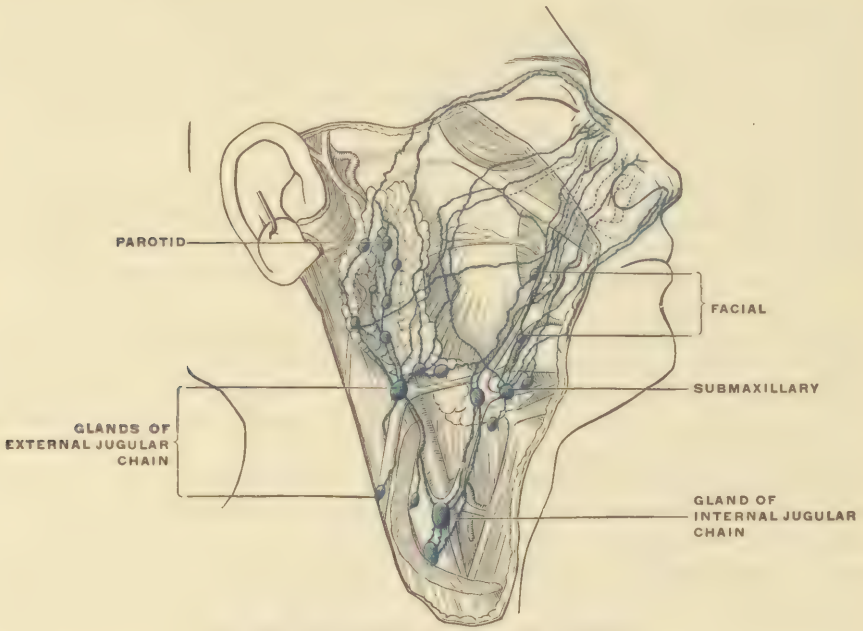

FIG. 489.—The lymphatics of the neck. (Küttner.)

The **Parotid Lymph-glands** (*lymphoglandulae auriculares anteriores*) (Figs. 488, 489, and 493) are divided into two groups, the superficial and the deep.

The Superficial Parotid or Pre-auricular Lymph-glands.—The superficial parotid lymph-glands are not the subcutaneous lymph-glands occasionally but very rarely

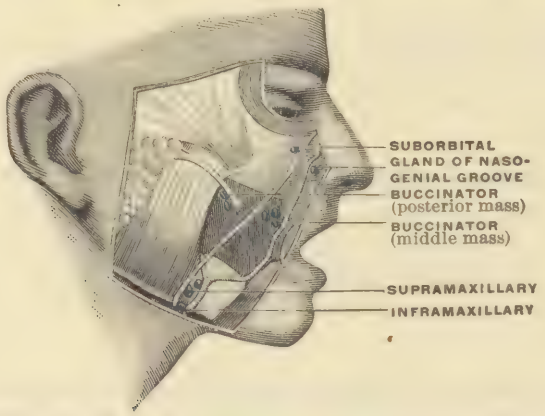

FIG. 490.—Facial glands. (Poirier and Charpy.)

found in this region, and which have been described by Richet, but are lymph-nodes situated between the parotid fascia and the parotid salivary gland. There may be three glands, two glands, or only one gland.

[1] The Lymphatics. By G. Delamare, P. Poirier, and B. Cunéo. English edition, translated and edited by Cecil H. Leaf.

The Deep Parotid Lymph-glands.—The deep parotid lymph-glands are situated **within the parotid salivary gland. There are from fifteen to twenty of the deep glands.** The parotid glands receive lymph from the eyelids, eyebrows, the root of the nose, upper portion of the cheek, frontal portion of the scalp, temporal portion of the scalp, from the outer surface of the pinna, from the external auditory meatus, from the tympanum, and possibly from the mucous membrane of the nose, the posterior alveolar region of the superior maxillary bone, and the soft palate. Lymphatics pass from the superficial parotid glands into the superficial cervical and the upper deep cervical glands. Lymphatics pass from the deep parotid glands into the upper deep cervical glands.

The Subparotid Glands (*lymphoglandulae parotidae*).—The subparotid glands lie between the parotid salivary gland and the pharynx, and they are close to the internal carotid artery and the internal jugular vein. They receive lymph from the nasal fossæ, naso-pharynx, and Eustachian tube, and send vessels to the upper deep cervical glands.

The Internal Maxillary or Zygomatic Glands (*lymphoglandulae faciales profundae*) (Fig. 493).—The internal maxillary glands lie in the course of the internal maxillary artery in the anterior pharyngeal wall. They receive vessels from the naso-pharynx, palate, zygomatic fossa, temporal fossa, and orbit. From them vessels go to the upper deep cervical glands.

The Facial Glands or Genial Glands (*lymphoglandulae faciales*) (Figs. 488, 489, and 490).—The facial glands lie in three groups in the course of the lymphatic vessels which are passing to the submaxillary glands. According to Poirier and Cunéo the **supramaxillary** or **inferior group** (Fig. 490) lies upon the outer surface of the mandible, at the anterior margin of the Masseter muscle, and beneath the Platysma myoides. There may be only one or two glands in this group, but often there are ten or twelve. These glands lie about the facial artery and vein and are not constantly present. In many cases a salivary gland, the **inframaxillary** (Fig. 490), is interposed between the supramaxillary and submaxillary glands. The **buccinator, buccal,** or **middle group** (Figs. 490 and 493) is present in about one-third of the subjects and lies upon the outer surface of the Buccinator muscle external to the buccal fascia. Some of these glands are situated in the region where Steno's duct perforates the Buccinator muscle. Others are beneath the posterior fibres of the Zygomaticus major muscle.

The **superior group** of facial glands (Fig. 490) includes a malar gland, a suborbital gland, and a gland in the naso-genial groove.[1] An **anterior gland** is sometimes found, subcutaneous, on the outer surface of the Orbicularis oris muscle, the **commissural gland.**

The Lymphatic Vessels of the Cranial Region (Figs. 487, 493).

The lymphatic vessels of the cranial subcutaneous tissues are divided into anterior, lateral, and posterior. The **anterior** or **frontal** terminate in the parotid lymph-glands. The **lateral** or **parietal** terminate in the parotid and mastoid lymph-glands. The **posterior** or **occipital** terminate in the sterno-mastoid and occipital glands.

The Lymphatic Vessels of the Face, the Interior of the Nose, Tongue, Floor of the Mouth, Pharynx, Larynx, and Thyroid Gland (Figs. 487, 489, 490, 491, 492, 494).

The lymphatic vessels of the face are more numerous than those of the cranial region, and commence over its entire surface. Those from the **frontal region** accompany the frontal vessels; they then pass obliquely across the face, running

[1] Article on the Lymphatics in the Treatise on Human Anatomy. By P. Poirier and B. Cunéo.

with the facial vein, pass through the glands on the buccal surface of the Buccinator muscle, and join the submaxillary lymphatic glands. The submaxillary lymph glands receive the lymphatic vessels from the **lips**, and are often found enlarged in cases of malignant disease of those parts.

The lymphatics of the **orbit** and of the **temporal** and **zygomatic fossæ** run with the branches of the internal maxillary artery to the maxillary glands, and afterward to the deep cervical glands.

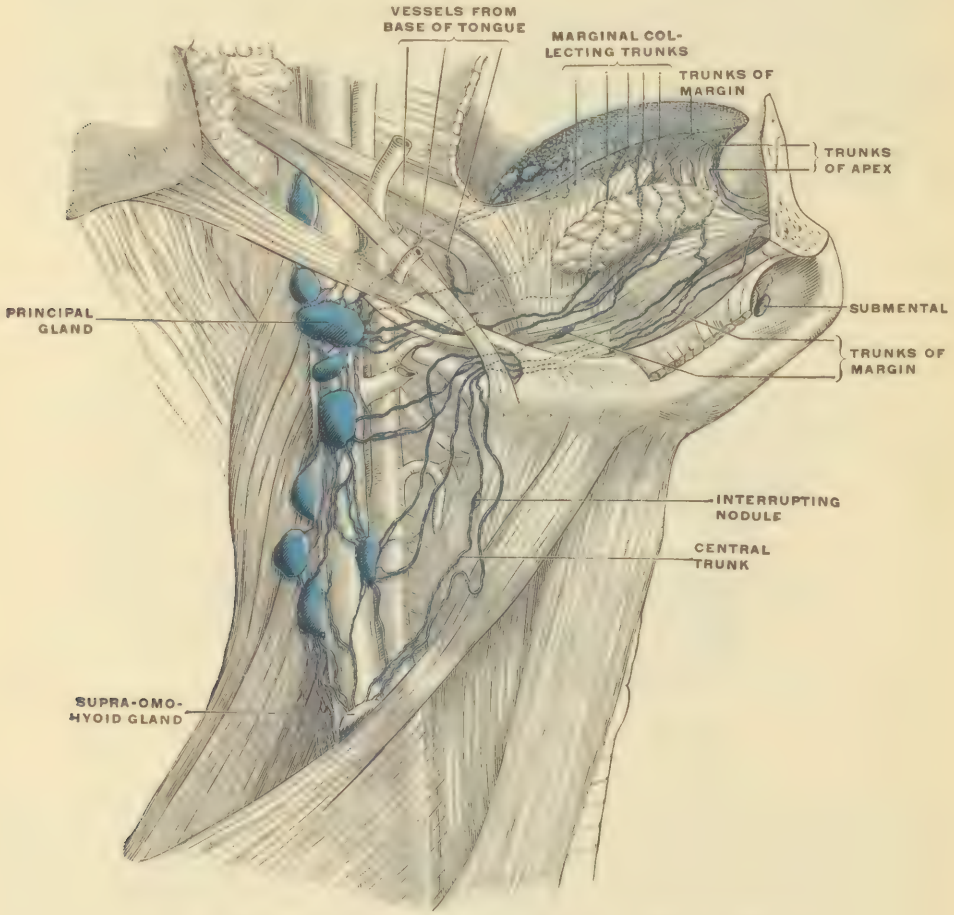

FIG. 491.—The lymphatics of the tongue; anterior view. (Poirier and Charpy.)

The lymphatics of the **nose** can be injected from the subdural and subarachnoid spaces. They terminate in the retro-pharyngeal and suprahyoid glands. The lymphatics of the **tongue** (Fig. 491) chiefly accompany the ranine vein first to the lingual glands and from these to the deep cervical glands. The lymphatics from the **anterior part of the tongue** and **floor of the mouth** pierce the Mylo-hyoid muscles and so reach the submaxillary lymph-glands (p. 1093). From the **upper part of the pharynx** the lymphatics pass to the retro-pharyngeal glands; from the **lower part of the pharynx** to the deep cervical glands. From the **larynx** two sets of vessels arise: an *upper*, piercing the thyro-hyoid membrane and joining the upper set of deep cervical glands; and a *lower*, perforating the crico-thyroid membrane to join the lower set of deep cervical glands. The lymphatics of the **thyroid gland** accompany the superior and inferior thyroid arteries, and open partly into the upper and partly into the lower set of deep cervical glands.

The Lymphatic Glands of the Neck.

The lymphatic glands of the neck are:

1. The Superficial Cervical, including the external jugular and the superficial anterior cervical.
2. The Submaxillary.
3. The Submental.
4. The Retro-pharyngeal.
5. The Deep Cervical, including the anterior deep cervical.

The Superficial Cervical Glands (*lymphoglandulae cervicales superficiales*) (Figs. 492 and 493).—The superficial cervical glands are composed of two groups, the **external jugular** and the **superficial anterior cervical glands.**

The External Jugular Glands (Figs. 489 and 492).—The external jugular glands are superficial to the Sterno-cleido-mastoid muscle. They are four to six in

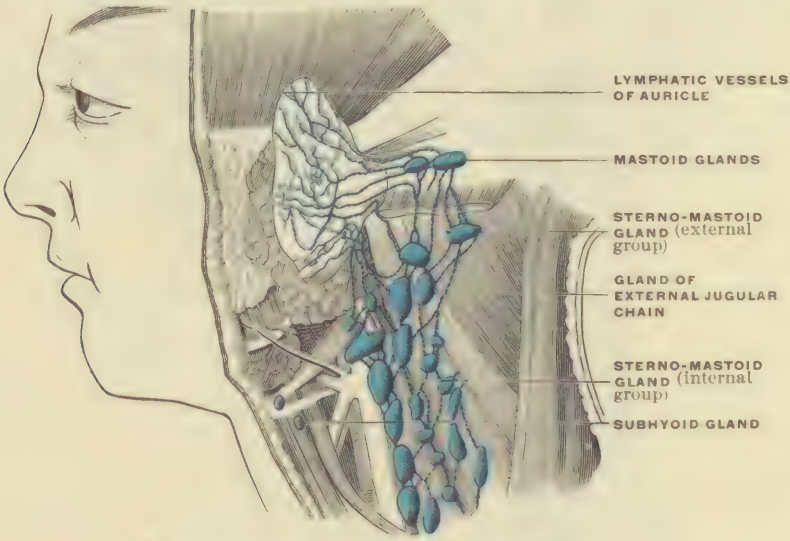

FIG. 492.—Deep cervical chain. (Poirier and Charpy.)

number and lie along the external jugular vein upon the outer surface of the deep cervical fascia, each gland occupying a depression in the fascia. The sterno-cleido-mastoid muscle is beneath them. They are usually gathered in a group a little below the parotid gland, but sometimes extend to the middle of the vein. They receive vessels from the occipital, the posterior auricular, the parotid, and the submaxillary lymph-glands, from the auricle, and from the skin and subcutaneous structures of the neck. From them lymphatic vessels pass to the upper deep cervical and to the lower deep cervical glands.

The Superficial Anterior Cervical Glands.—The superficial anterior cervical glands lie along the anterior jugular vein and from them vessels pass to the deep cervical glands.

The Submaxillary or Lateral Suprahyoid Glands (*lymphoglandulae submaxillares*) (Figs. 488, 489, and 493).—The submaxillary glands are in the submaxillary triangle beneath the deep fascia. They number three to six; are embedded in the superficial surface of the sheath of the submaxillary gland, but are not found within the sheath. Occasionally one or two are found in the deep portion of the sheath toward the floor of the mouth. The **middle gland of Stahr** is situated at the point where the submaxillary group is crossed by the facial artery. This is the largest gland of the group. The submaxillary glands receive vessels from the

"nose, the cheek, the upper lip, and the external part of the lower lip, almost the whole of the gums, and the anterior third of the lateral border of the tongue."[1] They also obtain lymph from the floor of the mouth and from the sublingual and submaxillary salivary glands.[2] They send vessels to the jugular and to the upper deep cervical glands.

The Submental or Median Suprahyoid Glands (Figs. 488, 491, and 493).—There are usually two glands situated between the anterior bellies of the two digastric muscles and upon the Mylo-hyoid muscle. They receive lymph from the cutaneous surface of the chin, from the cutaneous and mucous surfaces of the

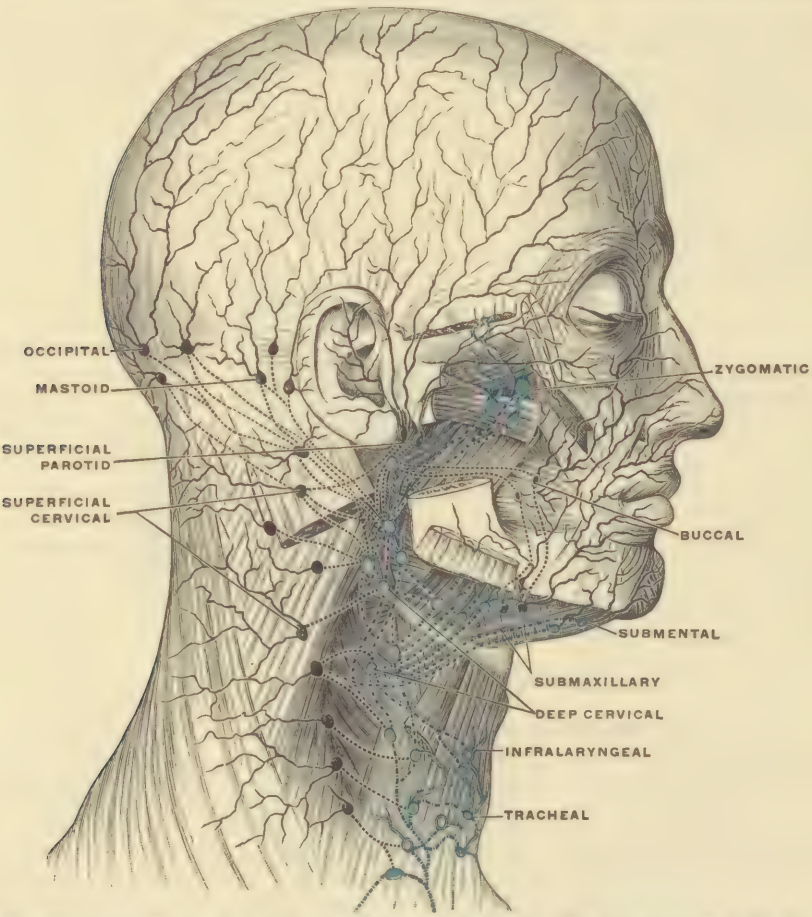

FIG. 493.—The lymphatic glands and vessels of the head and neck. The deep lymphatics are colored blue and the superficial black. In each set the afferent vessels are shown in continuous lines; the efferent and interglandular vessels are represented by dotted lines. (Cunningham.)

central portion of the lower lip, from the central portion of the gums, from the floor of the mouth, and from the tip of the tongue. They send some vessels to the submaxillary lymph-glands, and frequently a gland is interposed on the anterior belly of the Digastric muscle. They send other vessels to the upper deep cervical glands.

The Retro-pharyngeal or Post-pharyngeal Glands (Fig. 494).—The retro-pharyngeal glands are placed between the upper lateral portion of the posterior part of the pharynx and the first two cervical vertebræ. Leaf tells us that, as a

[1] The Lymphatics. By G. Delamare, P. Poirier, and B. Cunéo. Translated and edited by Cecil H. Leaf.
[2] Cunningham's Text-book of Anatomy.

rule, there is but one gland on each side, though two may be present. The retro-pharyngeal glands lie upon the Rectus capitis anticus major muscle, which separates them from the vertebræ. They receive vessels from the muscles and fascia in front of the vertebræ, from the nasal fossæ and accessory cavities, from the naso-pharynx and Eustachian tube, and possibly from the cavity of the tympanum. They send vessels to the upper deep cervical glands.

The Deep Cervical, Carotid, or Sterno-mastoid Glands (*lymphoglandulae cervicales profundae*) (Figs. 488, 489, 491, 492, 493, and 494).—The deep cervical glands are divided into the **upper deep cervical** and the **lower deep cervical,** and are associated with certain accessory glands, including the **jugular** and **superficial anterior cervical,** which have been discussed under the head of superficial cervical glands; and the **anterior deep cervical** and the **recurrent glands,** which have not yet been studied. The deep cervical chain extends from the apex of the mastoid process of the temporal bone to the junction of the internal jugular and subclavian veins.

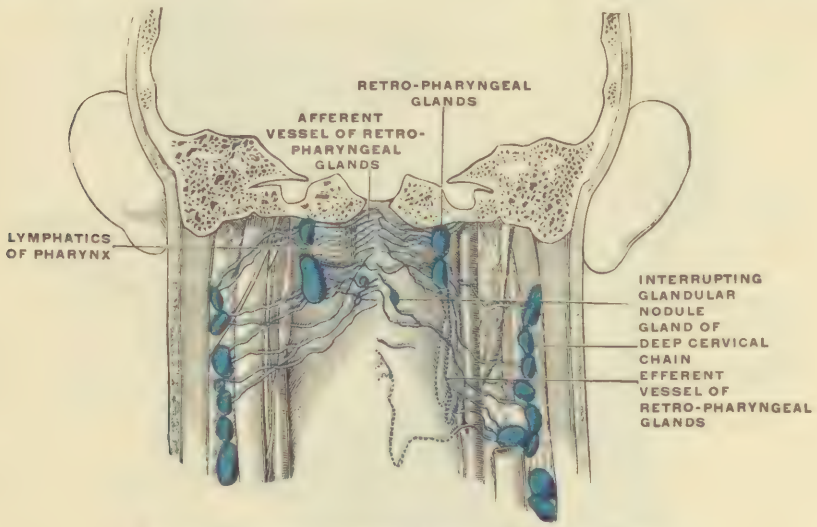

FIG. 494.—The retro-pharyngeal glands. (Poirier and Charpy.)

The Upper Deep Cervical or Substerno-mastoid Glands (*lymphoglandulae cervicales profundae superiores*).—The upper deep cervical glands extend from the tip of the mastoid process of the temporal bone to about the region where the common carotid artery is crossed by the Omo-hyoid muscle. One group, the **external group,** is placed external and posterior to the internal jugular vein. The glands are small and numerous, are embedded in the fatty tissue about the nerves from the deep cervical plexus, and at the posterior margin of the Sterno-cleido-mastoid muscle constitute a continuous mass passing to join the subclavian glands. Another group, known as the **internal group** or the **internal jugular glands,** lie directly upon or close by the outer border of the internal jugular vein. This group forms a chain along the internal jugular vein, and the glands are of larger size than those of the external group. Some glands of this group are beneath the vein. The glands of the internal jugular group communicate freely with each other and with the external group. The **external group** receives lymph-vessels from the posterior auricular, occipital, and external jugular glands, from the occipital region of the scalp, from the auricle, and from the skin, subcutaneous tissue, and muscles of the upper portion of the neck.[1] The **internal group** receives lymph-vessels from the retro-pharyngeal, parotid, subparotid, sub-

[1] The Lymphatics. By G. Delamare, P. Poirier, and B. Cunéo. Translated and edited by Cecil H. Leaf.

maxillary, and submental glands, the anterior cervical glands (superficial and deep), and the recurrent glands, and from the tongue, naso-pharynx, larynx, soft palate, roof of the mouth, œsophagus (cervical portion), nasal fossæ, trachea (cervical portion), and the thyroid gland.[1] The external group terminates in the supraclavicular glands. The internal jugular group terminates in the jugular trunk, which, on the right side, helps to form the right lymphatic duct or empties directly into the junction of the internal jugular and subclavian veins, and on the left side empties directly into the venous junction or into the thoracic duct.

The Lower Deep Cervical or Supraclavicular Glands (*lymphoglandulae cervicales profundae inferiores*).—The lower deep cervical glands lie along the internal jugular vein in the lower part of its course. They receive lymph-vessels from the superficial cervical glands, the upper deep cervical glands, the axillary glands, the accessory chain, the occipital region of the scalp, the skin of the neck, the lower prevertebral muscles, the skin of the pectoral and mammary regions, and the skin of the arm. The supraclavicular glands send vessels which unite with the vessels of the upper deep glands to form the **jugular lymphatic trunk.** The jugular trunk on the right side may empty directly into the junction of the internal jugular and subclavian veins or may unite with the subclavian trunk to form the **right lymphatic duct.** On the left side it may empty into the thoracic duct or directly into the venous junction.

Accessory Chains to the Deep Cervical Glands.—The accessory chains to the deep cervical glands are: 1. The **external jugular glands** (p. 784). 2. The **superficial anterior cervical** (p. 784). 3. The **prelaryngeal** or **infralaryngeal glands** (Fig. 493) between the Crico-thyroid muscles. They receive lymph from the trachea, larynx, and thyroid gland, and send vessels to the pretracheal glands and to the upper deep cervical glands. 4. The **tracheal** or **pretracheal glands** (Fig. 493) lie upon the front of the trachea, receive vessels from the trachea, thyroid body, and prelaryngeal glands, and send vessels to the lower deep cervical glands. Some anatomists speak of the prelaryngeal and the pretracheal glands as the **anterior deep cervical glands.** 5. The **recurrent glands** lie on the sides of the œsophagus and trachea, by the recurrent laryngeal nerves. They receive vessels from the larynx, trachea, œsophagus, and thyroid gland, and send vessels to the upper and lower deep cervical glands.

The Lymphatic Vessels of the Neck (Figs. 487, 491, 492, 493).

The superficial and deep cervical lymphatic vessels are continuations of those already described on the cranium and face. After traversing the glands in those regions, they pass through the chain of glands which lie along the sheath of the carotid vessels, being joined by the lymphatics from the pharynx, œsophagus, larynx, trachea, and thyroid gland. At the lower part of the neck, after receiving some lymphatics from the thorax, they unite to form the **jugular trunk** (Fig. 486), which often terminates, on the left side, in the thoracic duct, and on the right side, in the right lymphatic duct, but which may on either side open directly into the vein.

Surgical Anatomy.—In *secondary syphilis* there is general enlargement of the lymphatic glands, and in the posterior triangle of the neck the enlarged glands are distinctly palpable. The occipital glands may enlarge because of *inflammation* or *suppuration* about the *occipital region* of the *scalp*, and the posterior-auricular glands enlarge from *inflammation* or *suppuration* of the *temporal portion* of the *scalp*, the *external ear* (except the lobule), and the *external auditory meatus*. *Otorrhœa* sometimes causes them to enlarge.

The cervical glands are very frequently the seat of *tuberculous disease*. This condition is usually preceded by a lesion in those parts from which they receive their lymph. The lesion may be tuberculous or inflammatory. If tuberculous it furnishes bacilli directly to the lymph. If inflammatory it lessens tissue resistance and opens the portals to infection. The glands receive

[1] The Lymphatics. By G. Delamare, P. Poirier, and B. Cunéo. Translated and edited by Cecil H. Leaf.

the lymph from the seat of primary disease and become tuberculous. It is very desirable, therefore, for the surgeon, in dealing with these cases, to possess a knowledge of the relation of the respective groups of glands to the periphery. Some years ago Sir Frederick Treves prepared a table to show to what glandular group lymph from each region is sent. The table is practically as follows:

Scalp.—Posterior part = suboccipital and mastoid glands. Frontal and parietal portions = parotid glands.

Lymphatic vessels from the scalp also enter the superficial cervical set of glands.

Skin of face and neck = submaxillary, parotid, and superficial cervical glands.

External ear = superficial cervical glands.

Lower lip = submaxillary and suprahyoid glands.

Buccal cavity = submaxillary and upper set of deep cervical glands.

Gums of lower jaw = submaxillary glands.

Tongue.—Anterior portion = suprahyoid and submaxillary glands. Posterior portion = upper set of deep cervical glands.

Tonsils and palate = upper set of deep cervical glands.

Pharynx.—Upper part = parotid and retro-pharyngeal glands. Lower part = upper set of deep cervical glands.

Larynx, orbit, and roof of mouth = upper set of deep cervical glands.

Nasal fossæ = retropharyngeal glands, upper set of deep cervical glands. Some lymphatic vessels from posterior part of the fossæ enter the parotid glands.

Treves's table indicates the glands usually involved, but the seat of primary disease cannot invariably be affirmed from a knowledge of the seat of glandular involvement, because the course of the lymphatic vessels is sometimes varied from that which usually maintains; for instance, in some cases lymphatics from the right side of the tongue pass to glands in the left side of the neck.

Glands may *enlarge* directly because of primary inflammation, injury, or tumor, but usually a glandular enlargement is secondary to a bacterial disease or to cancer involving the lymph-vessels which come to the gland. The seat of disease may be distant. Disease of the nasal fossæ may cause *retropharyngeal abscess* or enlargement of the submaxillary glands. *Cancer* of the *breast, stomach*, or *œsophagus* may be followed by disease of the cervical glands. Disease of the teeth, tongue, gums, floor of the mouth, and alveolar processes may cause enlargement of the submaxillary and other glands, and disease of the tonsil may lead to enlargement of the glands at the angle of the jaw.

The modern radical surgery of cancer depends on a knowledge of these glandular relations, and consists in thoroughly removing the growth and also the associated lymphatic glands, and, when possible, the lymph-vessels running from the tumor to the glands. The lower deep cervical glands occasionally enlarge secondarily to malignant growths of the abdomen or mediastinum, but this is not due to a direct flow of lymph, as the mediastinal glands do not send vessels to the supraclavicular glands. It is due to blocking of lymphatic vessels and reversal of the lymph-stream, so that lymph containing cancerous cells regurgitates.

A *retropharyngeal abscess* begins to the side of the pharynx. It enlarges toward the centre rather than from it, because the constrictions of the pharynx limit the outward progress of the pus.

The glands within the parotid salivary gland not unusually become tuberculous, and the surgeon may be led to believe that the salivary gland is the seat of primary disease.

Sometimes, though seldom, after the extensive removal of lymph-glands the region drained by their tributaries becomes the seat of persistent hard œdema (*lymph œdema*). It used to be thought that wounds of the thoracic duct were of necessity fatal, but it is now known that, unless close to the vein, they are seldom even very dangerous. It may be possible to suture a partly divided duct.[1] In an unsutured wound of the duct recovery follows if a collateral lymphatic circulation is established.[2]

THE LYMPHATICS OF THE UPPER EXTREMITY.

The Lymphatic Glands of the Upper Extremity.

The lymphatic glands of the upper extremity are divided into two sets, **superficial** and **deep**.

Superficial Lymphatic Glands (Figs. 495 and 503).—The superficial lymphatic glands of the upper extremity are few in number and small in size. They lie in the

[1] Dudley P. Allen's case. See Allen and Briggs, in American Medicine, September 21, 1901.
[2] Harvey Cushing, Annals of Surgery, June, 1898.

subcutaneous tissue. They are not receiving depots of great areas, but interrupt lymphatic vessels here and there. The glands in the axilla receive all of the lymphatic vessels, superficial and deep. There may be three sets of superficial glands.

One set, the **ante-cubital glands,** lies in front of the elbow. These glands are often absent. When these glands are present they receive vessels from the anterior portion of the forearm and the middle of the palm. The vessels from them pass upward along the front and inner aspect of the arm.

FIG. 495.—The superficial lymphatics and glands of the upper extremity.

Another superficial gland lies above the internal condyle. It is the **supratrochlear** or **supraepitrochlear gland** or **group of glands.** There is usually but one gland, but there may be two or more. It receives vessels from the inner portion of the hand, the three inner fingers, and the inner portion of the forearm, but, because of free anastomoses, also may receive lymph from any portion of the hand and forearm. Lymph-vessels from the supratrochlear gland pass up along the basilic vein to the axillary glands.

There are sometimes several small glands by the cephalic vein in the groove between the Deltoid and great Pectoral muscles. These are called **infraclavicular glands.** The lymph-tract from the infraclavicular glands does not terminate in the axillary glands, but ends in the subclavian glands.

The Deep Lymphatic Glands of the Upper Extremity or the Axillary Glands (*lymphoglandulae axillares*) (Figs. 495, 496, 497, 498, and 503).—The chief deep glands are situated adjacent to the axillary vessels. There are also a few small glands along the radial, ulnar, and brachial arteries which receive deep lymphatics from bones, muscles, and ligaments, and send lymphatics to the axillary glands. The axillary glands number from fifteen to thirty-five in each axilla. They are embedded in the axillary fat and receive the lymphatic vessels from the upper extremity, from the skin of the upper portion of the chest, from the Pectoral muscles, and from the mammary gland. The following division of the axillary glands is made by Poirier, Cunéo, and Delamare:[1] 1. An **external group,** the

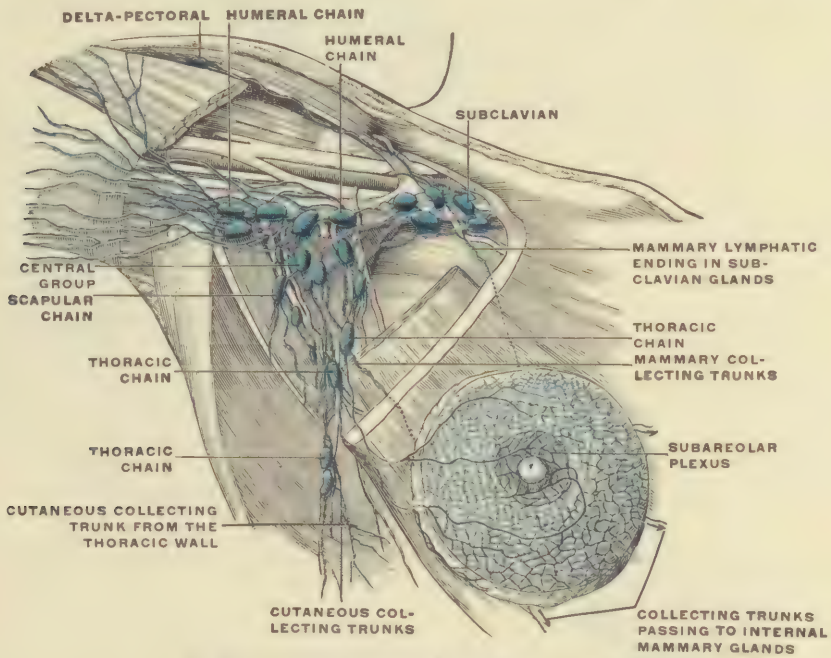

FIG. 496.—Axillary glands and lymphatics of the breast.

humeral chain, lying on the inner surface of the vessels and nerves, particularly the axillary vein, to the sheath of which they are adherent. Occasionally one or several of these glands are found beneath the vein. Some of the vessels from these glands pass into the central group of lymph-nodes; others enter the subclavian glands; others pass above the clavicle and terminate in glands situated in that region. 2. An **anterior group,** the **thoracic chain,** called also the **pectoral glands.** One mass of this chain, the **supero-internal,** is situated in the second or third intercostal space in front of the long thoracic artery and beneath the lower edge of the great Pectoral muscle. Another mass, the **infero-external,** is situated in the fourth and fifth intercostal spaces along the course of the long thoracic artery. The vessels from this chain end in the central group, and some few of them in the subclavian glands. 3. A **posterior group,** the **scapular chain,** lying along the dorsalis scapulæ artery in the groove between the Teres major and the Subscapularis muscles. They send vessels

[1] The Lymphatics. Translated and edited by Cecil H. Leaf.

to the humeral and central chains. 4. A **central group**, the **intermediate glands**, placed near the base of the axilla, between the previously described chains. Their efferent

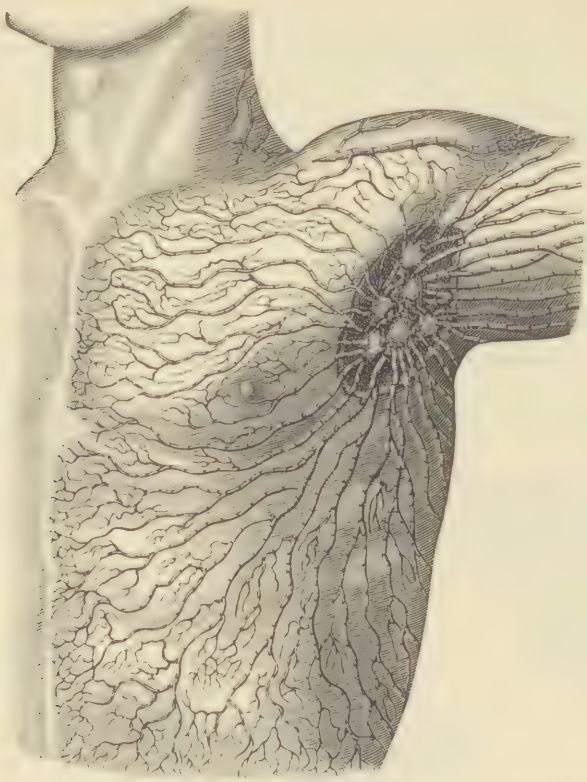

FIG. 497.—Lymphatics of the antero-lateral portion of the thorax. (Sappey.)

vessels end in the subclavian glands. The glands of the central group in many individuals protrude through the opening in the axillary fascia known as the **foramen**

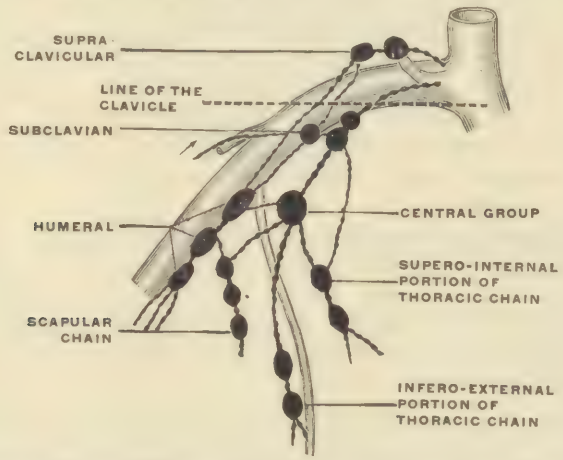

FIG. 498.—Scheme of the axillary glands. The dotted line indicates the position of the clavicle. (Poirier and Charpy.)

of Langer (Fig. 313). 5. A **subclavian group**, situated above the upper margin of the lesser Pectoral muscle. Most of them are internal to the axillary vein,

"between this vein and the first digitation of the Serratus magnus."[1] The humeral chain and the thoracic chain come together and form the **subclavian group of glands** situated at the apex of the axilla. From the axillary glands come many vessels which, by anastomosing, form the **infraclavicular plexus,** they then unite into a trunk, the **subclavian trunk,** which courses between the subclavian vein and Subclavius muscle. On the right side it empties into the junction of the internal jugular and subclavian vein or unites with the jugular trunk to form the right lymphatic duct. On the left side it may empty into the venous junction or into the thoracic duct.

The Lymphatic Vessels of the Upper Extremity (Figs. 495, 496, 497, 498, 499).

The lymphatic vessels of the upper extremity are divided into the **superficial** and the **deep.**

The Superficial Lymphatic Vessels of the Upper Extremity.—The superficial vessels begin as plexuses in the skin and form vessels which ascend in the subcutaneous tissue. These plexuses are particularly plentiful in the palm and palmar surface of the digits (Fig. 499). On each side of each finger two lymph-

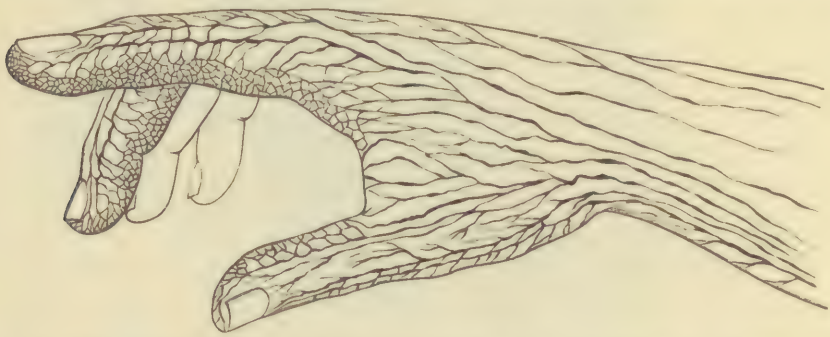

FIG. 499.—Superficial lymphatics of the digits and of the dorsal aspect of the hand. (Cunningham.)

vessels are formed; they ascend toward the hand, cross the dorsum, and anastomose frequently with each other. The vessels from the dorsum of the hand join the lymph-vessels of the forearm, which ascend chiefly along the superficial veins. The lymph-vessels which ascend with the superficial ulnar vein pass into the supratrochlear gland. The vessels which accompany the median veins pass into the ante-cubital or supratrochlear glands. Some of the lymph-vessels on the radial side of the forearm run up along the cephalic vein. All the other lymph-vessels of the upper extremity pass direct to the axillary glands. In the forearm there are about thirty vessels, in the middle of the arm there are from fifteen to eighteen (Sappey).

The Deep Lymphatic Vessels of the Upper Extremity.—The deep lymph-vessels convey the lymph from bone, periosteum, muscle, ligament, etc. They pass up the limb with the chief vessels, there usually being two trunks to each artery. In the arm there are two or three vessels. Some few vessels terminate in the small glands along the radial, ulnar, and brachial arteries, but most of them pass directly to the axillary glands.

Surgical Anatomy.—In *malignant diseases*, or other affections implicating the upper part of the back and shoulder, the front of the chest and mamma, the upper part of the front and side of the abdomen, or the hand, forearm, or arm, the axillary glands are liable to be found enlarged.

In *secondary syphilis* the supratrochlear gland is found to be enlarged. This gland is subcutaneous and readily palpable when enlarged. Normal axillary glands cannot be palpated.

[1] The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.

The axilla is a passage-way for structures between the neck and the upper extremity, and purulent collections or tumors may extend from the neck into the axilla or from the axilla into the neck.

The axillary glands are involved early in cases of cancer of the mammary gland, and later the lower deep cervical glands are involved, and, as Snow has pointed out, regurgitation of lymph containing cancer cells leads to retrosternal involvement and to secondary cancer of the head of the humerus. In operating for cancer of the breast, follow the principle of Halsted and remove the breast, the skin over it, the muscles and fascia, the lymph-vessels, and the axillary glands in one piece. By this plan thorough removal is possible, and as lymph-vessels containing carcinoma cells are not cut across, the wound is not grafted with malignant epithelial cells. Diseased axillary glands are apt to adhere to the sheath of the vein. In removing cancerous glands, always excise the sheath of the vein.

THE LYMPHATICS OF THE LOWER EXTREMITY.

The Lymphatic Glands of the Lower Extremity.

The lymphatic glands of the lower extremity are divided into two sets, **superficial** and **deep.** The superficial are confined to the inguinal region, forming the **superficial inguinal lymphatic glands.**

The Superficial Inguinal Lymphatic Glands (*lymphoglandulae inguinales superficiales*) (Figs. 500, 501, 502, and 503).—The superficial inguinal lymphatic glands, placed immediately beneath the integument in Scarpa's triangle, are of

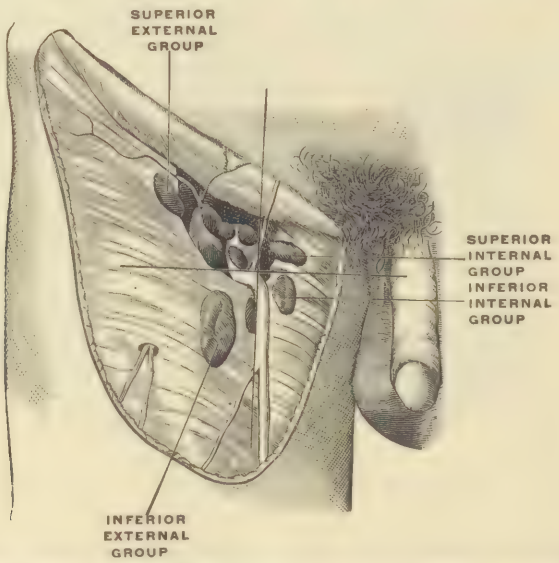

FIG. 500.—Superficial inguinal glands. Cribriform fascia has been removed so as to expose the femoral vessels. (Poirier and Charpy.)

large size, and vary in number from ten to twenty. It is customary to divide these glands into groups according to the region in which they are found. The following division is suggested by Poirier, Cunéo, and Delamare:[1] A horizontal line carried through the saphenous opening divides the glands into two groups, a **superior group** and an **inferior group.** A vertical line through the saphenous opening divides each of the two groups into two secondary groups, an **external** and an **internal group.** We thus have an **external** and **superior group,** and **internal** and **superior group,** an **external** and **inferior group,** and an **internal** and **inferior group.**

[1] The Lymphatics. Translated and edited by Cecil H. Leaf.

Directly in the saphenous opening there are often several glands constituting a **central group.**

Leaf points out that a gland usually exists near the saphenous opening, which is interposed between the superficial inguinal and deep inguinal glands. The superior group of glands, sometimes called the oblique group, is so placed that the glands lie with a certain regularity along and below Poupart's ligament, the long axis of each gland corresponding with the direction of the ligament. It is now known that each group of the superficial glands does not receive with regularity the lymph from and only from a definite and accurately determined area. Hence, it is not possible, as was once taught, to determine with certainty the exact situation of a lesion by the group of superficial glands involved. The superficial inguinal glands receive vessels from the skin of the lower extremity, gluteal region, peri-

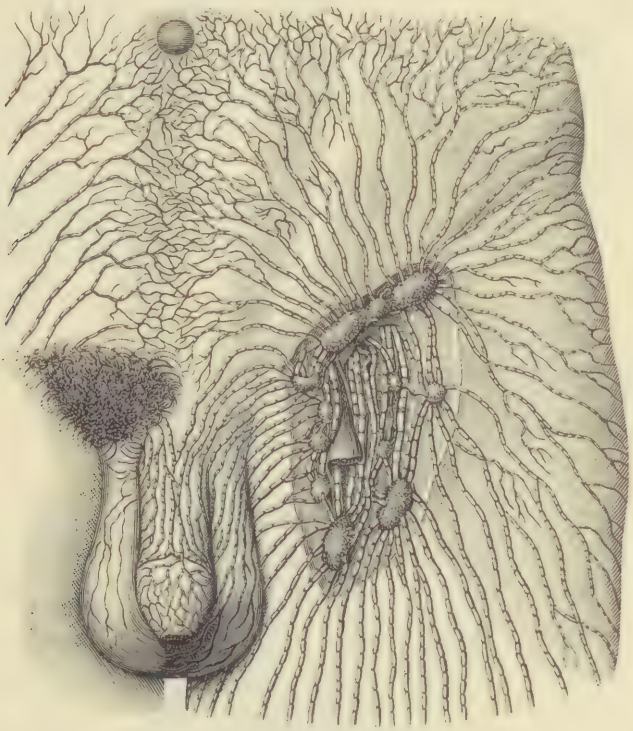

FIG. 501.—Glands of the inguinal region with the afferent and efferent lymphatics. (Poirier and Charpy.)

neum, abdominal wall, scrotum, anus, and from the prepuce of the clitoris and penis. Occasionally, though not normally, they receive vessels from the glans penis and glans clitoris. The superficial glands send vessels to the deep inguinal glands and to the external iliac glands, and these vessels penetrate the femoral sheath. The vessels which go to the iliac glands ascend with the femoral vessels. Leaf[1] figures some of the efferent vessels from these glands as terminating directly in the veins of this region.

Surgical Anatomy.—The superficial inguinal glands frequently become enlarged in diseases implicating the parts from which their lymphatics originate. Thus, in *malignant* or *syphilitic affections* of the prepuce and penis, or of the labia majora in the female, in cancer scroti, in abscess in the perinæum, and in other diseases affecting the integument and superficial structures

[1] The Surgical Anatomy of the Lymphatic Glands, 1898.

in those parts, or the subumbilical part of the abdominal wall or the gluteal region, the upper chain of glands is almost invariably enlarged, the lower chain being implicated in diseases affecting the lower limb.

The Deep Lymphatic Glands of the Lower Extremity.—The deep glands are the **inguinal, anterior tibial, popliteal, gluteal,** and **ischiatic.**

The Deep Inguinal or Deep Femoral Lymphatic Glands (*lymphoglandulae inguinales profundae*) (Fig. 503).—The deep inguinal lymphatic glands are beneath the deep fascia. There are only two or three of them, and they lie to the inner side of the femoral vein, the upper gland being in the crural canal and projecting into the pelvis. It is called the **gland of Cloquet** or the **gland of Rosenmuller.** The deep inguinal glands receive vessels from the superficial inguinal glands, deep lymphatics from along the femoral vessels, and vessels from the glans penis or clitoris. They send vessels to the ilio-pelvic glands.

The Anterior Tibial Gland (*lymphoglandula tibialis anterior*) (Fig. 503).—The anterior tibial gland is not constant in its existence. It is generally found by the side of the anterior tibial artery, upon the interosseous membrane at the upper part of the leg. Occasionally, two glands are found in this situation. It receives a deep anterior tibial lymphatic trunk and sends off a vessel to the popliteal glands.

The Popliteal Glands (*lymphoglandulae popliteae*).—The popliteal glands are embedded in the cellular tissue and fat of the popliteal space and about the perineal vessels The *juxta-articular* gland receives lymph-vessels from the knee-joint. The popliteal glands send vessels to the superficial and deep inguinal glands.

The popliteal glands are divided into three groups:[1] 1. A gland external to the termination of the external saphenous vein, the **external saphenous gland.** 2. A middle group of three or four glands on the sides of the popliteal vessels. The inferior glands of this group are the **intercondyloid glands of Leaf.** The superior glands are the **supracondyloid glands of Leaf.** 3. A gland adherent to the posterior

FIG. 502.—The superficial lymphatics and glands of the lower extremity.

[1] The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.

ligament of the knee-joint, the **juxta-articular gland of Poirier and Cunéo.** The external saphenous gland receives vessels which ascend along the external saphenous

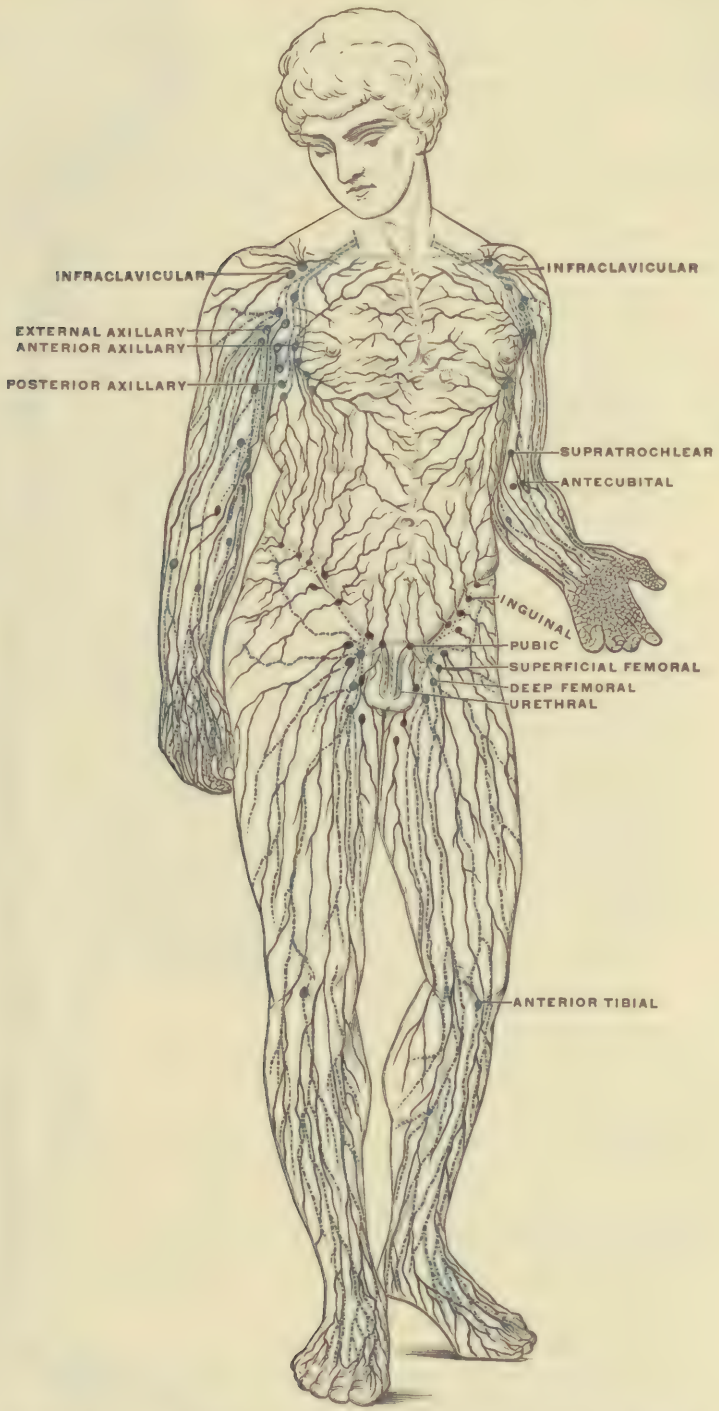

FIG. 503. — Superficial lymphatic vessels of the trunk, and the lymphatic glands and vessels, superficial and deep, of the limbs (diagrammatic). Afferent vessels are represented by continuous lines; efferent and interglandular vessels by dotted lines. (Cunningham.)

vein. The middle group receives vessels from the anterior tibial glands and deep lymphatic vessels which ascend with the posterior tibial.

The Gluteal and Ischiatic Glands.—The gluteal and ischiatic glands are placed, the former above, the latter below, the Pyriformis muscle, resting on their corresponding blood-vessels as they pass through the great sacro-sciatic foramen.

The Lymphatic Vessels of the Lower Extremity (Figs. 502, 503).

The lymphatic vessels of the lower extremity, like the veins, may be divided into two sets, **superficial** and **deep**.

The Superficial Lymphatic Vessels of the Lower Extremity.—The superficial lymphatic vessels are placed beneath the integument in the superficial fascia, and are divisible into three sets: trunks which follow the course of the internal saphenous vein, trunks which accompany the external saphenous vein, and trunks from the gluteal region. 1. Trunks which follow the course of the internal saphenous vein arise from a plexus on the dorsum of the foot, which plexus obtains lymphatics from all the toes, the sole, and both borders of the foot. The internal trunks, three or four in number, pass to the superficial inguinal glands. The external trunks run upward and inward and end in the internal trunks. 2. The trunks which follow the external saphenous vein number two or three, and they take origin from the heel and from the posterior half of the outer edge of the foot. They empty into the superficial inguinal glands. 3. The lymph-trunks from the gluteal region join vessels from the anus and enter the superficial inguinal glands.

The Deep Lymphatic Vessels of the Lower Extremity.—The deep lymphatic vessels of the lower extremity are few in number and accompany the deep blood-vessels. In the leg they consist of three sets, the anterior tibial, peroneal, and posterior tibial, which accompany the corresponding blood-vessels, two or three to each artery; they ascend with the blood-vessels and enter the lymphatic glands in the popliteal space; the efferent vessels from these glands accompany the femoral vein and join the deep inguinal glands; from these glands vessels pass beneath Poupart's ligament and communicate with the chain of glands surrounding the external iliac vessels. The deep lymphatic vessels of the gluteal and ischiatic regions follow the course of the blood-vessels, and join the gluteal and ischiatic glands at the great sacro-sciatic foramen.

THE LYMPHATICS OF THE PELVIS AND ABDOMEN.

The lymphatics of the pelvis and abdomen constitute a continuous chain, but for convenience of study it is customary to divide them into two groups, which we call, with Poirier and Cunéo,[1] the **ilio-pelvic glands** and the **abdomino-aortic glands**; the first group being below and the second above the level of the bifurcation of the aorta into the two common iliac arteries.

The Iliac or Ilio-pelvic Glands (Lymphoglandulae Iliacae) (Figs. 504, 505).

The ilio-pelvic glands are at the level of the inlet of or in the cavity of the pelvis. They follow the course of the blood-vessels and are divisible into the **external iliac**, the **internal iliac**, and the **common iliac chains**.

The External Iliac Glands.—The external iliac glands form chains around the external iliac vessels. There are three chains of these glands. An *external chain* of three or four glands lies between the artery and the Psoas muscle.

[1] Treatise on Human Anatomy.

The lowest gland of the external chain is called by Poirier and Cunéo the **external retro-crural gland** (Fig. 504). A *middle chain* of three glands lies upon the front surface of the external iliac vein. The lowest gland of this group is called by Poirier and Cunéo the **middle retro-crural gland.** An *internal chain* of three or four glands is placed to the inner side of the external iliac vein. The lowest gland of this chain is called the **internal retro-crural gland,** and is close to the upper gland of the deep inguinal chain, the **gland of Cloquet.** The **obturator gland** belongs to the inner chain of external iliac glands. The external iliac glands receive vessels from the superficial and deep iliac glands, from the glans penis or glans clitoris,

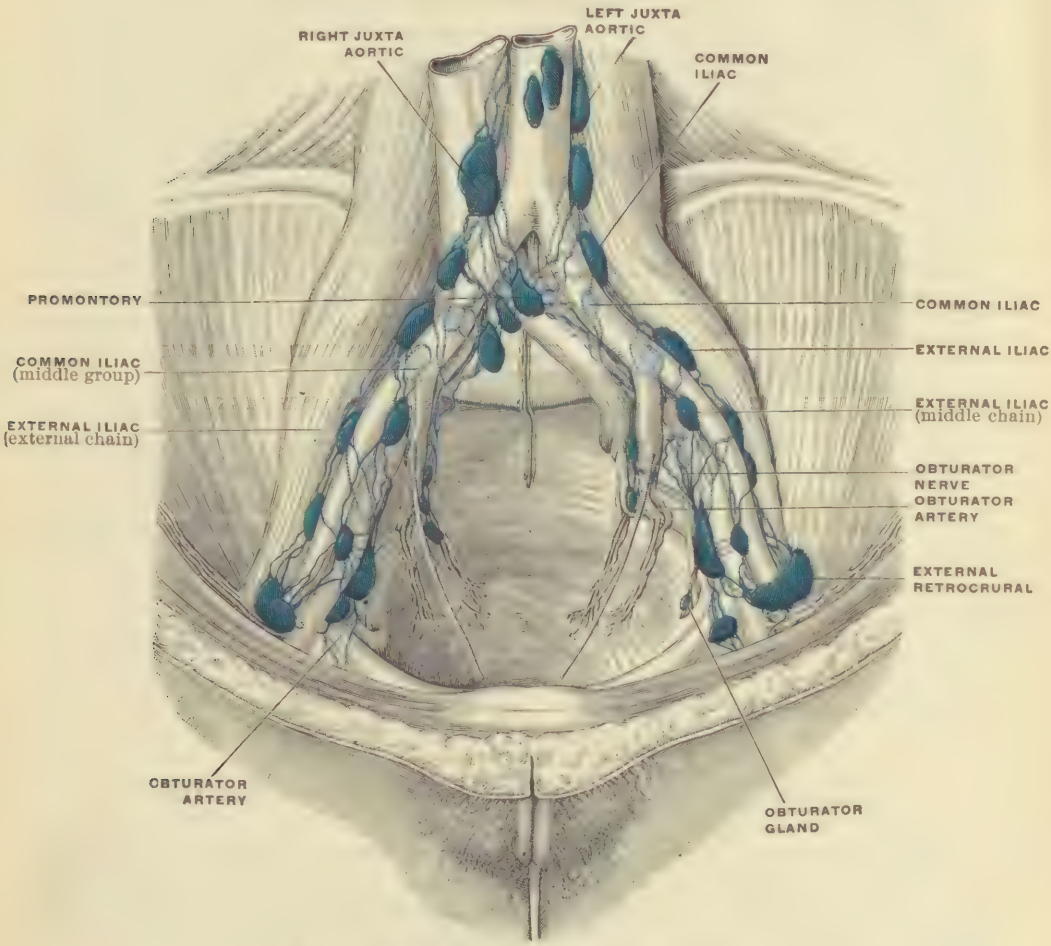

FIG. 504.—Ilio-pelvic glands. (Poirier and Charpy.)

deep lymphatics from the umbilicus and lower part of the belly wall, vessels from the superior portion of the vagina, the uterine neck, the prostate gland, the bladder, the membranous portion of the urethra, and the internal iliac glands, and the obturator gland receives deep lymph-vessels from along the course of the obturator vessels. The external iliac glands send vessels direct to the common iliac glands and also lymphatics to join vessels from the internal iliac glands on their way to the common iliac group. The glands along the deep epigastric artery and those along the deep circumflex iliac artery are accessory chains to the main group of external iliac glands.

The Internal Iliac or Hypogastric Glands.—The internal iliac glands are placed along the internal iliac artery and its branches. The gland on the middle hæmorrhoidal artery is called the **middle hæmorrhoidal gland**. The **lateral sacral gland** is on the lateral sacral artery. The internal iliac glands receive lymph from the pelvic viscera, perinæum, and penile portion of the urethra, deep tissues of the posterior portion of the thigh, and from the buttocks. They send vessels to the common iliac glands and also to the external iliac glands.

The Common Iliac Glands.—The common iliac glands are found about the common iliac artery and are divided into an *external group*, which lies upon the

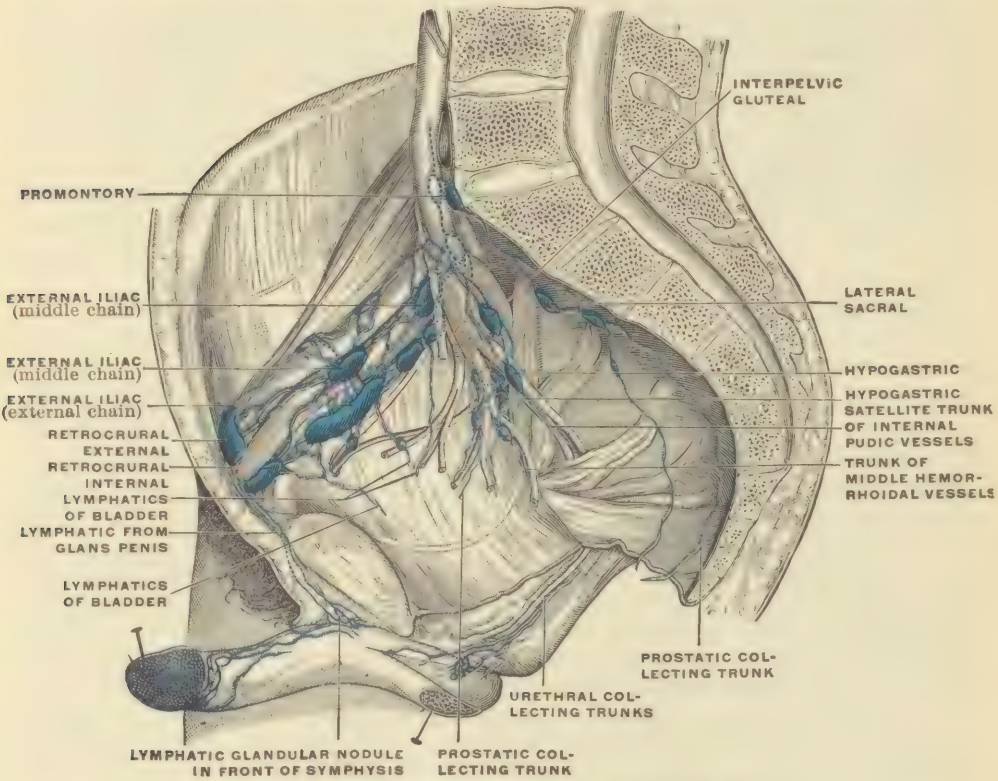

FIG. 505.—Ilio-pelvic glands (lateral view.) (Poirier and Charpy.)

inner edge of the Psoas muscle; a *middle group*, behind the artery, and an *internal group*, which lies upon the front of the body of the fifth lumbar vertebra or upon the sacro-vertebral junction. They receive vessels from the external and internal iliac glands and from the pelvic viscera, the vessels from the pelvic viscera ascending to the promontory of the sacrum and containing perhaps, here and there, interrupting glands, known as **sacral glands** (*lymphoglandulae sacrales*) (Fig. 511). They also receive lymph-vessels from the lumbo-sacral region. They send vessels to the aortic glands. Some anatomists place the common iliac glands and the glands about the lower portion of the aorta and vena cava in a group called the **lumbar glands** (*lymphoglandulae lumbales*) (Fig. 511).

The Abdomino-aortic Glands (Figs. 484, 511).

The abdomino-aortic glands are placed about the abdominal aorta. There are twenty-five or thirty of them. They are divided by Poirier, Cunéo, and Delamare[1]

[1] The Lymphatics. Translated and edited by Cecil H. Leaf.

into the **right** and **left juxta-aortic glands**, the **retro-aortic glands**, and the **pre-aortic glands.**

The Right Juxta-aortic Glands.—The right juxta-aortic glands are grouped in front of and behind the inferior vena cava, the posterior glands lying upon the Psoas muscle and the adjacent pillar of the Diaphragm. They receive lymph-vessels from the right common iliac glands, from the right testicle or the right half of the uterus, and the right tube, ovary, broad ligament, the right kidney and suprarenal capsule, and also lymph-vessels which pass along the lumbar arteries. They send vessels to the pre-aortic and the retro-aortic glands and the receptaculum chyli.

The Left Juxta-aortic Glands.—The left juxta-aortic glands lie by the side of the abdominal aorta, upon the Psoas muscle, and the left pillar of the Diaphragm. They receive tributaries from the left side corresponding to those received by the glands of the right side, and also send out corresponding efferent vessels, and several additional vessels which pass through the left pillar of the Diaphragm and empty into the thoracic duct.

The Retro-aortic Glands.—The retro-aortic glands are placed beneath the receptaculum chyli and in front of the bodies of the fourth and fifth lumbar vertebræ. They receive lymph-vessels from both juxta-aortic groups, and also from the pre-aortic glands, and they send vessels to the receptaculum chyli.

The Pre-aortic Glands.—The pre-aortic glands lie upon the front of the aorta, and in most subjects are divisible into three groups: an *inferior*, lying at the origin of the inferior mesenteric artery; a *middle*, at the origin of the superior mesenteric artery, and a *superior*, about the cœliac axis, the **cœliac glands** (*lymphoglandulae coeliacae*). Glands which are found along the course of all the branches of the abdominal aorta empty into and belong to the group of pre-aortic glands. The pre-aortic glands receive vessels from the juxta-aortic glands and from all the glands along the mesenteric vessels and the cœliac axis and its branches, and receive lymph from the stomach, intestines, liver, pancreas, and spleen. They anastomose with each other and send vessels to the retro-aortic glands and to the receptaculum chyli. Instead of the glands terminating in the receptaculum by separate vessels, the vessels may unite and form a common trunk, the **intestinal trunk** (*truncus intestinalis*), which runs along with the common trunk from the juxta-aortic glands, and empties into the receptaculum (Fig. 484).

1. **The Glands along the Mesenteric Arteries** (*lymphoglandulae mesentericae*) receive the lymph from the colon, cæcum, appendix, ileum, jejunum, duodenum, and perhaps also some from the stomach.

2. **The Glands Connected with the Cœliac Axis and its Branches.**—There are three groups of these glands: the **gastric** or **coronary**, the **splenic**, and the **hepatic** (including those of the bile-ducts).

The Gastric Glands (*lymphoglandulae gastricae*).—One group is situated in the gastro-pancreatic fold; another group is connected with the lesser curvature of the stomach (Fig. 508). Some of them are in the lesser omentum close to insertion of the thicker part upon the stomach, and lie near the ascending branches of the gastric artery, that is to say, upon the vertical portion of the lesser curvature. Others lie within the lesser omentum and accompany the descending branches of the gastric artery, and particularly gather near the point where the gastric artery comes toward the stomach wall. The gastric glands receive lymph from most of the stomach. They send lymph to the upper group of pre-aortic glands, the **cœliac glands.**

The Splenic Glands (*lymphoglandulae pancreaticolienales*).—The splenic glands accompany the splenic artery and lie upon the posterior surface of the spleen, between the spleen and pancreas. They receive lymph from the fundus of the stomach, from the spleen, and from the pancreas, and send it to the cœliac glands.

The Hepatic Glands (*lymphoglandulae hepaticae*).—These glands lie along the hepatic artery, some on the level of the floor of the foramen of Winslow, others by the left side of the portal vein.[1] The authors previously quoted point out that there is a secondary chain of hepatic glands about the right gastro-epiploic artery, the **gastro-epiploic chain**, and that this comprises a **subpyloric group** and a **retro-pyloric group**. The subpyloric group (Fig. 508) is placed in the great omentum below the pylorus, and is usually distinctly separated from it. The retro-pyloric group is not constant. It is placed along the gastro-duodenalis artery back of the pylorus. There is also a group of glands, secondary to the hepatic glands, to the right of or posterior to the cystic duct and the common bile-ducts. The hepatic glands proper receive lymph from the liver and send it to the cœliac glands. The subpyloric glands receive lymph from the inferior portion of the stomach and from the superior portion of the great omentum. They send lymph to the hepatic glands proper, the retro-pyloric glands, and sometimes also to the glands about the superior mesenteric artery. The retro-pyloric glands receive lymph from the subpyloric glands, from the upper surface and from the posterior surface of the pylorus, and from the duodenum. They send lymph to the hepatic glands proper and sometimes to the glands along the superior mesenteric artery. The glands along the gall-ducts empty into the hepatic glands proper.

The Lymphatic Vessels of the Abdomen and Pelvis.

The lymphatic vessels of the abdomen and pelvis may be divided into two sets, **superficial** and **deep**.

The Superficial Lymphatic Vessels of the Walls of the Abdomen.—The superficial lymphatic vessels of the walls of the abdomen follow the course of the superficial blood-vessels. The superficial lymphatics are derived from the integument. Those of the lower part of the abdomen below the umbilicus follow the course of the superficial epigastric vessels and converge to the superior group of the superficial inguinal glands (Figs. 501 and 503). Those from the costal margins of the abdomen terminate in the axillary glands (Fig. 497). The superficial lymphatics from the sides of the lumbar part of the abdominal wall wind around the crest of the ilium, accompanying the superficial circumflex iliac vessels, to join the superficial inguinal glands (Fig. 501).

The Superficial Lymphatic Vessels of the Gluteal Region.—The superficial lymphatic vessels of the gluteal region turn horizontally around the outer side of the nates, and join the superficial inguinal glands.

The Superficial Lymphatic Vessels of the Scrotum and Perinæum.—The superficial lymphatic vessels of the scrotum and perinæum terminate in the superficial inguinal glands.

The Superficial Lymphatic Vessels of the Penis.—The superficial lymphatic vessels of the penis occupy the sides and dorsum of the organ, the latter receiving the lymphatics from the prepuce; they all converge to the superficial inguinal glands. Lymph vessels from the glans penis empty into the deep inguinal and the external iliac glands.

In the female the lymphatic vessels of the vulva and prepuce of the clitoris pass to the superficial inguinal glands; those of the glans of the clitoris pass to the deep inguinal and the external iliac glands.

The Deep Lymphatic Vessels of the Abdominal Wall.—The deep lymphatic vessels of the abdominal wall take the course of the principal blood-vessels, and arise from muscular or aponeurotic layers. One set of lymph-vessels runs along with the deep epigastric artery and terminates in the external iliac glands. Another

[1] The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.

accompanies the deep circumflex iliac artery, and also terminates in the external iliac glands. Several lymph-vessels accompany the lumbar arteries and empty into the juxta-aortic glands. A vessel accompanies the internal mammary artery and empties into the internal mammary glands. Lymph-vessels of the parietes of the pelvis, which accompany the gluteal, ischiatic, and obturator vessels, follow the course of the internal iliac artery, and ultimately join the external iliac, internal iliac, and common iliac glands, and the glands about the lower portions of the aorta and vena cava.

The Lymphatic Vessels of the Umbilicus.—The lymphatics of the umbilicus are divided into three groups:[1] The **cutaneous lymphatics,** which are very superficial, and empty into the superficial inguinal glands. The **lymphatics of the fibrous nucleus,** which pass through the rectus sheath, reach the deep epigastric artery and join the deep lymphatics which come from the muscular and aponeurotic layers of the belly wall. The **lymphatics of the aponeurotic margin** are in two sets: An *anterior* set, some of which penetrate the rectus sheath and join the lymphatics from the fibrous nucleus; others of which pass outward, penetrate the external and internal oblique muscles, and join the posterior lymph-vessels from the aponeurotic margin. A *posterior* set, which forms a collection of vessels on the posterior aspect of the rectus sheath, from which several trunks emerge. One trunk passes outward, penetrates the Transversalis muscle, joins the anterior trunk from the aponeurotic margin, and empties into the external iliac glands.[2] Other ducts run along with the deep epigastric artery and pass into the external iliac glands. Glands lie along the lower portion of these lymph-ducts, and are known as the **superior epigastric glands,** and a gland may exist in the subperitoneal tissue beneath the umbilicus.

The Lymphatic Vessels of the Peritoneum.—It seems probable that the peritoneal cavity is a lymph-sac and that lymphatics take origin from the peritoneum in several ways. Byron Robinson[3] points out three modes of origin: 1. By stomata between endothelial cells. These stomata are in direct communication with lymph-vessels. 2. By interstitial spaces in the subperitoneal tissue. 3. By a plexiform origin similar to interstitial spaces.

Surgical Anatomy.—The fact emphasized by Byron Robinson that the peritoneum is a great lymph-sac explains the quick absorption of septic material and the rapid spread of infectious processes. If the exudate clots and blocks the lymph-channels, absorption is slow and life may be saved. If it does not clot, absorption is rapid and death is certain. Whether it clots or not depends on the nature of the bacteria present.[4] Fowler, impressed by the fact that absorption takes place most rapidly from the diaphragmatic region and least rapidly from the pelvic region, advises placing the victim of peritonitis in bed, with his head and body elevated.[5]

The Lymphatic Vessels of the Bladder.—No lymphatics exist in the mucous membrane of the bladder, although they do exist in the mucous membrane of the prostate. There are some lymphatics in the bladder muscle, and numerous lymphatics in the subperitoneal tissue. The network of lymph-vessels in the muscles is connected with the network beneath the peritoneum and prevesical fascia, and collecting trunks come from both the anterior and posterior surfaces of the bladder. The anterior collecting trunks are divided into two sets. One set comes from the inferior portion of the anterior surface and passes outward to terminate in an external iliac gland "between the external iliac vein and the obturator nerve."[6] The other set comes from the superior and anterior vesical surface, runs upward and outward, and terminates in the external iliac glands. Each set of vessels possesses interrupting lymph-nodes, some of which are directly in front of the bladder.

[1] The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
[2] Poirier, Cunéo, and Delamare. [3] The Peritoneum. [4] Byron Robinson. The Peritoneum.
[5] George Ryerson Fowler, on Diffuse Septic Peritonitis, in the Medical Record, April 14, 1900.
[6] The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.

The posterior collecting trunks are divided into four sets. The first set comes from the superior and posterior portion and passes outward, exhibiting interrupting nodes in its course. These trunks terminate in the external iliac glands. The second set runs directly back into the external iliac glands. The third set comes from the middle of the posterior portion of the bladder and terminates in the hypogastric glands. The fourth set comes from the vesical neck, passes back and then ascends and terminates in the glands in front of the sacral promontory. This fourth set joins with the lymphatics from the prostate and seminal vesicles.

The Lymphatic Vessels of the Prostate Gland.—These vessels form a peri-prostatic plexus, which receives its afferents from the gland structure. This plexus is drained by four vessels, three of which commence on the posterior surface of the gland. Although these vessels begin on the posterior surface of the prostate, their termination in each case is different. One passes on the under surface of the bladder, crosses the superior vesical artery, runs outward, and ends in the middle chain of the external iliac group. Another passes upward, outward, and backward, and terminates in the hypogastric group. A third passes along the floor of the pelvis, runs by the side of the rectum, and ascends on the anterior surface of the sacrum to terminate in the lateral sacral glands and in the hypogastric group. Occasionally a fourth trunk is found on the anterior surface of the prostate, which descends and joins the vessels from the membranous urethra and ends in the hypogastric glands.

The Lymphatic Vessels of the Male Urethra.—These vessels are divided into two groups: First, those of the penile portion of the urethra; second, those of the bulb and membranous portion. The lymphatics of the prostatic urethra belong to those of the prostate gland. The lymph-vessels of the penile urethra in front of the sulcus all run toward the frænum, at which point they bend backward to the sulcus; here they run to the dorsal surface of the penis and terminate in the same manner as the vessels from the glans. The trunks from the remainder of the penile urethra emerge from the inferior surface, run around the corpus cavernosa, and mostly unite with the vessels from the glans penis. One vessel, though, passes over the symphysis and enters in the internal retro-crural gland, whilst another passes beneath the symphysis and terminates with the vessels from the bulb and membranous portion of the urethra. The lymphatics of the bulb and membranous portions end in three trunks, one of which accompanies first the artery of the bulb and then the internal pudic artery, and ends in the hypogastric gland attached to the pelvic portion of this artery. A second trunk runs behind the pubes, to end in the internal retro-crural gland. A third trunk runs on the bladder, where it joins with vessels from this organ, to end in the internal chain of external iliac glands.

The Lymphatic Vessels of the Female Urethra.—The lymphatics of the female urethra terminate in the same manner as do the lymphatics of the bulb and membranous portions of the male urethra

The Lymphatic Vessels of the Uterus.—These consist of three sets, each of which arises by a network of capillaries. There is a mucous network, a muscular network, and a peritoneal network. The vessels from these three regions of origin are collected in the subperitoneal tissue, from which area the collecting trunks take origin. From the *cervix*, according to Poirier and Cunéo, come from five to eight collecting trunks, which pass toward the sides of the body of the uterus, forming on each side, by twisting and dilatation, the **juxta-cervical lymphatic knot** of Cunéo. The cervical connecting trunks are divisible into three groups on each side. One group is composed of two vessels, which pass to the middle chain of the external iliac glands (superior and middle glands). Another group is composed of two vessels, which enter the hypogastric glands. A third group is composed of several vessels, some of which enter the lateral sacral glands, and the balance of which terminate

in the glands of the sacral promontory. From the **body of the uterus** come three groups on each side. One group is composed of four or five vessels which emerge below the uterine cornu, pass beneath the ovary, where they receive the ovarian lymphatics, and terminate in the juxta-aortic glands of the same side. One so-called accessory lymphatic pedicle terminates in the external iliac glands, the other in the inguinal glands.

The Lymphatic Vessels of the Fallopian Tube.—The lymphatics of the Fallopian tube join with those of the uterus and ovary and terminate in the lateral aortic glands.

The Lymphatic Vessels of the Ovary.—The ovary is extremely rich in lymphatics; they form a plexus which is superficial to the veins. The vessels leading from this plexus, four or five in number, pass upward in company with the ovarian vessels and end in the lateral aortic glands. Above the fifth lumbar vertebra these vessels anastomose with the lymphatics from the fundus of the uterus and Fallopian tube. Quite often there is a lymph-vessel which emerges from the ovary, passes downward and outward and ends in the middle chain of the internal iliac glands.

The Lymphatic Vessels of the Vagina.—The lymphatics of the vagina are divided into those of the mucous coat and those of the muscular coat; these anastomose freely with each other and terminate in a peri-vaginal network, which is drained by three groups of trunks. One group drains the upper third of the vagina and passes to the middle chain of the external iliac glands. A second group is efferent to the middle third of the vagina and ends in the hypogastric glands. A third group carries the lymph from the lower third of the vagina to the gland of the promontory.

The Lymphatic Vessels of the Testicle.—The lymphatic vessels of the testicle consist of two sets, **superficial** and **deep**; the former commence on the visceral surface of the tunica vaginalis, the latter in the epididymis and body of the testis. They form several large trunks which ascend with the spermatic cord, and, accompanying the spermatic vessels into the abdomen, terminate in the juxta-aortic and sometimes also in the pre-aortic glands; hence the enlargement of these glands in malignant disease of the testis.

The Lymphatic Vessels of the Vas Deferens.—These lymphatics empty into the external iliac glands.

The Lymphatic Vessels of the Seminal Vesicles.—A network exists on the surface of each vesicle, formed by a collection of lymph-vessels from the mucous lining and from the muscular structure of the vesicle. The trunks from this network empty into the external and internal iliac glands.

The Lymphatic Vessels of the Kidney, Ureter, and Suprarenal Capsule.—Their courses and terminations differ on the two sides. They take origin from a superficial network just beneath the capsule of the kidney and a deep network in the interior of the organ. The superficial network is connected to the collecting vessels of the deep network at the hilum. From the superficial network numerous vessels penetrate the capsule of the kidney and join the lymphatics of the fatty capsule. According to Poirier, Cunéo, and Delamare,[1] anterior and posterior trunks come off from the deep lymphatics of the right kidney. The anterior trunk usually terminates in the right juxta-aortic glands which lie upon the vena cava. The posterior trunks terminate in the juxta-aortic glands which lie behind the vena cava. On the left side all the collecting trunks terminate in the juxta-aortic glands of the left side of the aorta.

The lymphatics of the **fatty capsule of the kidney** communicate with the lymphatics of the kidney, and both terminate in the same glands. The lymphatics of the **suprarenal capsule** terminate in the juxta-aortic glands of the same side. From

[1] The Lymphatics. Translated and edited by Cecil H. Leaf.

the **ureter** lymph-vessels come off and terminate in the juxta-aortic and adjacent glands.

The Lymphatic Vessels of the Liver.—The lymphatic vessels of the liver are divisible into two sets, **superficial** and **deep**. The former arise in the lobules at the periphery of the liver and pass to the subperitoneal connective tissue over the entire organ. The latter arise from the deeper lobules, and emerge from the liver along the portal vein or the hepatic veins.

According to Poirier, Cunéo, and Delamare,[1] three groups of superficial collecting trunks arise from the subperitoneal network. The *posterior trunks* divide into three groups. The single *right posterior trunk* terminates in a gland about the cœliac axis. The *middle posterior trunks* (five to seven in number) pass through the opening in the Diaphragm. The *left posterior trunks* pass into glands

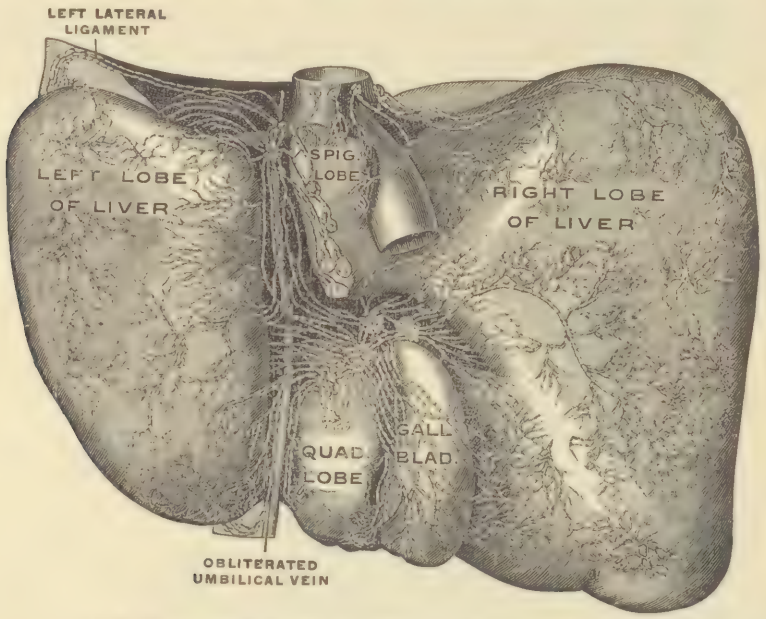

FIG. 506.—Lymphatics of the inferior surface of the liver. (Sappey.)

about the subdiaphragmatic portion of the œsophagus. The *anterior collecting trunks* terminate in the lymph-glands of the hilum of the liver. The *superior trunks* ascend. One of these trunks or a posterior trunk passes with the vena cava through the Diaphragm and terminates in glands about the vena cava. Another trunk, an anterior one, passes over the anterior border of the liver, runs for a time with the round ligament, and terminates in the hepatic glands. Numerous **middle trunks** ascend in the suspensory ligament, unite beneath the Diaphragm into a short trunk of large size, which passes through the Diaphragm and divides into several smaller ducts, which terminate in the glands back of the xiphoid cartilage. Trunks from the superficial lymphatic network also emerge from the inferior surface of the liver. The posterior trunks from the right lobe reach the vena cava and terminate in the glands about the intra-thoracic end of that vessel. The middle and anterior trunks from the right lobe reach the glands along the cystic duct. The trunks from the left lobe terminate in the glands along the hepatic artery. The trunks from the lobus Spigelii reach the glands of the hilum and the glands about the lower intra-thoracic portion of the vena cava. The trunks from the quadrate lobe terminate in the glands of the hilum. The *deep collecting trunks*

[1] The Lymphatics. Translated and edited by Cecil H. Leaf.

are divisible into two groups. One group descends along the portal vein, the other ascends along the hepatic veins.

Sappey pointed out that the **deep descending trunks** accompany the bile passages and the branches of the portal vein, several anastomosing vessels accompanying each branch of the portal vein. The same authority affirmed that from fifteen to eighteen trunks emerge from the hilum and terminate in the adjacent glands. The *deep ascending trunks* surround as a sheath the branches of the hepatic vein (Sappey). As they approach the Diaphragm they diminish in number to five or six, pass through the opening for the vena cava, and terminate in the glands about the lower portion of the intra-thoracic cava.

The Lymphatic Vessels of the Bile-ducts.—The lymphatics of the *bile-ducts* arise from the mucous membrane and from within the muscular tissue, and terminate in glands along the cystic and common ducts.

The Lymphatic Vessels of the Stomach (Figs. 507 and 508).—The lymphatic vessels of the stomach consist of two sets, **superficial** and **deep**. The superficial arise from the outer (serous) and the middle (muscular) coats. The deep arise from the mucous membrane and form a network in the submucous tissue. Trunks from the submucous network pass through the muscular tunic and terminate in the trunks coming from the sero-muscular layers. These latter, the musculo-serous

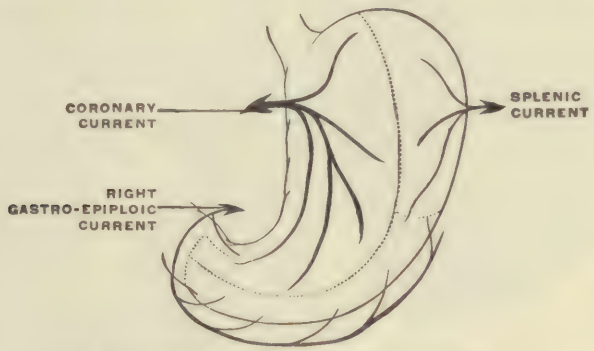

FIG. 507.—Lymphatic areas of the stomach. (Cunéo.)

collecting trunks, are divided into three groups. The first group is composed of six or eight vessels which pass toward the lesser curvature (Sappey). There are from three to ten glands upon the lesser curvature along the course of the gastric artery which receive these superior trunks. Vessels come to these glands from the cardia, from the body of the stomach, and from the pyloric end. In the lesser curvature the lymphatic vessels lie in the wall of the stomach. According to Cunéo, two-thirds of the stomach is drained by the lymph-vessels of group I. The second group comprises the trunks from the greater curvature which end in the subpyloric glands. The glands along the greater curvature are some distance from the stomach wall in the pyloric region, and lymph-streams flow from left to right, that is, toward the pylorus and not from it. These lymphatics drain one-third of the stomach. The first and second groups send lymph eventually to the cœliac glands and juxta-aortic glands. The third group comprises trunks which come from the fundus of the stomach and enter the lymphatic glands about the spleen.

Surgical Anatomy.—Mikulicz pointed out the early infection of the glands of the lesser curvature in pyloric cancer, and insisted that in operation for pyloric cancer the entire lesser curvature must be removed. Cunéo showed us that in pyloric cancer the fundus and two-thirds of the greater curvature usually remain free from disease, because the lymph-current is toward the pylorus and not from it. Of course, if the lymphatics become blocked, the lymph-current may be reversed (regurgitation), and then infection of these parts can occur. William J. Mayo has noted the "lymphatic isolation" of the dome of the stomach. In operating for cancer of the

pylorus, make the section of the stomach as directed by Hartmann, that is, a section which removes all of the lesser curvature and cuts the greater curvature well to the left of the subpyloric glands.

The Lymphatic Vessels of the Pancreas.—The lymphatics of the pancreas arise from a network about the pancreatic lobules. The collecting trunks anastomose freely on the surface of the pancreas. Some of the trunks terminate in the splenic glands, which send vessels to the cœliac glands. Others terminate directly in the cœliac glands. The lymphatics of the head of the pancreas communicate with the duodenal lymphatics and the lymphatics of the lower end of the common duct. The pancreatic and splenic lymphatics probably communicate.

The Lymphatic Vessels of the Spleen.—The lymphatics of the spleen consist of two sets, **superficial** and **deep**; the former are placed beneath its peritoneal covering, the latter in the substance of the organ; they accompany the blood-vessels, passing through a series of small glands, and pass into the splenic glands which are placed in the omentum between the spleen and pancreas. The gastro-splenic omentum contains no glands.

THE LYMPHATIC SYSTEM OF THE INTESTINES.

The Lymphatic Glands of the Small Intestine (Fig. 509).—The lymphatic glands of the small intestine are placed between the layers of the mesentery, and are

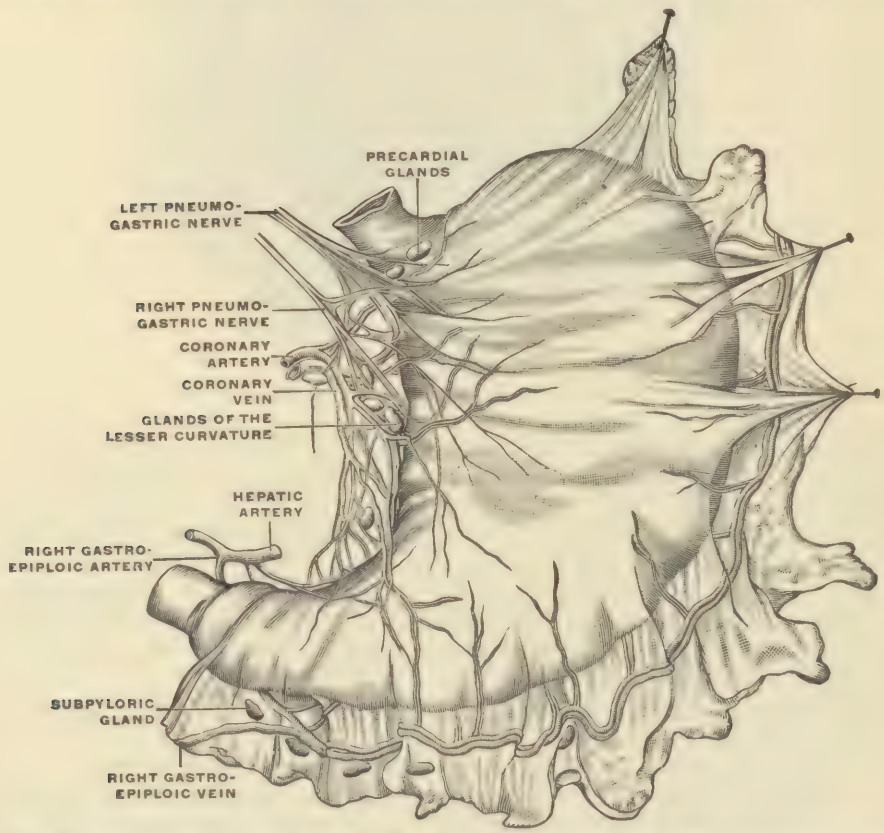

FIG. 508.—General view of the subperitoneal lymphatic plexus of the stomach prepared by the method of Gerota. (Cunéo.)

called **mesentery glands** (*lymphoglandulae mesentericae*). They vary in number from a hundred to a hundred and fifty, and in size from that of a pea to that of a small

almond.[1] These glands are most numerous and largest above, the glands of the jejunum being more numerous than those of the ileum. This latter group becomes enlarged and infiltrated with deposit in cases of fever accompanied with ulceration of the intestines. The glands diminish in number as we descend until the ileo-cæcal region is reached, when a number of glands appear about the ileo-cæcal artery. The mesenteric glands receive the lacteals and send out trunks to the receptaculum chyli. The chyle from the intestine passes through the glands on its way to the thoracic duct.

The glands may be divided into: I. A group of glands the members of which are chiefly found along the terminal vessels from the vascular loops of the intestinal branches of the superior mesenteric artery. Some glands of this group are placed upon "the anterior surface of the upper end of the jejunum."[2] II. A group of glands along the vascular loops of the superior mesenteric artery. Most of them are between the primary loops. Some of them are between the secondary and tertiary loops. III. A group of glands along the trunk of the superior mesenteric artery.

FIG. 509.—Lymphatics of the small intestine. (Poirier and Charpy.)

The Lymphatic Vessels of the Small Intestine (Fig. 509).—The lymphatic vessels of the small intestine are called **lacteals**, from the milk-white fluid they usually contain. They take origin in the intestinal villi and in lymphatic sinuses around the bases of the solitary glands. Lymphatic plexuses exist in the submucous tissue, the muscular coat, and the subserous tissue. The lymphatic vessels pass between the layers of the mesentery, enter the mesenteric glands, and finally unite to form two or three large trunks which terminate separately in the receptaculum chyli; frequently, however, they first unite to form a single large trunk, termed the **intestinal lymphatic trunk** (Figs. 483, 484, and 511).

The Lymphatic Glands of the Large Intestine.—The lymphatic glands of the large intestine are divided into the **colic glands** and **rectal glands.**

The Colic Glands (*lymphoglandulae coliacae*).—The colic glands are subdivided into: 1. The ileo-colic or ileo-cæcal glands (Fig. 510), which lie along the course of the ileo-colic artery, one or two of the glands being placed upon the anterior surface of the cæcum. The mesoappendix also contains a gland which com-

[1] Leaf (Surgical Anatomy of the Lymphatic Glands) says it is very common to find not more than forty or fifty.

[2] The Surgical Anatomy of the Lymphatic Glands. By Cecil H. Leaf.

municates with glands in the mesocolon, and receives lymph from the appendix and, in the female, from the ovary. 2. Glands in the mesocolon along the right colic artery, which receive lymph from the ascending colon and the hepatic flexure. 3. Glands in the mesocolon along the middle colic artery, which receive lymph from the hepatic flexure and transverse colon. 4. Glands in the mesocolon along the left colic artery, which receive lymph from the descending colon and sigmoid flexure. The vessels from the colic glands pass to the pre-aortic glands.

The Rectal Glands.—The rectal glands lie in the mesorectum; they receive lymph from the anus and rectum and it passes from them to the lumbar and sacral glands.

The Lymphatic Vessels of the Large Intestine.—The lymphatic vessels of the large intestine consist of three sets: those of the cæcum, ascending and transverse

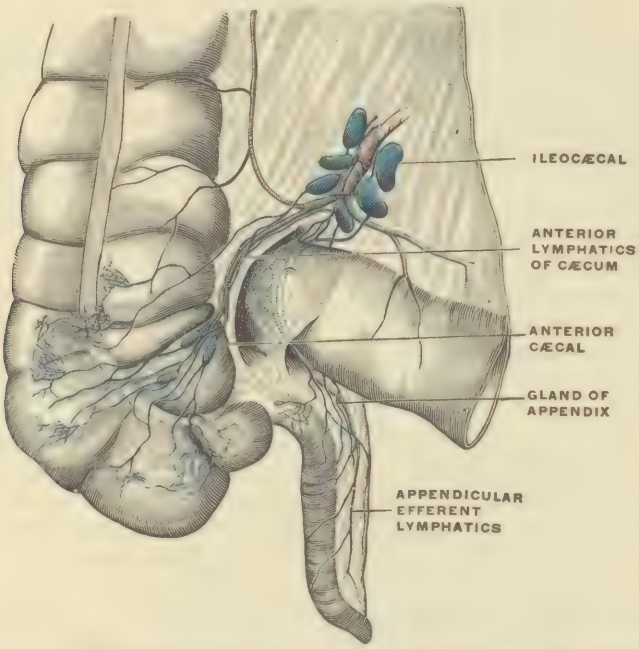

FIG. 510.—Anterior view of the lymphatics of the cæcum and appendix. (Poirier and Charpy.)

colon, which, after passing through their proper glands, enter the mesenteric glands; those of the descending colon and sigmoid flexure, which pass to the lumbar glands, and those of the rectum and anus, which pass to the sacral and superficial inguinal glands.

Lymphatics of the Anus and Rectum.—These vessels take origin from two networks, one from the skin and mucous membrane and the other from the muscular coat. The lymph-vessels from the skin at the anal margin pass to the superficial inguinal glands. Some vessels from the skin of the anus ascend and reach the submucous plexus of the rectum, from which region lymph-vessels pass to the rectal glands, to the glands along the middle hæmorrhoidal artery, and along the inferior hæmorrhoidal artery, and to a pelvic gland near the origin of the internal pudic artery.[1] The vessels from the anal mucous membrane and from the muscular wall of the rectum penetrate the muscular wall of the rectum with the arteries and reach the rectal glands.

[1] The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.

THE LYMPHATICS OF THE THORAX.

The thoracic lymphatics are divided into the **deep lymphatics of the chest wall,** the **diaphragmatic lymphatics,** and the **visceral lymphatics.**

The Lymphatic Glands of the Thoracic Wall or the Parietal Lymphatics.

The lymphatic glands of the thoracic wall include the **internal mammary** and **intercostal glands.**

The Internal Mammary Glands.—The internal mammary, **retro-sternal,** or *sternal glands* form a chain of five or six glands on each side of the sternum along the course of the corresponding internal mammary artery, and back of the Internal intercostal muscles. The glands are separated from the pleura by cellular tissue. The internal mammary glands receive vessels from the diaphragmatic glands, the abdominal muscles above the umbilicus, the anterior ends of the intercostal spaces, the skin over the sternum, and the mammary gland. The vessels given off by each chain form a single trunk. On the right side this trunk terminates at the junction of the internal jugular and subclavian veins, unites with the subclavian lymph-trunk to form the right lymphatic duct, or empties directly into the subclavian trunk (Fig. 486). On the left side it empties either at the junction of the subclavian and internal jugular veins or into the thoracic duct.

The Intercostal Glands (*lymphoglandulae intercostales*) (Fig. 511).—The intercostal glands are small glands lying in the intercostal spaces along the intercostal arteries. In the posterior end of each space they are constantly found. These are called the **posterior glands,** and there are one, two, or three in each space. These glands are opposite the neck of the rib or over the articulation of the rib with the vertebra. The pleura is in front of them, and they lie upon the external intercostal muscles. In the middle of the intercostal spaces are inconstant glands which are called **lateral glands.** They are merely interrupting nodes in the trunks from the intercostal muscles. The intercostal glands receive vessels from the intercostal muscles and pleura. They send vessels back toward the spine, which unite with lymphatics from the back part of the thorax and spinal canal, and which pass down the spine and terminate in the thoracic duct.

The Diaphragmatic Lymphatics.—The diaphragmatic lymph-glands are distinct and numerous. These glands are on the convex surface of the Diaphragm and are divided into an anterior, a middle, and a posterior group. They receive vessels from the Diaphragm and liver and send vessels to the internal mammary and posterior mediastinal glands. The lymph-vessels of the Diaphragm take origin from a capillary network contained in the spaces between the muscular and tendinous fasciculi of the Diaphragm. Numerous lymph-vessels descend until they reach the subperitoneal tissues and then ascend. Others immediately ascend to beneath the pleura. The collecting trunks are all on the convex surface of the Diaphragm. The lymphatic vessels of the Diaphragm anastomose with the lymphatic vessels of the pleura and the peritoneum. This subperitoneal network is so extensive that absorption in this region is extremely rapid. Hence, after an abdominal operation, if salt solution has been left in the abdomen, it will be very rapidly absorbed if the foot of the bed is elevated. Influenced by the knowledge that the pelvic peritoneum absorbs comparatively slowly and the peritoneum in the upper abdomen very rapidly, and that septic processes in the upper abdomen are more rapidly fatal than septic processes in the pelvis, Fowler was led to recommend the elevation of the head of the bed after operations for abdominal infections. This posture causes poisonous fluids to gravitate away from the Diaphragm.

The Visceral Lymphatics.—The visceral lymphatics include the **anterior mediastinal glands**, the **posterior mediastinal glands**, and the **peritracheo-bronchial glands.**

The Anterior Mediastinal Glands (*lymphoglandulae mediastinales anteriores*).—The anterior mediastinal glands are in the upper portion of the anterior mediastinum, a group of six or seven glands lying above and upon the front of the transverse

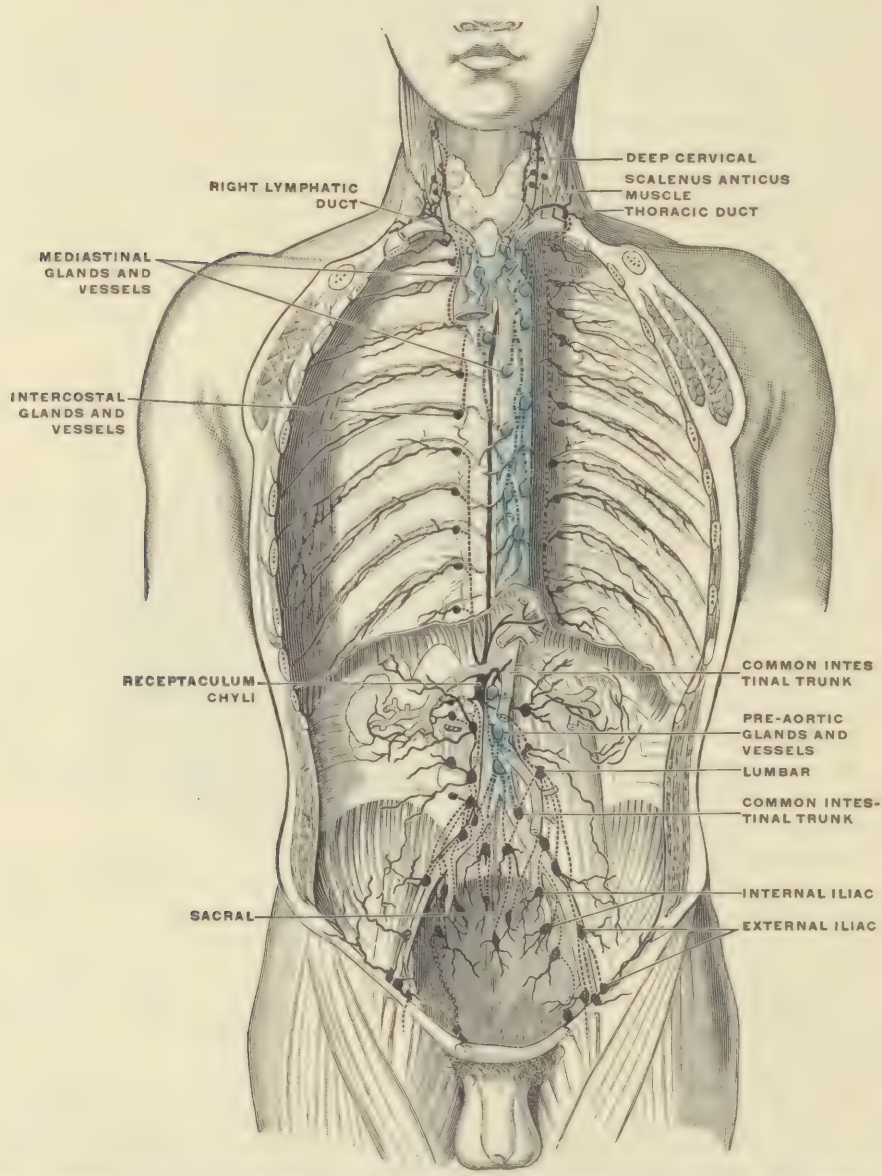

FIG. 511.—Deep lymphatic glands and vessels of the thorax and abdomen (diagrammatic). Afferent vessels are represented by continuous lines, and efferent and interglandular vessels by dotted lines. (Cunningham.)

portion of the arch of the aorta and sending glandular chains toward the neck. On the right side these glands are found between the innominate artery and vein and in front of the vein. On the left side they are in front of and behind the left common carotid and left subclavian arteries. They receive lymph from the heart, pericardium, thymus gland, and anterior mediastinum.

The Posterior Mediastinal Glands (*lymphoglandulae mediastinales posteriores*) (Fig. 511).—The posterior mediastinal glands are behind the pericardium and in front of the œsophagus. Occasionally one or two are placed back of the œsophagus. They receive vessels from the intercostal glands, aortic glands, deep cervical glands, and pleura, and send vessels to the thoracic duct.

The Peritracheo-bronchial Glands.—The peritracheo-bronchial glands are divided by Baréty into four groups. One group is in the angle formed by the junction of the trachea and right bronchus. Another group is in a corresponding situation on the left side. Another group is below the tracheal bifurcation. The glands of the fourth group are about the points of division of the larger bronchi. The peritracheo-bronchial glands receive lymph-vessels from the lung, heart, pericardium, œsophagus, trachea, and thymus.

In infancy these glands present the same appearance as the lymphatic glands in other situations. In early adult life they assume a brownish tinge, and in old age become deep black, because they arrest particles of carbon brought from the bronchi. This change is known as *anthracosis*, and the darkened glands are usually sclerotic. In fact, in old age these glands often lose all lymphatic characters and become fibrous masses. These glands enlarge from infection, and when very large may compress the bronchi, the pulmonary artery, etc. They are often the seat of *tuberculous deposits*.

The Lymphatic Vessels of the Thoracic Wall.—The lymphatic vessels of the thoracic wall include the deep lymphatic vessels, **intercostal** and **internal mammary**, which have been described, the **cutaneous lymphatics**, and the **lymphatics of the mammary gland.**

The Cutaneous Lymphatics (Fig. 497).—The area drained by these lymphatics is very extensive. It is divided by Poirier, Cunéo, and Delamare into three regions. The *anterior region* extends from over the middle of the sternum to the anterior axillary line. The trunks pass to the axilla and terminate in the thoracic chain of the axillary glands. From this anterior region some accessory trunks pass above the clavicle and reach the supra-clavicular glands, and trunks may arise to one side of the mid-sternal line and pass to the opposite axilla. From the *lateral region* the trunks ascend to the thoracic chain of axillary glands. This region is between the anterior and posterior axillary lines. The *posterior region* is back of the posterior axillary line, and includes the thorax to the mid-line, and the posterior portion of the root of the neck. The trunks from the posterior area empty into the scapular group of axillary glands.

Lymphatics of the Mammary Gland (Figs. 496 and 512).—There are two sets of lymphatics in this gland, the **cutaneous** or **superficial** and the **glandular** or **deep.**

The Peripheral Cutaneous Lymphatics of the Mammary Gland.—The peripheral cutaneous lymphatics do not arise from the nipple. Their collecting trunks are arranged as are other collecting trunks of the anterior portion of the thorax, and end in the thoracic group of axillary glands of the same side. Trunks arising from the sternal margin of the skin of the breast may run to the glands of the opposite axilla.

The Central Deep Lymphatics of the Mammary Gland.—The central lymphatics form a very extensive network in the nipple and areola, and from this network numerous vessels pass into a plexus beneath the areola, **Sappey's subareolar plexus;** most of the trunks coming from the gland also enter the subareolar plexus.

The Glandular Lymphatics of the Mammary Gland.—The glandular lymphatics arise from spaces about the lobules and from networks about the milk-ducts. We can distinguish a chief lymphatic channel and three accessory channels.

The chief lymphatic channel takes origin from collecting trunks which begin in the spaces about the lobules and in the lymph-capillaries about the milk-ducts. These collectors pass toward the nipple and terminate in the *subareolar plexus*, which plexus also receives the vessels from the areola and nipple. Two large

trunks take origin from the subareolar plexus: one from its inner side, the other from its outer side. "The internal trunk runs at first downward and then outward, turning round the inferior border of the subareolar plexus. It is thus directed toward the axilla and runs in the subcutaneous cellular tissue, along the lower border of the Pectoralis major, which it crosses at the level of the third rib to reach the base of the axilla. This collecting trunk constantly receives as afferents one or two fair-sized trunks coming directly from the inferior portion of the mammary gland. The external trunk, which is usually smaller than the preceding, runs directly outward toward the axilla. Before it reaches the latter it is augmented by a vessel coming from the superior part of the gland. At the base of the axilla these two collecting trunks perforate the axillary aponeurosis and terminate in one or two glands, placed on the inner wall of the axilla on the third digitation of the Serratus magnus muscle. These glands (the principal regional glands of the breast) may or may not be covered by the lower part of the Pec-

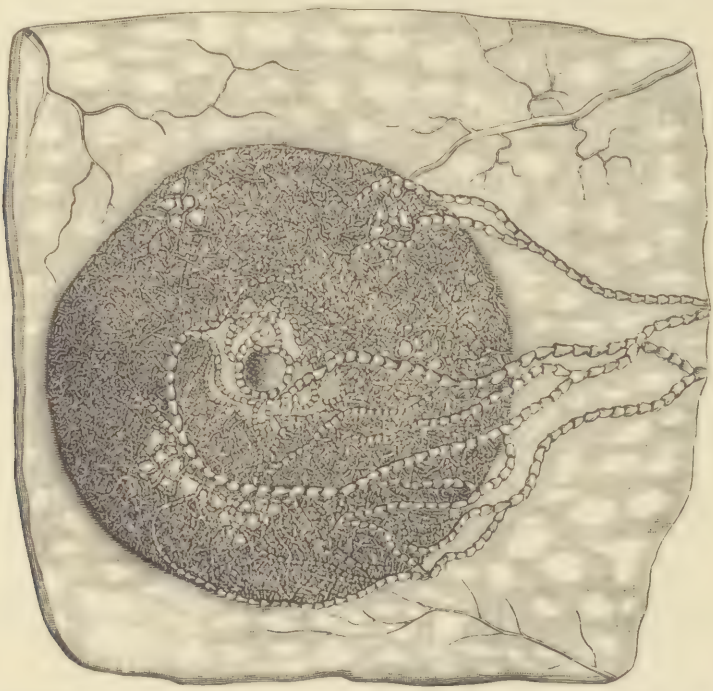

FIG. 512.—The vessels and lymphatics of the anterior face of the mammary glands. (Sappey.)

toralis major muscle according to the muscular development of the subject (Surgius)."[1] These glands constitute the supero-internal mass of the anterior axillary chain. An interrupting gland is sometimes found in the course of these two trunks, the **paramammary gland.**

The Accessory Channels from the Mammary Gland.—The accessory channels from the mammary gland, according to Poirier, Cunéo, and Delamare, are three. They call one the **accessory axillary channel.** It is not constant, and there may be interrupting glands on its collectors. Its collectors come off from the inferior portion of the mammary gland and pass directly to the axillary glands. Another channel is the **subclavian channel.** Neither is it constant. It comes off from the posterior surface of the mammary gland, pierces the great Pectoral muscle, and ascends between the greater and lesser Pectorals to reach the subclavian glands. There

[1] The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.

are usually interrupting glands along this channel, the **retro-pectoral glands.** The subclavian channel runs along the superior thoracic artery. They call the third accessory channel the **internal mammary channel.** The collecting trunks arise from the inner portion of the mammary gland and pass along the vessels sent off from the internal mammary artery to the gland. They pierce the Pectoral and Intercostal muscles and reach the internal mammary glands. This channel is constant and along it there may be interrupting glands.

Lymphatics of the Great Pectoral Muscle.—The lymphatics of the great Pectoral muscle end in the subclavian glands, the thoracic group of axillary glands, and the internal mammary glands.

Surgical Anatomy.—A knowledge of the lymphatics of the breast and of the glands into which the lymphatics drain is of the first importance to a surgeon. Certain surgical deductions from the anatomy of this region are perfectly obvious—viz.: 1. If the skin of the mammary gland is involved in carcinoma, the thoracic group of axillary glands of the same side is involved. If the skin over the sternal margin of the gland is involved, the glands of the opposite axilla may be cancerous, as from this point lymph-vessels rise and pass across the mid-line. If the skin of the sternal margin is involved the prognosis is worse than if it is free, the opposite axilla may be cancerous, and the opposite breast may become diseased. 2. When lymphatic ducts become blocked by cancer cells the lymph backs up, flows backward instead of in its proper direction, and may cause infecton in the most unsuspected situations. For instance, a block in the cutaneous lymphatics of a portion of the breast may lead to infection of the opposite breast and axilla, though, of course, it is not so likely to as is cancer of the skin of the sternal margin. By regurgitation of lymph the head of the humerus or the retro-sternal structures may become diseased in mammary cancer. 3. If the nipple or areola is cancerous, the entire gland is sure to be diseased, as the lymphatic network of this region empties into the subareolar plexus, and most of the trunks coming from the gland also enter this plexus. 4. If the mammary gland is cancerous, all of the axillary glands are regarded as diseased, as the main lymphatic channel from the breast reaches the glands on the inner wall of the axilla upon the third digitation of the Serratus magnus. Furthermore, in many cases an accessory lymph-channel comes off from the lower portion of the mammary gland and passes directly to the axilla. 5. The subclavian glands are to be regarded as diseased, because in a certain proportion of cases (the exact proportion being uncertain) an accessory lymph-channel comes off from the posterior surface of the mammary gland, passes through the great Pectoral muscle and ascends between the greater and lesser Pectorals to reach the subclavian glands. 6. The element which greatly interferes with the cure of mammary carcinoma is the existence of lymph-channels which arise from the inner portion of the mammary gland, pierce the greater Pectoral and Internal intercostal muscles, and reach the internal mammary glands. Mediastinal involvement is apt to be earlier in carcinoma of the inner portion of the breast than in carcinoma of other portions, and the prognosis is particularly bad in cancer of the inner portion of the breast. What is known as the *sternal symptom* of Snow is bulging of the sternum due to involvement of the thymus gland. 7. The sternal portion of the great Pectoral and the tissue between it and the lesser Pectoral muscle are to be regarded as diseased, because in some cases an accessory lymph-channel from the breast penetrates the greater Pectoral and ascends to the subclavian glands. This trunk has several interrupting or satellite glands, the **retro-pectoral glands,** in the tissue back of the great Pectoral muscle. 8. When the great Pectoral muscle is diseased, cancer cells soon spread widely through the sternal portion of the muscle, and this entire portion of the muscle becomes cancerous. The clavicular portion does not suffer early, but escapes until the cancer becomes extensive, as it is anatomically distinct from the sternal portion. If the fibres of the great Pectoral are extensively diseased, the thoracic group of axillary glands, the subclavian glands, and possibly the internal mammary glands are involved. 9. The only operation in cancer of the breast which offers any real hope of cure is one which is done early and is radical. 10. It must be done early, because delay permits involvement of the mediastinum, and if the disease has entered the mediastinum operation is hopeless. If the sternum is bulged operation is useless, and nothing short of amputation at the shoulder-joint could be of help if the head of the humerus is enlarged by the disease. Even this radical procedure is of no avail, because the mediastinum is certainly involved if the head of the humerus is diseased. 11. If the lymph-glands above the clavicle are extensively diseased operation is useless, as in such cases the mediastinum is sure to be involved. 12. A radical operation means the removal of the skin of the breast with the nipple and areola, the subcutaneous tissue of this region, the entire breast the sternal portion of the great Pectoral with its fascia, the retro-pectoral glands and tissue, all the contents of the axilla except vessels and nerves, the glands and cellular tissue beneath the anterior margin of the Latissimus dorsi, and the subclavian glands. It is probably always wisest to open above the clavicle as well as below to facilitate the removal of glands. It is seldom necessary

to remove the clavicular portion of the greater Pectoral. The lesser Pectoral does not require removal, but it should be taken away, because of the added safety and speed thus obtained in cleaning the great vessels and because its retention does not improve the functional result. The surgeon must remember that the breast is a much larger organ than we used to think, and all of its irregular projections and outlying lobules must be removed (p. 793). Formerly, surgeons did not completely remove the breast, but only got rid of a large portion of it.

The Pulmonary Lymphatics.—The pulmonary lymphatics arise from networks between the lobules, around the bronchi and under the mucous membrane. The collecting trunks are in two sets, **superficial** and **deep**: the former are placed beneath the pleura, forming a minute plexus which covers the outer surface of the lung; the latter accompany the blood-vessels and run along the bronchi; they both terminate at the root of the lungs in the tracheo-bronchial glands.

The Pleural Lymphatics.—The lymphatics of the pulmonary pleura pass into the superficial pulmonary trunks; those from the costal pleura enter the intercostal trunks; those from the diaphragmatic pleura enter the diaphragmatic trunks, and those from the mediastinal pleura enter the posterior mediastinal glands.[1]

The Cardiac Lymphatic Vessels.—The cardiac lymphatic vessels consist of two sets, **superficial** and **deep**: the former arise in the subpericardial areolar tissue of the surface, and the latter in the subendocardial tissue. From the network of deep lymphatics trunks pass to the superficial lymphatics. The superficial lymphatics follow the course of the coronary vessels. Two trunks are formed: an anterior, which lies in the anterior interventricular furrow, and an inferior, which lies in the inferior interventricular furrow. These two trunks collect the lymph from the ventricles and pass to the base of the heart, where they receive lymph from the auricles. The anterior or left trunk ascends between the left auricle and the pulmonary artery on the posterior surface of the artery, perforates the pericardium, and enters the glands about the tracheal bifurcation. The right, posterior or inferior trunk ascends between the aorta and pulmonary artery and terminates in the same group of glands as the left trunk.

The Thymic Lymphatic Vessels.—The thymic lymphatic vessels arise from the under surface of the thymus gland, and enter the anterior mediastinal, the internal mammary, and the peritracheo-bronchial glands.

The Lymphatic Vessels of the Œsophagus.—The lymphatics of the thoracic œsophagus arise from two networks, one beneath the mucous membrane and one beneath the muscular fasciculi. The connecting trunks terminate in the peri-œsophageal glands.

The Lymphatic Vessels of the Thoracic Trachea.—The lymphatics of the thoracic trachea take origin from a network in the submucous tissue. From this a number of collecting trunks pass through the trachea in the line of junction of the cartilaginous with the membranous portion. They terminate the peritracheo-bronchial glands.

[1] The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.

THE NERVOUS SYSTEM.

THE nervous system consists of (1) the **cerebro-spinal nervous system** and (2) the **sympathetic nervous system.**

1. The **Cerebro-spinal Nervous System** is composed of the spinal cord and brain and of nerves joined to the brain and cord. The spinal cord and brain constitute the **cerebro-spinal axis,** or, as it is also called, the **encephalo-spinal axis,** the **neuraxis,** or the **central nervous system.** The nerves which join the cord and which join the brain constitute the **peripheral nervous system.** The term central nervous system is applied to structures contained altogether within the spinal and cranial cavities, but this narrow use is not strictly accurate. By far the greater part of the central nervous system is contained within those cavities, but any centre of energy must be regarded as a portion of the central system, and certain ganglia which are centres of energy lie along certain nerves and really belong to the central nervous system, though they are discussed with the peripheral nerves.

The term peripheral nervous system does not mean, as it would seem to, structures outside the spinal and cranial cavities. The chief part of the peripheral system is outside of the spinal and cerebral cavities, but peripheral nerves "sometimes run a considerable distance within these cavities."[1] The peripheral nervous system is composed of thirty-one pairs of **spinal nerves** and twelve pairs of **cranial nerves.** Each spinal nerve is joined to the spinal cord by two roots, an **anterior** and a **posterior root,** and the posterior root at one point has an enlargement called a **spinal ganglion.** The fifth cranial nerve, alone among cranial nerves, takes origin by two roots, as does a spinal nerve. Five of the cranial nerves possess ganglia similar to the ganglia on the posterior roots of the spinal nerves. The cranial nerves which possess ganglia are the trigeminal or fifth, the facial or seventh, the auditory or eighth, the glosso-pharyngeal or ninth, and the pneumo-gastric or tenth.

2. The **Sympathetic Nervous System** consists of a chain of ganglia on either side of the vertebral column. The ganglia of each chain are joined by cords of nervous matter. The sympathetic system contains, beside the gangliated cords, numerous nerve plexuses and ganglia in various regions. The sympathetic nervous system is closely connected at many points with the cerebro-spinal nervous system, and the two systems in all probability develop from a common origin.

Structure of the Cerebro-spinal Nervous System.—The spinal cord and brain contain **gray matter** and white matter. The gray matter is vascular and is composed chiefly of **nerve-cells**: the white matter is less vascular and is composed chiefly of **nerve-fibres.** Until recently it was the custom to regard nerve-cells and nerve-fibres as definitely distinct elements, but we now know that nerve-fibres are processes of nerve-cells. One process, several processes, or many processes come off from nerve-cells. If there is but one process from a cell, that process becomes **Deiters' process,** the **axis-cylinder** or **axone** of a nerve-fibre. If more than one process comes off from a cell, one of the processes becomes an axone, and the other processes are known as **protoplasmic** or **dendritic processes,** or, as His named

[1] The Nervous System and its Diseases. By Charles K. Mills.

them, **dendrites**. There are no nerve-fibres unconnected with cells. The nerve-cell, with its axone and its dendrites, constitutes what is called a **nerve-unit** or **neurone**. The nervous system is said to be composed of aggregations of multitudes of neurones. The term neurone was devised by Waldeyer in 1891.

Gray, vesicular, or **cineritious substance** is of a dark, reddish-gray color and of a soft consistence. It is found in the spinal cord, brain, and various ganglia, in some of the nerves of special sense, and in gangliform enlargements in the course of certain spinal nerves. It is composed of nerve-cells and contains blood-vessels, both the cells and vessels being embedded in a ground substance named by Virchow the **neuroglia.** The nerve-fibres and the vessels in the white substance are also embedded in neuroglia. Neuroglia consists of fibres and neuroglia cells. Some of the cells are stellate in shape and their fine processes become neuroglia-fibres, which extend radially and unbranched (Fig. 513 *B*) among the nerve-cells and fibres, which they aid in supporting. Other cells give off fibres, which branch repeatedly (Fig. 513 *A*).

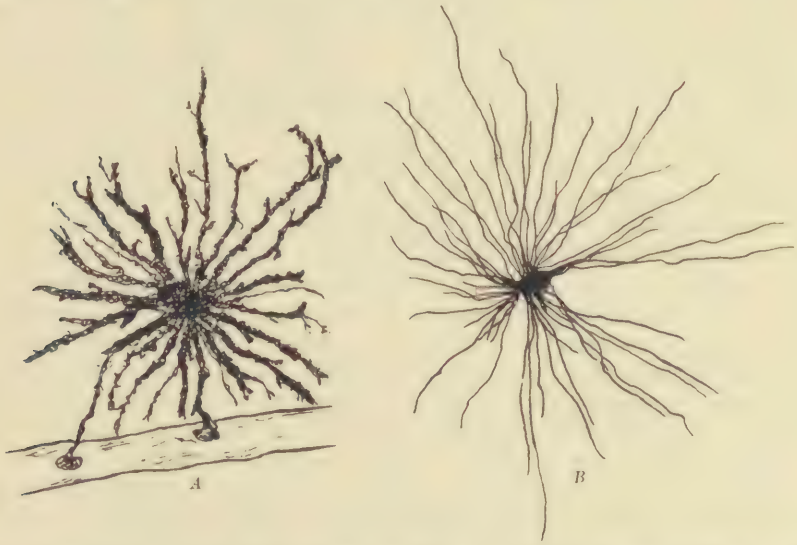

FIG. 513.—Neuroglia-cells of brain shown by Golgi's method. *A*. Cell with branched processes. *B*. Spider-cell with unbranched processes. (After Andriezen.) (Copied from Schäfer's Essentials of Histology.)

In addition to these fibres there are others which do not appear to be connected with the neuroglia-cells. They start from the *lining ependymal cells*, that is, the epithelial cells lining the ventricles of the brain and central canal of the spinal cord, and pass through the nervous tissue, branching repeatedly, to terminate in slight enlargements on the pia mater. Thus, neuroglia is evidently a connective tissue in function, though it is not in development; it is epiblastic in origin, whereas all true connective tissues are mesoblastic.

The **white** or **fibrous tissue** is composed of nerve-fibres, which, with blood-vessels, are embedded in neuroglia.

Nerve-cells or the Cell-bodies of the Neurones (Figs. 514, 515, 516, 517, 518, and 519).—Nerve-cells constitute the essential element of nervous tissue. They are the originators of nervous impulses and impressions. All nervous conduction is from nerve-cell to nerve-cell by contact (Mills), and the transmission of an impulse from one nerve-cell to another may be over a long distance. The nerve-cells of the brain and cord differ in origin, development, and connections from the nerve-cells of the spinal ganglia. They vary greatly in shape and size (Fig. 515). Some are so small that they become visible only under a microscope of high

power; some "almost come within the range of unaided vision."[1] The largest cells are found in the anterior cornua of the spinal cord, in the vesicular columns of Clarke, in the large pyramidal cell-layer of the cerebral cortex, and the Purkinjean cell-layer of the cerebellum. The smallest cells are in the olfactory bulbs, in the substantia gelatinosa Rolandi of the cord, and in the granular cortical layers of the cerebrum and cerebellum.

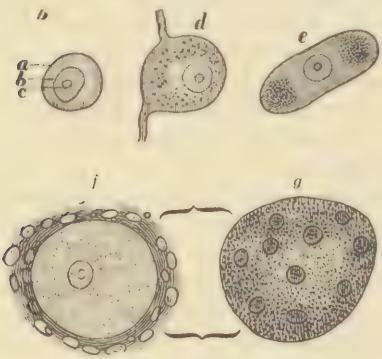

FIG. 514.—Nerve-cells from the Gasserian ganglion of the human subject. *a*. A globular one with defined border. *b*. Its nucleus. *c*. Its nucleolus. *d*. Caudate cell. *e*. FIG. 516.—Bipolar nerve-cells from the spinal ganglion of the pike. (After Kölliker.)

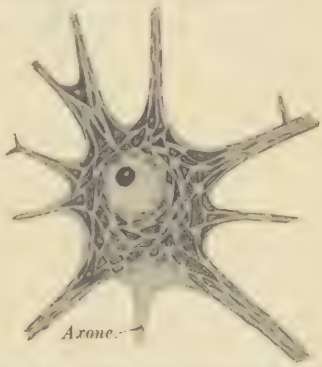

FIG. 517.—Motor nerve-cell from ventral horn of spinal cord of rabbit. The angular and spindle-shaped Nissl bodies are well shown. (After Nissl.)

The **Body** of the nerve-cell may possess a limiting membrane, as is seen in the cells of the spinal ganglia (Fig. 516) and sympathetic ganglia, and some of the cells of the Gasserian ganglion (Figs. 514, *f* and *g*), but may be devoid of any limiting membrane, as is seen in the motor cells of the anterior cornua of the cord (Fig. 517). All cell-bodies, like all cell-processes, show intracellular fibrillation, and the fibrils of the cell-body are continuous with those of the axone and run in

[1] Text-book of Anatomy. By Prof. D. J. Cunningham.

various directions. The cell-body is composed of protoplasm, which contains, besides fibrils, many fine spindle-shaped granules. The granules stain deeply and are called **chromatophile granules, Nissl's bodies,** or **trigoid bodies** (Fig. 517). They are probably nucleo-albumins (Held). Most nerve-cells, certainly most large nerve-cells, possess considerable pigmented material, a nucleus, and a nucleolus.

The nucleus (Fig. 514 *b*) is, as a rule, a large, well-defined, round, vesicular body, often presenting an intranuclear network. It contains a nucleolus (Fig. 514 *c*), which is peculiarly clear and brilliant. Pigment granules (Fig. 514 *e*), when present, lie by the side of the nucleus. Masses of pigment are present in the cells of the substantia nigra and locus cæruleus.

Nerve-cells are divided for purposes of study into three groups, according to the number of their processes.

1. **Unipolar Cells.**—The single process of such a cell, after a short course, divides in a T-shaped manner. Unipolar cells are found in the spinal ganglia of the adult and among the olfactory cells of mammals.

FIG. 518.—Pyramidal cell from the cerebral cortex of a mouse. (After Ramón y Cajal.)

FIG. 519.—Cell of Purkinje from the cerebellum of a cat. (After Ramón y Cajal.)

2. **Bipolar cells** (Fig. 516) are found in spinal ganglion-cells when the cells are in an embryonic condition. They are best demonstrated in the sympathetic ganglion-cells of a frog. Sometimes the processes come off from opposite poles of the cell, and the cell then assumes a spindle shape; in others they both emerge at the same point. In some cases where two fibres are apparently connected with a cell, one of the fibres is really derived from an adjoining nerve-cell and is passing to end in a ramification around the ganglion-cell, or, again, it may be coiled spirally around the nerve-process which is issuing from the cell.

3. **Multipolar cells** (Fig. 517) are caudate or stellate in shape, and are characterized by their large size and by the tail-like processes which issue from them. The processes are of two kinds: one of them is the axis-cylinder or axone; the others are the protoplasmic processes or dendrites.

The Axone (Figs. 515, 516, 517, 518, and 519).—The axone emerges from the nerve-cell by a slender stalk; it is smooth and free from Nissl's bodies; it maintains a uniform diameter for a considerable distance; it does not, as a rule, divide into branches, although it may possess collaterals, and it becomes the axis-cylinder of a nerve-fibre. Cerebro-spinal axones, as a rule, are medullated, except near their terminations. Sympathetic axones are non-medullated. Axones may be extremely short or may be several feet in length. The fibres of the pyramidal tract are axones of great length. Some short axones divide at their terminations into many branches. Short axones are called **dendraxones**, and the cells with dendraxones are called the **second type of Golgi cells**. An axone may remain throughout its entire course in the brain or cord or may enter into a spinal or cerebral nerve. Most cells possess but one axone, and such a neurone is called **monoaxonic**. A cell may possess two axones, the neurone being called **diaxonic**, or several axones, the neurone being called **polyaxonic**. The **collaterals** are branches given off from the neurone at right angles to it. Some axones have a number of collaterals; others do not have any. They are present everywhere in the central nervous system (Cajal, Kölliker). Some collaterals are medullated; others are not. They approach the dendrites of the nerve-cells of the neurones. Each axone and collateral ends in a button-like termination or **end-tuft**, or in a free arborization, the **end-brush**. If the termination is within the brain or cord, it may wrap around nerve-cells or arborize about dendrites. If the axone emerges from the cerebro-spinal axis, it terminates about muscle-cell or some other structure. The termination of the axone or the collateral is never continued into the structure about which it lies. It may surround that tissue; it may touch it; it may lie close against it, but the termination is free, and the relation is simply one of contact and not of continuity.

The Dendrites.—The dendrites are protoplasmic processes resembling in structure and staining reactions the protoplasm of the body of the cell. Each emerges by a thick base (**gemmule**), and divides into many fine branches, with free ends. They are not straight, are not smooth, and do not maintain the same diameter for a considerable distance as does the axis-cylinder. A dendrite may branch at any distance from the body of the cell, and the branches do not join. The dendrites from a single cell vary greatly in number, thickness, and length. Some cells are devoid of dendrites; some give off a few; some give off many. As a rule, they are non-medullated.

The Theory of Neurones.—This theory maintains that the nervous system is composed of a multitude of units called **neurones**. Each neurone consists of a cell and processes. The neurones in aggregation form cell groups and fibre systems. The connection of nerve-cells with other nerve-cells is not by continuity of structure. It is by contact and not by actual junction; it is physiological and not anatomical. "When fully developed in man, perhaps a very small number of neurones are united together by concrescence or protoplasmic bridges, but their predominant relation is certainly that of contact or synapsis."[1] Process comes in contact with process, or process with cell. The terminal tufts of the axone of a cortical motor-cell surround a cell in the anterior horn of the spinal cord, and this spinal cell sends out an axone, the termination of which reaches a muscle. Doubt has of late arisen as to the neurone theory, because of the investigations of Apáthy and others. Apáthy claims that ganglion cells join directly and that the ultimate

[1] Anatomy of the Brain and Nervous System. By Harris E. Santee.

elements of the nervous system are **neurofibrils**, which pass from cell to cell. However, as stated by Szymonowicz,[1] Apáthy's observations, even if correct, do not disprove the neurone theory, but indicate that the nervous units or neurones are occasionally connected by neurofibrils.

Nerve-fibres.—Nerve-fibres serve to conduct nervous impulses and bring nerve-cells into relation with each other and into relation with other structures. Nerves are composed of numbers of nerve-fibres bound into bundles. There are two sorts of fibres: **medullated** or **white** and **non-medullated** or **gray**.

The **Medullated** fibres form the white part of the brain and spinal cord, and also the greater part of the cerebro-spinal nerves, and gives to these structures their opaque, white aspect. When perfectly fresh they appear to be homogeneous; but soon after removal from the body they present, when examined by transmitted light, a double outline or contour, as if consisting of two parts (Figs. 520 and 521). The central portion is named the **axis-cylinder of Purkinje** (Fig. 521); around this is a sort of sheath of fatty material, staining black with osmic

Fig. 520. White or medullated nerve-fibres showing the sinuous outline and double contours. (After Schäfer.)

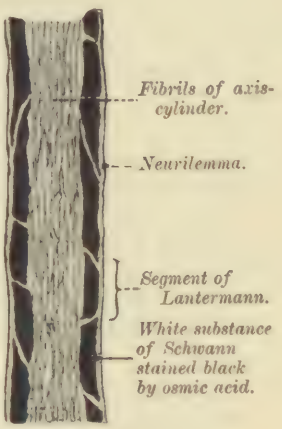

Fig. 521. Longitudinal section through a nerve-fibre from the sciatic nerve of a frog. × 830. (After Böhm and Davidoff.)

acid, named the **white substance of Schwann** (Fig. 521), which gives to the fibre its double contour, and the whole is enclosed in a delicate membrane, the **neurilemma, primitive sheath,** or **nucleated sheath of Schwann** (Fig. 521).

The **axis-cylinder** is the essential part of the nerve-fibre, and is always present; the other parts, the medullary sheath and the neurilemma, being occasionally absent, especially at the origin and termination of the nerve-fibre. It undergoes no interruption from its origin in the nerve-centre to its peripheral termination, and must be regarded as a direct prolongation of a nerve-cell. It constitutes about one-half or one-third of the nerve-tube, the whole substance being greater in proportion in the nerves than in the central organs. It is perfectly transparent, and is therefore indistinguishable in a perfectly fresh and natural state of the nerve. It is made up of exceedingly fine fibrils, which stain darkly with gold chloride (Fig. 521). At its termination the axis-cylinder of a nerve-fibre may be seen to break up into fibrillæ, confirming the accepted view of its structure. These fibrillæ have been termed the **primitive fibrillæ of Schultze**. The axis-cylinder is said

[1] Text-book of Histology and Microscopic Anatomy. By Dr. Ladislaus Szymonowicz. Translated and edited by John Bruce MacCallum, M.D.

by some to be enveloped in a special, reticular sheath, which separates it from the white matter of Schwann, and is composed of a substance called **neurokeratin**. The more common opinion is that this network or reticulum is contained in the white matter of Schwann, and by some it is believed to be produced by the action of the reagents employed to demonstrate it. The **medullary sheath** or **white substance of Schwann** (Fig. 521) is regarded as being fatty matter in a fluid state, which insulates and protects the essential part of the nerve—the axis-cylinder. The white matter varies in thickness to a very considerable extent, in some nerve-fibres forming a layer of extreme thinness, so as to be scarcely distinguishable; in others forming about one-half of the nerve-tube. The size of the nerve-fibres, which varies from $\frac{1}{2000}$ to $\frac{1}{120}$ of an inch, depends mainly upon the amount of the white substance, though the axis-cylinder also varies in size within certain limits. The white substance of Schwann does not always form a continuous sheath for the axis-cylinder, but undergoes interruptions in its continuity at regular intervals, giving to the fibre the appearance of constriction at these points. These constrictions were first described by Ranvier, and are known as the **nodes of Ranvier** (Fig. 522). The portion

FIG. 522.—A node of Ranvier of a medullated nerve-fibre, viewed from above, magnified about 750 diameters. The medullary sheath is discontinuous at the node, whereas the axis-cylinder passes from one segment into the other. At the node the sheath of Schwann appears thickened. (Klein and Noble Smith.)

of nerve-fibre between two nodes is called an **internodal segment**. The neurilemma or primitive sheath is not interrupted at the nodes, but passes over them as a continuous membrane. In addition to these interruptions oblique clefts may be seen in the medullary sheath, subdividing it into irregular portions, which are termed **medullary segments** or **segments of Lantermann** (Fig. 521). There is reason to believe that these clefts are artificially produced in the preparation of the specimens. Medullated nerve-fibres, when examined, frequently present a beaded or varicose appearance; this is due to manipulation and pressure causing the oily matter to collect into drops, and in consequence of the extreme delicacy of the primitive sheath, even slight pressure will cause the transudation of the fatty matter, which collects as drops of oil outside the membrane. This is, of course, promoted by the action of certain reagents.

The **neurilemma** or **primitive sheath**, sometimes called the **tubular membrane** or **sheath of Schwann** (Fig. 521), presents the appearance of a delicate, structureless membrane. Here and there beneath it, and situated in depressions in the white matter of Schwann, are nuclei surrounded by a small amount of protoplasm. The nuclei are oval and somewhat flattened, and bear a definite relation to the nodes of Ranvier; one nucleus generally lying in the centre of each internode. The primitive sheath is not present in all medullated nerve-fibres, being absent in those fibres which are found in the brain and spinal cord.

Non-medullated Fibres.—Most of the nerves of the sympathetic system, and some of the cerebro-spinal, consist of another variety of nervous fibres, which are called the **gray** or **gelatinous nerve-fibres**—**fibres of Remak** (Fig. 523). These consist of a central core or axis-cylinder enclosed in a nucleated sheath, which tends to split into fibrillæ, and is probably of the nature of neurokeratin. In external appearance the gelatinous nerves are semi-transparent and gray or yellowish-gray. The individual fibres vary in size, generally averaging about half the size of the medullated fibres.

Development of Nerve-cells and Fibres.—The nerve-cells are developed from certain of the cells which line the neural canal and form the neural crest of the embryo. Some of these cells assume a rounded form and are termed **neuroblasts**,

and from each neuroblast there grows out a process, the axis-cylinder process or axone, and subsequently the branching processes or dendrons. The axis-cylinders, at first naked, acquire their medullary sheaths, possibly by some metamorphosis of their outer layer. The neurilemma is thought to be derived from mesoblastic cells which become flattened and wrapped around the fibre, the cement-substance at their opposed ends forming the material which stains with silver nitrate at the nodes of Ranvier. Nerve-cells in the sympathetic and peripheral ganglia take their origin from small collections of neuroblasts, which are split off from the rudimentary spinal ganglia. Cells which are, originally, similar to neuroblasts seem to give rise to neuroglia-cells, numerous processes sprouting from the cell to form the neuroglial fibres.

Chemical Composition.—The amount of water in nervous tissue varies with the situation. Thus in the gray matter of the cerebrum it constitutes about 83 per cent., in the white matter from the same region about 70 per cent., while in the peripheral nerves, such as the sciatic, it may fall to 60 per cent. The solids consist of proteids (in the gray matter proteids constitute half the total solids), neurokeratin, nuclein, protagon, lecithin, cerebrosides, cholesterin, nitrogenous extractives, and salts, with some gelatin and fat from the adherent connective tissue.

FIG. 523.—A small nervous branch from the sympathetic of a mammal. *a*. Two medullated nerve-fibres among a number of gray nerve-fibres, *b*.

FIG. 524.—Transverse section through a microscopic nerve, representing a compound nerve-bundle, surrounded by perineurium. Magnified 120 diameters. The medullated fibres are seen as circles with a central dot—viz., medullary sheath and axis-cylinder—in transverse section. They are embedded in endoneurium, containing numerous nuclei, which belong to the connective-tissue cells of the latter. *p*. Perineurium, consisting of laminæ of fibrous connective tissues, alternating with flattened nucleated connective-tissue cells. *l*. Lymph-space between epineurium and surface of nerve-bundle. (Klein and Noble Smith.)

The nervous structures are divided, as before mentioned, into two great systems —viz., the **cerebro-spinal,** comprising the spinal cord and brain, the nerves connected with these structures and the ganglia situated on them; and the **sympathetic,** consisting of a double chain of ganglia and the nerves connected with them. All these structures require separate consideration; they are composed of the two kinds of nervous tissue above described, intermingled in various proportions, and having, in some parts, a very intricate arrangement.

The **nerves** are round or flattened cords, formed of a number of nerve-fibres. They are connected at one end with the cerebro-spinal centre or with the ganglia, and are distributed at the other end to the various textures of the body; they are subdivided into two great classes—the **cerebro-spinal,** which proceed from the cerebro-spinal axis, and the **sympathetic** or **ganglionic nerves,** which proceed from the ganglia of the sympathetic. The **cerebro-spinal nerves** consist of numerous

nerve-fibres collected together and enclosed in a membranous sheath (Fig. 524). A small bundle of primitive fibres, enclosed in a tubular sheath, is called a **funiculus**: if the nerve is of small size, it may consist only of a single funiculus; but if large, the funiculi are collected together into larger bundles or fasciculi, which are bound together in a common membranous investment.

In structure the common membranous investment, or **sheath** of the whole nerve, which is called the **epineurium**, as well as the **septa** given off from it, and which separate the fasciculi, consists of connective tissue, composed of white and yellow elastic fibres, the latter existing in great abundance. The tubular sheath of the funiculi, called the **perineurium**, consists of a fine, smooth, transparent membrane, which may be easily separated, in the form of a tube, from the fibres it encloses; in structure it consists of connective tissue, which has a distinctly lamellar arrangement, being composed of several lamellæ, separated from each other by spaces containing lymph. The nerve-fibres are held together and supported within the funiculus by delicate connective tissue called the **endoneurium**. It is continuous with septa which pass inward from the innermost layer of the perineurium, and consists of a ground-substance in which are embedded fine bundles of fibrous connective tissue which run for the most part longitudinally. It serves to support the capillary vessels, which are arranged so as to form a network with elongated meshes. The cerebro-spinal nerves consist almost exclusively of medullated nerve-fibres the non-medullated existing in very small proportions.

The *blood-vessels* supplying a nerve terminate in a minute capillary plexus, the vessels composing which pierce the perineurium and run, for the most part, parallel with the fibres; they are connected together by short, transverse vessels, forming narrow, oblong meshes, similar to the capillary system of muscle. Fine non-medullated nerve-fibres accompany these capillary vessels, the **vaso-motor fibres**, and break up into elementary fibrils, which form a network around the vessel. Horsley has also demonstrated certain medullated fibres as running in the epineurium and terminating in small spheroidal tactile corpuscles or end-bulbs of Krause. These nerve-fibres, which Marshall believes to be sensory, and which he has termed **nervi nervorum**, are considered by him to have an important bearing upon certain neuralgic pains.

Nerves, in their course, subdivide into branches, and these frequently communicate with branches of a neighboring nerve.

The nerve-fibres, as far as is at present known, do not coalesce, but pursue an uninterrupted course from the centre to the periphery. In separating a nerve, however, into its component funiculi, it may be seen that they do not pursue a perfectly insulated course, but occasionally join at a very acute angle with other funiculi proceeding in the same direction; from this, branches are given off, to join again in like manner with other funiculi. It must be distinctly understood, however, that in these communications the nerve-fibres do not coalesce, but merely pass into the sheath of the adjacent nerve, become intermixed with its nerve-fibres, and again pass on, to become blended with the nerve-fibres in some adjoining funiculus.

The communications which take place between two or more nerves form what is called a **plexus**. Sometimes a plexus is formed by the primary branches of the trunks of the nerves—as the cervical, brachial, lumbar, and sacral plexuses—and occasionally by the terminal funiculi, as in the plexuses formed at the periphery of the body. In the formation of a plexus the component nerves divide, then join, and again subdivide in such a complex manner that the individual funiculi become interlaced most intricately; so that each branch leaving a plexus may contain filaments from each of the primary nervous trunks which form it. In the formation also of smaller plexuses at the periphery of the body there is a free interchange of the funiculi and primitive fibres. In each case, however, the

individual filaments remain separate and distinct, and do not inosculate with one another.

It is probable that through this interchange of fibres the different branches passing off from a plexus have a more extensive connection with the spinal cord than if they each had proceeded to be distributed without such connection with other nerves. Consequently the parts supplied by these nerves have more extended relations with the nervous centres; by this means, also, groups of muscles may be associated for combined action.

The **sympathetic nerves** are constructed in the same manner as the cerebro-spinal nerves, but consist mainly of non-medullated fibres, collected into funiculi, and enclosed in a sheath of connective tissue. There is, however, in these nerves a certain admixture of medullated fibres (Fig. 523), and the amount varies in different nerves, and may be known by their color. Those branches of the sympathetic which present a well-marked gray color are composed more especially of gelatinous nerve-fibres, intermixed with a few medullated fibres; while those of a white color contain more of the latter fibres and a few of the former. Occasionally, the gray and white cords run together in a single nerve, without any intermixture, as in the branches of communication between the sympathetic ganglia and the spinal nerves, or in the communicating cords between the ganglia.

The nerve-fibres, both of the cerebro-spinal and sympathetic system, convey impressions of a twofold kind. The sensory nerves, called also **centripetal** or **afferent nerves**, transmit to the nervous centres impressions made upon the peripheral extremities of the nerves, and in this way the mind, through the medium of the brain, becomes conscious of external objects. The **motor nerves**, called also **centrifugal** or **efferent nerves**, transmit impressions from the nervous centres to the parts to which the nerves are distributed, these impressions either exciting muscular contraction, or influencing the processes of nutrition, growth, and secretion.

Origin and Termination of Nerves.—By the expression "the termination of nerve-fibres" is signified their connection with the nerve-centres, and with the parts they supply. The former are sometimes called their **origin**, or **central termination**; the latter their **peripheral termination**. The origin in some cases is single—that is to say, the whole nerve emerges from the nervous centre by a single root; in other instances the nerve arises by two or more roots, which come off from different parts of the nerve-centre, sometimes widely apart from each other, and it often happens, when a nerve arises in this way by two roots, that the functions of these two roots are different; as, for example, in the spinal nerves, each of which arises by two roots, the anterior of which is motor and the posterior sensory. The point where the nerve-root or roots emerge from the nervous centre is named the **superficial** or **apparent origin**, but the fibres of which the nerve consists can be traced for a certain distance into the nervous centre to some portion of the gray substance, which constitutes the **deep** or **real origin** of the nerve.

The manner in which these fibres arise at their deep origin varies with their functions. The centrifugal or efferent nerve-fibres originate in the nerve-cells of the gray substance, the axis-cylinder processes of these cells being prolonged to form the fibres. In the case of the centripetal or afferent nerves the fibres grow inward either from nerve-cells in the organs of special sense (*e. g.*, the retina) or from nerve-cells in the ganglia. Having entered the nerve-centre, they branch and send their ultimate twigs among the cells, without, however, uniting with them.

Peripheral Terminations of Nerves.—Nerve-fibres terminate peripherally in various ways, and these may be conveniently studied in the sensory and motor nerves, respectively. **Sensory nerves** would appear to terminate either in minute primitive fibrillæ or networks of fibrillæ; or else in special terminal organs, which

have been termed **peripheral end-organs**, and of which there are several principal varieties—viz., the **end-bulbs of Krause**, the **tactile corpuscles of Wagner**, the **Pacinian corpuscles**, and the **neuro-tendinous** and **neuro-muscular spindles.**

Termination in Fibrillæ.—When a medullated nerve-fibre approaches its termination, the white matter of Schwann suddenly disappears, leaving only the axis-cylinder, surrounded by the neurilemma, and forming a non-medullated fibre. This, after a time, loses its neurilemma, and consists only of an axis-cylinder, which can be seen, in preparations stained with chloride of gold, to be made up of fine varicose fibrils. Finally, the axis-cylinder breaks up into its constituent primitive nerve-fibrillæ, which often present regular varicosities and anastomose with one another, thus forming a network. This network passes between the elements of the tissue to which the nerves are distributed, which is always epithelial, the nerve-fibrils lying in the interstitial substance between the epithelial cells, and there terminating, though some observers maintain that the actual terminations are within the cells. In this way nerve-fibres have been found to terminate in the epithelium of the skin and mucous membranes, and in the anterior epithelium of the cornea.

The **End-bulbs of Krause** (Fig. 525) are minute cylindrical or oval bodies, consisting of a capsule formed by the expansion of the connective-tissue sheath of a medullated fibre, and containing a soft semifluid core in which the termination of the axis-cylinder is situated, ending either as a bulbous extremity, or in a coiled-up plexiform mass. End-bulbs are found in the conjunctiva of the eye, where they are spheroidal in shape in man, but cylindrical in most other animals, in the mucous membrane of the lips and tongue, and in the epineurium of nerve-trunks. They are also found in the genital organs of both sexes, the penis in the male, and the clitoris in the female. In this situation they have a mulberry-like appearance, from being constricted by connective-tissue septa into from two to six knob-like masses, and have received the name of **genital corpuscles.** Very similar corpuscles are found in the epineurium of nerve-trunks. In the synovial membrane of certain joints (*e. g.*, those of the fingers) rounded or oval end-bulbs have been found; these are designated **articular end-bulbs.**

Tactile Corpuscles, known as Grandry's corpuscles, have been described by Grandry as occurring in the papillæ of the beak and tongue of birds, and by Merkel as occurring in the papillæ and epithelium of the skin of man and animals,

especially in those parts of the skin devoid of hair. They consist of a capsule composed of a very delicate, nucleated membrane, and contain two or more granular, somewhat flattened cells, between which the medullated nerve-fibre, which enters the capsule by piercing its investing membrane, is supposed to terminate.

Meissner's corpuscles are the tactile corpuscles (Fig. 526), described by Wagner and Meissner. They are oval-shaped bodies, made up of connective tissue, and consisting of a capsule, and imperfect membranous septa, derived from it, which penetrate its interior. The axis-cylinder of the medullated fibres passes through the capsule, and having entered the corpuscle terminates in a small globular or pyriform enlargement, near the inner surface of the capsule. These tactile corpuscles have been described as occurring in the papillæ of the corium of the skin, hand, foot, front of the forearm, and skin of the lips, and the mucous membrane of the tip of the tongue, the palpebral conjunctiva, and the skin of the nipple. They are not found in all the papillæ, but from their existence in those parts in which the skin is highly sensitive, it is probable that they are especially concerned in the sense of touch, though their absence from the papillæ of other tactile parts shows that they are not essential to this sense. They may be regarded as end-bulbs.

Ruffini has described a special variety of nerve-ending in the subcutaneous tissue of the human finger (Fig. 527). These are usually known as **Ruffini's**

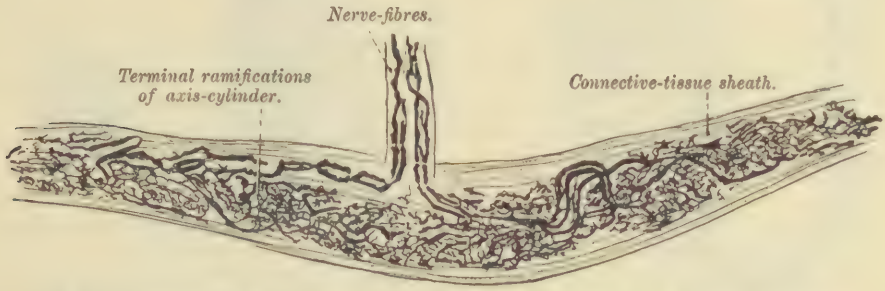

Fig. 527.—Nerve-ending of Ruffini. (After A. Ruffini, Arch. ital. de Biol., Turin, 1894, t. xxi.)

nerve-endings. They are principally situated at the junction of the corium with the subcutaneous tissue; they are oval in shape, and consist of a strong connective-tissue sheath, inside which the nerve-fibre divides into numerous branches, which show varicosities and end in small free knobs. They resemble the corpuscles of Golgi.

The **Pacinian Corpuscles** or **Corpuscles of Vater** (Fig. 528) are found in the human subject chiefly on the nerves of the palm of the hand and sole of the foot and in the genital organs of both sexes, lying in the subcutaneous tissue; but they have also been described as connected with the nerves of the joints, and in some other situations in the lower animals, as the mesentery of the cat and along the tibia of the rabbit. Each of these corpuscles is attached to and encloses the termination of a single nerve-fibre. The corpuscle which is perfectly visible to the naked eye (and which can be most easily demonstrated in the mesentery of a cat) consists of a number of lamellæ or capsules, arranged more or less concentrically around a central clear space, in which the nerve-fibre is contained. Each lamella is composed of bundles of fine connective-tissue fibres, and is lined on its inner surface by a single layer of cells. The central clear space, which is elongated or cylindrical in shape, is filled with a transparent material, in the middle of which is the single medullated fibre, which traverses the space to near its distal extremity. Here it terminates in a rounded knob or end, sometimes bifurcating previously, in which case each branch has a similar

arrangement. Todd and Bowman have described minute arteries as entering by the sides of the nerves and forming capillary loops in the intercapsular spaces, and even penetrating into the central space. Other authors describe the artery as entering the corpuscle at the pole opposite to the nerve-fibre.

Herbst has described a somewhat similar "nerve-ending" to the Pacinian corpuscle, as being found in the mucous membrane of the tongue of the duck and in some other situations. It differs, however, from the Pacinian corpuscles in being smaller, its capsules thinner and more closely approximated, and especially in the fact that the axis-cylinder in the central clear space is coated with a continuous row of nuclei. These bodies are known as the **corpuscles of Herbst.**

FIG. 528.—Pacinian corpuscle, with its system of capsules and central cavity. *a*. Arterial twig, ending in capillaries, which form loops in some of the intercapsular spaces, and one penetrates to the central capsule. *b*. The fibrous tissue of the stalk prolonged from the perineurium. *n*. Nerve-tube advancing to the central capsule, there losing the white matter, and stretching along the axis to the opposite end, where it is fixed by a tuberculous enlargement.

Neuro-tendinous Spindles.—The nerves supplying tendons have a special modification of the terminal fibres, especially numerous at the point where the tendon is becoming muscular. The tendon bundles become enlarged, and the nerve-fibres—one, two, or more in number—penetrate between the fasciculi of the tendon and spread out between the fibres to end in irregular disks or varicosities. A spindle-shaped body is thus formed, composed of tendon bundles and nerve-fibres, which is known as the **organ of Golgi** (Fig. 529).

Neuro-muscular Spindles. — In the majority of voluntary muscles there have been found special end-organs consisting of a small bundle of peculiar muscular fibres (intrafusal fibres), embryonic in type, invented by a capsule within which nerve-fibres, experimentally shown to be sensory in origin, terminate. These neuro-muscular spindles vary in length from $\frac{1}{30}$ to $\frac{1}{5}$ of an inch and have a distinctly fusiform appearance. The large medullated nerve-fibres passing to the end-organ are from one to three or four in number; entering the fibrous capsule

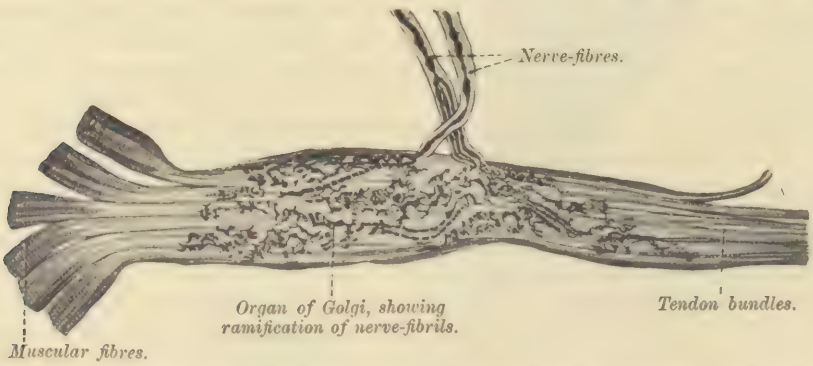

FIG. 529.—Organ of Golgi (neuro-tendinous spindle) from the human tendon Achillis. (After Ciaccio.)

they divide several times, and, losing their medulla, ultimately end in naked axis-cylinders encircling the intrafusal fibres by flattened expansions, or irregular ovoid

or rounded disks (Fig. 530). Neuro-muscular spindles have not yet been demonstrated in the tongue or eye muscles.

In the organs of **special sense** the nerves appear to terminate in cells which belong to the epithelial class, and have received the name of **sensory** or **nerve-epithelium cells**. This is not, however, the real state of the case; the nerve-fibre is in reality a process from the epithelial cell, and terminates by branching around a ganglion-cell. The stimulus carried by it is continued onward by an axis-cylinder, derived from the ganglion, to the brain. These nerve-epithelium cells must therefore be regarded as modified forms of nerve-cells. They will be more particularly described in connection with the description of the organs of special sense.

Motor nerves are to be traced either into unstriped or striped muscular fibres. In the **unstriped** or **involuntary muscles** the nerves are derived from the **sympa-**

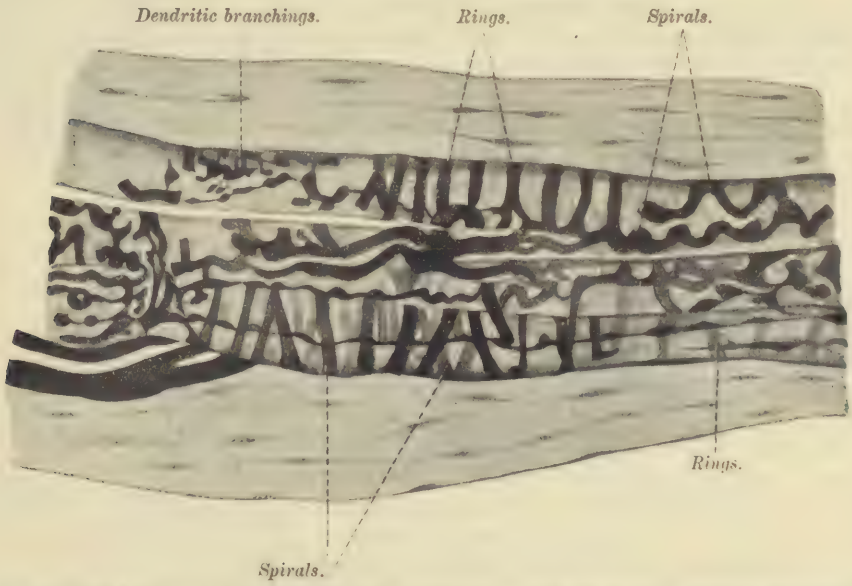

FIG. 530.—Middle third of a terminal plaque in the muscle spindle of an adult cat. (After Ruffini.)

thetic, and are composed mainly of the non-medullated fibres. Near their termination they divide into a number of branches, which communicate and form an intimate **plexus**. At the junction of the branches small triangular nuclear bodies, the ganglion-cells, are situated. From these plexuses minute branches are given off, which divide and break up into the **ultimate fibrillæ** of which the nerve is composed. These fibrillæ course between the involuntary muscle-cells, and, according to Elischer, terminate on the surface of the cell, opposite the nucleus, in a minute swelling. Arnold and Frankenhäuser believed that these ultimate fibrillæ penetrated the muscular cell and ended in the nucleus. More recent observation, however, has tended to disprove this.

In the **striped** or **voluntary muscle** the nerves supplying the muscular fibres are derived from the **cerebro-spinal nerves**, and are composed mainly of medullated fibres. The nerve, after entering the sheath of the muscle, breaks up into fibres, or bundles of fibres, which form **plexuses**, and gradually divide until, as a rule, a single nerve-fibre enters a single muscular fibre. Sometimes, however, if the muscular fibre is long, more than one nerve-fibre enters it. Within the muscular fibre the nerve-fibre terminates in a special expansion, called by Kuhne, who first

accurately described it, the **motorial end-plates** (Fig. 531).[1] The nerve-fibre, on approaching the muscular fibre, suddenly loses its white matter of Schwann, which abruptly terminates; the neurilemma becomes continuous with the sarco-

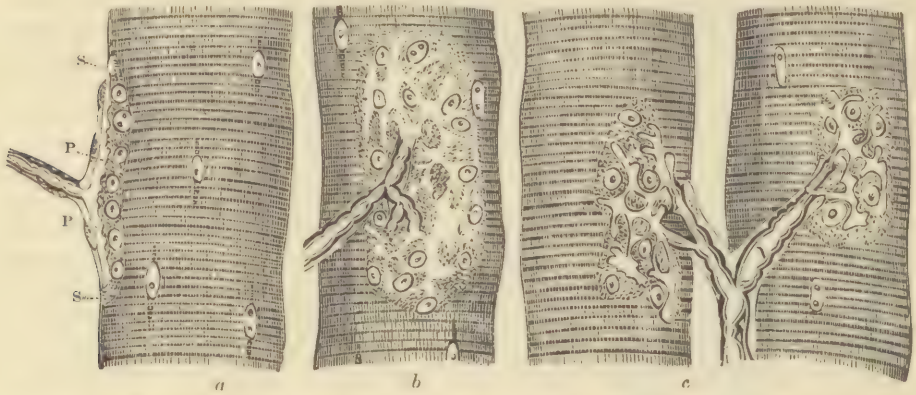

FIG. 531.—Muscular fibres of *Lacerta viridis* with the terminations of nerves. *a*. Seen in profile. P P. The nerve end-plates. S S. The base of the plate, consisting of a granular mass with nuclei. *b*. The same as seen in looking at a perfectly fresh fibre, the nervous ends being probably still excitable. (The forms of the variously divided plate can hardly be represented in a wood-cut by sufficiently delicate and pale contours to reproduce correctly what is seen in nature.) *c*. The same as seen two hours after death from poisoning by curare.

lemma of the muscle, and only the axis-cylinder enters the muscular fibre, where it immediately spreads out, ramifying like the roots of a tree, immediately beneath the sarcolemma, and is embedded in a layer of granular matter, containing a number of clear, oblong nuclei, the whole constituting an end-plate from which the contractile wave of the muscular fibre is said to start.

The **Ganglia** may be regarded as separate small aggregations of nerve-cells, connected with each other, with the cerebro-spinal axis, and with the nerves in various situations. They are found on the posterior root of each of the spinal nerves; on the posterior or sensory root of the fifth cranial nerve; on the facial and auditory nerves; and on the glosso-pharyngeal and pneumogastric nerves. They are also found in a connected series along each side of the vertebral column, forming the trunk of the sympathetic; and on the branches of that nerve, generally in the plexuses or at the point of junction of two or more nerves with each other or with branches of the cerebro-spinal system. On section they are seen to consist of a reddish-gray substance, traversed by numerous white nerve-fibres; they vary considerably in form and size; the largest are found in the cavity of the abdomen; the smallest, not visible to the naked eye, exist in considerable numbers upon the nerves distributed to the different viscera.

FIG. 532. Section through a microscopic ganglion. Magnified 300 diameters. *c*. Capsule of the ganglion. *n*. Nerve-fibres passing out of the ganglion. The nerve-fibres which entered the ganglion are not represented. The nerve-fibres are ordinary medullated fibres, but the details of their structure are not shown, owing to the low magnifying power. The ganglion-cells are invested by special capsules, lined by a few nuclei, which are here represented as if contained *in* the capsule. (Klein and Noble Smith.)

[1] They had, however, previously been noticed, though not accurately described, by Doyère, who named them "nerve-hillocks."—ED. of 15th English edition.

The ganglia are invested by a smooth and firm, closely adhering membranous envelope, consisting of dense areolar tissue; this sheath is continuous with the perineurium of the nerves, and sends numerous processes into the interior of the ganglion, which support the blood-vessels supplying its substance.

In structure all ganglia are essentially similar (Fig. 532), consisting of the same structural elements as the other nervous centres—viz., a collection of nerve-cells and nerve-fibres. Each nerve-cell has a nucleated sheath, which is continuous with the sheath of the nerve-fibre with which the cell is connected. The nerve-cells in the ganglia of the spinal nerves are pyriform in shape, and have only one process, the axis-cylinder or axone. A short distance from the cell, and while still within the ganglion, this process divides in a T-shaped manner, one limb of the cross-bar passing centrally and forming the central portion of a sensory nerve-fibre; the other limb passing peripherally to form the axis-cylinder process of the peripheral nerve-fibre. In the sympathetic ganglia the nerve-cells are multipolar and have one axis-cylinder process or axone and several protoplasmic processes or dendrons. The former of these emerges from the ganglion as a non-medullated nerve-fibre. Similar cells are found in the ganglia connected with the fifth cranial nerve, and these ganglia are therefore regarded by some as the cranial portions of the sympathetic system. The nerve-cells are disposed in the ganglia in groups of varying size, and these groups are separated from each other by bundles of nerve-fibres, some of which traverse the ganglia without being connected with the cells.

THE CEREBRO-SPINAL AXIS.

The cerebro-spinal axis consists of the **spinal cord** and the **brain** or **encephalon**, which are contained within the skull and spinal canal. The spinal cord and its coverings will be first considered, and then the brain and its membranes.

THE SPINAL CORD AND ITS MEMBRANES.

Dissection.—To dissect the cord and its membranes it will be necessary to lay open the whole length of the spinal canal. For this purpose the muscles must be separated from the vertebral grooves, so as to expose the spinous processes and laminæ of the vertebræ; and the latter must be sawed through on each side, close to the roots of the transverse processes, from the third or fourth cervical vertebra above to the sacrum below. The vertebral arches having been displaced by means of a chisel and the separate fragments removed, the dura mater will be exposed, covered by a plexus of veins and a quantity of loose areolar tissue, often infiltrated with serous fluid. The arches of the upper vertebræ are best divided by means of a strong pair of cutting bone-forceps.

MEMBRANES OF THE CORD.

The membranes which envelop the spinal cord are three in number. The most external is the **dura mater**, a strong fibrous membrane which forms a loose sheath around the cord. The most internal is the **pia mater**, a cellulo-vascular membrane which closely invests the entire surface of the cord. Between the two is the **arachnoid membrane**, a non-vascular membrane which envelops the cord and is connected to the pia mater by slender filaments of connective tissue.

The Spinal Dura Mater (Dura Mater Spinalis) (Figs. 533, 534, 535, 537).

The spinal dura mater represents only the meningeal or supporting layer of the cranial dura mater. The endocranial or endosteal layer ceases at the foramen magnum posteriorly, but reaches as low as the third cervical vertebra in front; below these levels its place is taken by the periosteum. The dura mater forms a

loose sheath which surrounds the cord and the cauda equina, and is loosely connected with the vertebral periosteum and the ligaments by a quantity of lax areolar tissue and a plexus of veins, the **meningo-rachidian veins** (*plexus venosi vertebrales interni*). The space containing the fat and veins is called the **epidural space** (*cavum epidurale*). The situation of the veins between the dura mater and the periosteum of the vertebræ corresponds therefore to that of the cranial sinuses between the endocranial and supporting layers. The dura is attached to the circumference of the foramen magnum and to the axis and third cervical vertebra; it is also fixed to the posterior common ligament, especially near the lower end of the spinal canal, by fibrous slips; it extends below as far as the second or third piece of the sacrum; here it becomes impervious, and, ensheathing the filum terminale, constitutes the **filum durae matris spinalis** (Fig. 537), and descends to the back of the coccyx, to blend with the periosteum. This part of the dura is called the **coccygeal ligament,**

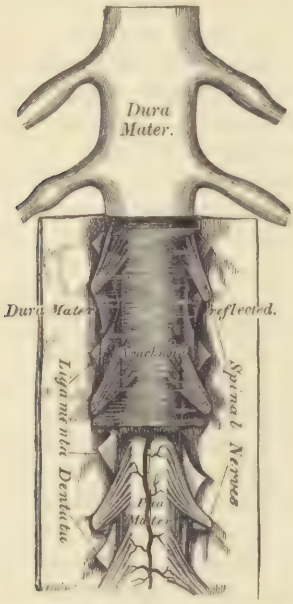

FIG. 533.—The spinal cord and its membranes.

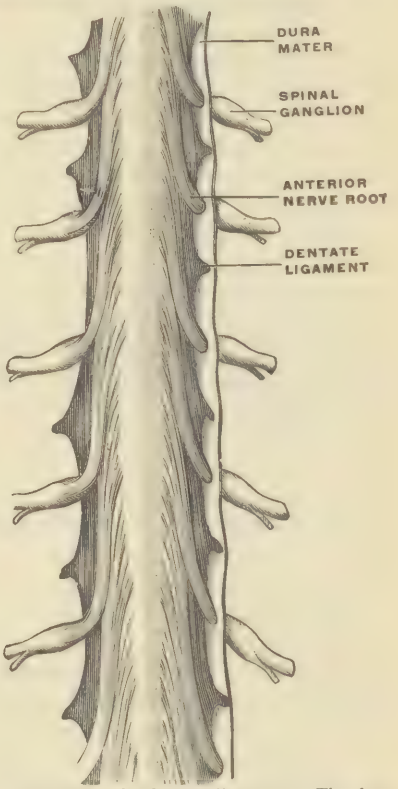

FIG. 534.—The dentate ligament. The dura mater has been opened and turned back. The anterior surface is seen. (Hirschfeld.)

(Fig. 537). The dura mater is much larger than is necessary for its contents, and its size is greater in the cervical and lumbar regions than in the dorsal. Its inner surface is smooth. On each side may be seen the double openings, which transmit the two roots of the corresponding spinal nerve, the fibrous layer of the dura mater being continued in the form of a tubular prolongation on them as they pass through these apertures. These prolongations of the dura mater are short in the upper part of the spine, but become gradually longer below, forming a number of tubes of fibrous membrane, which enclose the sacral nerves, and are contained in the spinal canal.

The chief peculiarities of the dura mater of the cord, as compared with that investing the brain, are the following:

The dura mater of the cord is not closely adherent to the bones of the spinal canal, and is not, as is the cerebral dura, the internal periosteum of the vertebræ. The vertebræ have an independent periosteum,

It does not send partitions into the fissures of the cord, as the cerebral dura sends partitions into certain fissures of the brain.

Its fibrous laminæ do not separate to form venous sinuses, as in the brain.

It contains no Pacchionian bodies.

Structure.—The dura mater consists of white fibrous and elastic tissue arranged in bands or lamellæ, which, for the most part, are parallel with one another and have a longitudinal arrangement. Each surface is covered by a layer of endothelial cells. It is sparingly supplied with vessels, and some few nerves have been traced into it.

The Arachnoid Membrane (Arachnoidea Spinalis) (Figs. 533, 535).

The arachnoid is exposed by slitting up the dura mater and reflecting that membrane to either side. It is a thin, delicate, tubular membrane which invests the surface of the cord, and is connected to the pia mater by slender filaments of connective tissue. Above, it is continuous with the cerebral arachnoid; on each side it is continued on the various nerves, so as to form a sheath for them as they pass outward to the intervertebral foramina. The outer surface of the arachnoid is in contact with the inner surface of the dura mater, and the two are, here and there, joined together by isolated connective-tissue trabeculæ. These trabeculæ are especially numerous on the posterior surface of the cord. For the most part, however, the membranes are not connected together, and the interval between them is named the **subdural space** (*cavum subdurale*). The subdural space contains a very small amount of lymph-like fluid. There is no communication between the subdural space and the subarachnoid space. The subdural space is prolonged outward for a short distance on each emerging nerve and communicates with the lymph tract of the nerve. The inner surface of the arachnoid is separated from the pia mater by a considerable interval, which is called the **subarachnoid** or **subarachnoidean space** (*cavum subarachnoideale*). The space is largest at the lower part of the spinal canal, and encloses the mass of nerves which form the cauda equina. Superiorly it is continuous with the cranial subarachnoid space, and communicates with the general ventricular cavity of the brain by means of openings in the pia mater, in the roof of the fourth ventricle, **foramen of Majendie** and **foramina of Key and Retzius** (p. 852). It contains an abundant serous secretion, the **cerebro-spinal fluid** (*liquor cerebro-spinalis*). This secretion is sufficient in amount to expand the arachnoid membrane, and thus to distend completely the whole of the space included in the dura mater. The subarachnoid space is occupied by trabeculæ of delicate endothelial covered connective tissue, connecting the pia mater on the one hand with the arachnoid membrane on the other. This is named **subarachnoid tissue.**

In addition to this the space is partially subdivided by a longitudinal membranous partition, the **septum posticum** or the **posterior fenestrated septum** (*septum subarachnoideale*), which serves to connect the arachnoid with the pia mater, opposite the posterior median fissure of the spinal cord. It is a partition, but an incomplete and cribriform partition, consists of bundles of white fibrous tissue interlacing with each other, and is coated with endothelium. The **ligamenta denticulata,** which run from the pia mater to the dura mater on either side of the cord, divide the subarachnoid space into an **anterior** and a **posterior space** (*cavum subarachnoideale anterius et posterius*), which join like spaces in the cavity of the cranium. The **medulli-spinal veins** (*venæ spinales externæ*) lie in the subarachnoid space.

Structure.—The arachnoid is a delicate membrane made up of closely arranged interlacing bundles of connective tissue in several layers. It con-

tains many elastic fibres, and is covered on each side by endothelial cells. The arachnoid contains neither vessels or nerves.

The Pia Mater of the Cord (Pia Mater Spinalis).

The pia mater of the cord is exposed on the removal of the arachnoid (Figs. 533 and 535). It covers the entire surface of the cord, to which it is very intimately adherent, forming its neurilemma, and sending a process downward into its anterior fissure. It also forms a sheath for each of the filaments of the spinal nerves, and invests the nerves themselves. A longitudinal fibrous band extends along the middle line on its anterior surface, called by Haller the **linea splendens**; and a somewhat similar band, the **ligamentum denticulatum**, is situated on each side. At the point where the cord terminates the pia mater becomes contracted, and is continued down as a long, slender filament, the **filum terminale** (Fig. 537), which descends within the sheath of the dura and the arachnoid and through the centre of the mass of nerves forming the *cauda equina*. It unites with the dura and arachnoid about the level of the third sacral vertebra, and as the **central ligament of the spinal cord**, the **coccygeal ligament**, or the **filum durae matris spinalis** the fused membranes extend downward as far as the base of the coccyx, where they blend with the periosteum. It assists in maintaining the cord in its position during the movements of the trunk. It contains a little gray nervous substance, which may be traced for some distance into its upper part, and is accompanied by a small artery and vein. At the upper part of the cord the pia mater presents a grayish, mottled tint, which is owing to yellow or brown pigment-cells scattered among the elastic fibres.

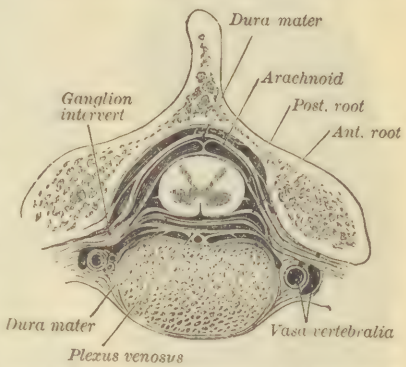

Fig. 535.—Transverse section of the spinal cord and its membranes. (Gegenbauer.)

Structure.—The pia mater of the cord is less vascular in structure, but thicker and denser, than the pia mater of the brain, with which it is continuous. It consists of two layers: an outer, resembling the arachnoid, composed of bundles of connective-tissue fibres, arranged for the most part longitudinally; and an inner (*intima pia*), consisting of stiff circular bundles of the same tissue, which present peculiar angular bends. It is covered on both surfaces by a layer of endothelium. Between the two layers are a number of cleft-like lymphatic spaces which communicate with the subarachnoid cavity, and a number of blood-vessels which are enclosed in a perivascular sheath, derived from the inner layer of the pia mater, into which the lymphatic spaces open. The pia mater contains the **anterior spinal artery** and its branches, the two **posterior spinal arteries**, and numerous veins which pass to the medulli-spinal veins. It is also supplied with nerves, which are derived in part from the **sympathetic** and in part from the **cerebro-spinal nerves**. These nerves supply the walls of the blood-vessels and enter the cord with the vessels.

The **Dentate Ligament** (*ligamentum denticulatum*) (Figs. 533 and 534) is a narrow fibrous band, situated on each side of the spinal cord, throughout its entire length, running from the pia mater to the dura mater, and separating the anterior from the posterior roots of the spinal nerves. It has received its name from the serrated appearance which it presents. Its inner border is continuous with the pia mater at the side of the cord. Its outer border presents a series of triangular, dentated serrations, the points of which are fixed at intervals to the dura mater. These

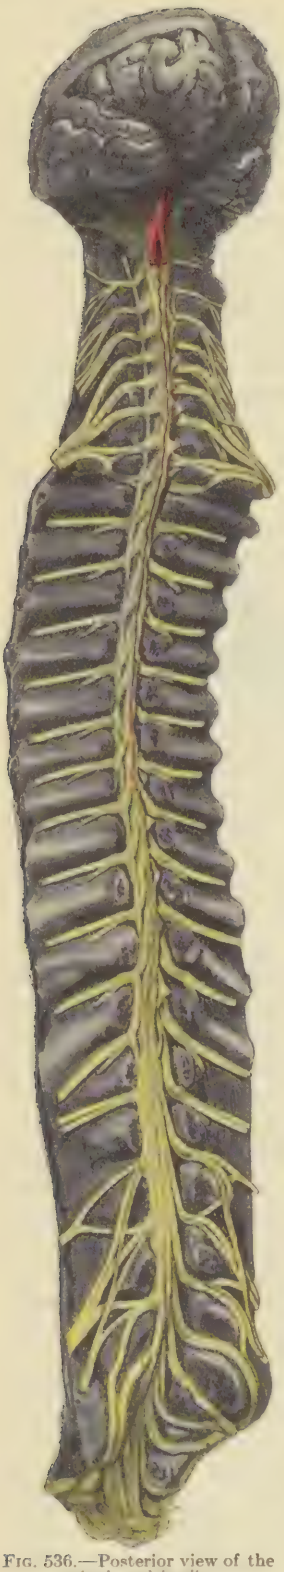

Fig. 536.—Posterior view of the spinal cord *in situ*.

serrations are twenty-one in number on each side, the first being attached to the dura mater, opposite the margin of the foramen magnum between the vertebral artery and the hypoglossal nerve, and the last near the lower end of the cord. Its use is to support the cord in the fluid by which it is surrounded.

Surgical Anatomy.—Evidence of value in the diagnosis of meningitis may be obtained by the operation of *lumbar puncture*, that is, by puncturing the theca of the cord and withdrawing some of the cerebro-spinal fluid, and the operation is regarded by some as curative, under the supposition that the draining away of the cerebro-spinal fluid relieves the patient by diminishing the intracranial pressure. Lumbar puncture may give important diagnostic aid after a head injury by disclosing bloody cerebro-spinal fluid. The operation is performed by inserting a trocar, of the smallest size, below the level of the fourth lumbar vertebra. In an adult the cord terminates at the lower border of the first lumbar vertebra, and in a child opposite the body of the third lumbar vertebra. The canal may be punctured below the fourth vertebra without any risk of injuring its contents. The point of puncture is indicated by laying the child on its side and dropping a perpendicular line from the highest point of the crest of the ilium; this will cross the upper border of the spine of the fourth lumbar vertebra. In a child the puncture is made just below the vertebral spine. In adults one-half an inch to one side of the end of the vertebral spine. However the preliminary puncture is made, the needle penetrates the dura in the middle line. In entering the needle it should be directed upward and forward in a child; upward, forward, and slightly inward in an adult.

THE SPINAL CORD (MEDULLA SPINALIS) (Fig. 536).

The spinal cord is the cylindrical, elongated part of the cerebro-spinal axis which is contained in the vertebral canal. Its length is usually about seventeen or eighteen inches, and its weight, when divested of its membranes and nerves, about one ounce and a half, its proportion to the encephalon being about 1 to 33. It does not nearly fill the canal in which it is contained, its investing membranes being separated from the surrounding walls by areolar tissue and a plexus of veins. It occupies, in the adult, the upper two-thirds of the vertebral canal, extending from the upper border of the atlas to the lower border of the body of the first lumbar vertebra, where it terminates in a slender filament of gray substance, which is continued for some distance into the filum terminale (Fig. 537). In the fœtus, before the third month, it extends to the bottom of the sacral canal, but after this period it gradually recedes from below, as the growth of the bones composing the canal is more rapid in proportion than that of the cord, so that in the child at birth the cord extends as far as the third lumbar vertebra. Its position varies also according to the degree of curvature of the spinal column, being raised somewhat in flexion of the spine. The spinal cord is cylindrical, being somewhat flattened

anteriorly and posteriorly (Fig. 538). On examining its surface it presents a difference in its diameter in different parts, being marked by two enlargements, an upper or cervical, and a lower or lumbar. The **cervical enlargement** (*intumescentia cervicalis*) extends from about the third cervical to the first or second dorsal vertebra; its greatest diameter is in the transverse direction (13 mm.), and it corresponds with the origin of the nerves which supply the upper extremities. The **lumbar enlargement** (*intumescentia lumbalis*) is situated opposite the last two or three dorsal vertebræ, and corresponds with the origin of the nerves which supply the lower extremities. Below the lumbar enlargement the cord gradually tapers to form a cone, the **conus terminalis** (*conus medullaris*), the apex of which is continuous with the filum terminale.

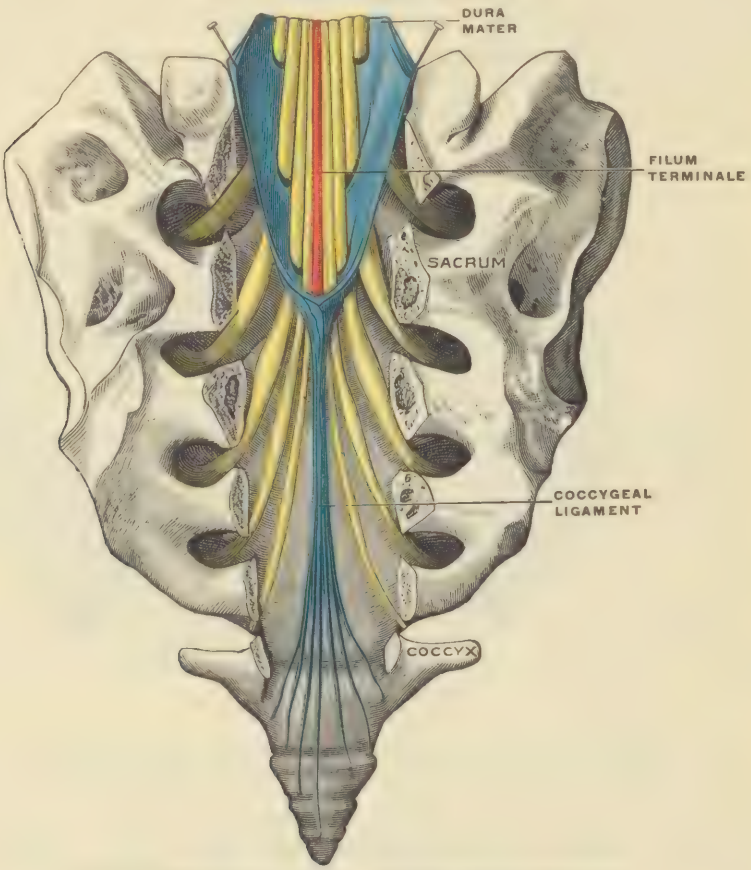

FIG. 537.—The filum terminale. (Poirier and Charpy.)

Fissures and Grooves (Fig. 538).—It presents on its anterior or ventral surface, along the middle line, a longitudinal fissure, the **anterior median** or **ventro-median fissure**, and on its posterior or dorsal surface another fissure, which also extends along the entire length of the cord, the **posterior median** or **dorso-median fissure** or **sulcus**. These fissures penetrate through the greater part of the thickness of the cord, and incompletely divide the cord into symmetrical halves, united in the middle line by a transverse band of nervous substance, the **commissure**.

The Anterior Median or Ventro-median Fissure (*fissura mediana anterior*) (Fig. 538).—The anterior median fissure is wider, but of less depth, than the posterior, extending into the cord for about one-third of its thickness, and is deepest at the

lower part of the cord. It contains a prolongation from the pia mater, and its floor is formed by the **anterior** or **white commissure**, which is perforated by numerous blood-vessels passing to the centre of the cord.

The Posterior Median or Dorso-median Fissure or Sulcus (*sulcus medianus posterior*) (Fig. 538).—The posterior median sulcus is not an actual fissure, as the space between the lateral halves of the posterior part of the cord is crossed by connective tissue and numerous blood-vessels, so that no actual hiatus exists, and there is consequently no prolongation of the pia mater into it. It extends into the cord to about one-half its width. The floor of the posterior median sulcus is formed by the **posterior or gray commissure**.

Lateral Fissures.—On each side of the posterior median fissure, along the line of attachment of the posterior roots of the nerves, a delicate fissure may be seen, leading down to the gray matter which approaches the surface in this situation; this is called the **postero-lateral** or **dorso-lateral sulcus** or **fissure of the spinal cord** (*sulcus lateralis posterior*). On the posterior surface of the spinal cord, between

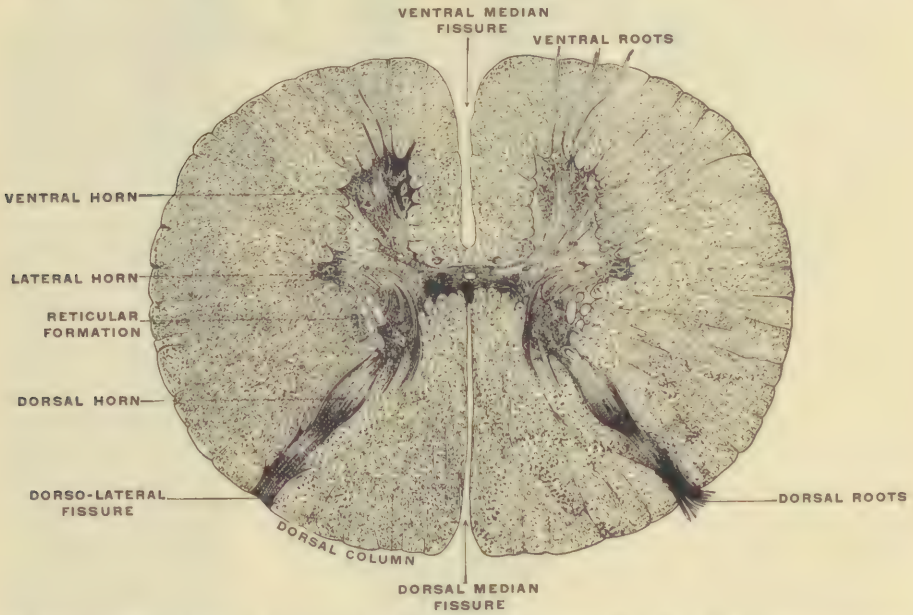

FIG. 538.—Transverse section of the spinal cord at the middle of the thoracic region. The neuroglia septum has been removed from between the dorsal columns. (Testut, after Pierret.)

the posterior median fissure and the postero-lateral fissure on each side, is a slight longitudinal furrow, the **posterior intermediate furrow** or the **posterior paramedian groove** (*sulcus intermedius posterior*), marking off two slender tracts, the **postero-median** and **postero-lateral columns**. These are most distinct in the cervical region, but are stated by Foville to exist throughout the whole length of the cord. On each side of the anterior median fissure the anterior roots of the spinal nerves emerge from the cord, not in one vertical line, but by separate bundles which occupy an area of some width. This is called, by some anatomists, the **antero-lateral fissure of the cord** (*sulcus lateralis anterior*), although no actual fissure exists in this situation.

Columns of the Cord (*funiculi medullae spinalis*) (Figs. 538 and 539).—Each half of the spinal cord is thus divided into four columns: an **anterior column**, a **lateral column**, a **posterior column**, and a **postero-median column**. This division, however, is very imperfect, since the limit between the so-called anterior and lateral columns cannot be defined on account of the bundles of the anterior roots being spread over

a considerable area. It is therefore customary to divide each half of the spinal cord into two columns, separated by the postero-lateral sulcus: (1) a small **posterior column** (*funiculus posterior*), which is bounded internally by the posterior median fissure, and externally by the postero-lateral sulcus, and the posterior column is subdivided by the posterior intermediate septum into an outer portion, the **column** or **tract of Burdach** (*fasciculus cuneatus*), and an inner portion, the **column** or **tract of Goll** (*fasciculus gracilis*); (2) a large **antero-lateral column,** which comprises the rest of the cord. The antero-lateral column is divided arbitrarily into the **lateral column** (*funiculus lateralis*) and the **anterior column** (*funiculus anterior*).

Structure of the Cord (Fig. 538).—If a transverse section of the spinal cord be made, it will be seen to consist of white and gray nervous substance. The white matter is situated externally, and constitutes the greater part. The gray substance occupies the centre, and is so arranged as to present on the surface of the section two crescentic masses, placed one in each lateral half of the cord, united together by a transverse band of gray matter, the **gray commissure.** Each crescentic mass has an **anterior** or **ventral horn** (*columna grisea anterior*) and a **posterior** or **dorsal horn** (*columna grisea posterior*). The **posterior horn** is long and narrow, and approaches the surface of the postero-lateral fissure, near which it presents a slight enlargement, the **caput cornu**; from this it tapers to form the **apex cornu** (*apex columna grisea posterior*), which at the surface of the cord becomes continuous with some of the fibres of the posterior roots of the spinal nerves. The constriction near the gray commissure is called the **cervix cornu** (*cervix columna grisea posterior*). The **anterior horn** is short and thick, and does not quite reach the surface, but extends toward the point of attachment of the anterior roots of the nerves. Its margin presents a dentate or stellate appearance. What is known as the **lateral horn** (*columna grisea lateralis*) projects from the outer aspect of the gray matter nearly on the line of the gray commissure. It is distinct in the upper dorsal region; in the cervical enlargement it is merged in the anterior horn, but it reappears in the upper cervical region. In the lumbar region it merges with the anterior horn. Owing to the projections toward the surface of the anterior and posterior horns of the gray matter, each half of the cord is divided by the gray matter, more or less completely, into three columns, anterior, middle, and posterior, the anterior and middle being joined to form the antero-lateral column, as the anterior horn does not quite reach the surface.

The Commissure of the Spinal Cord.—The commissure of the spinal cord is composed of white and gray matter, and is therefore divided into the **white** and **gray commissure.**

The **Anterior** or **White Commissure** (*commissura anterior alba*) is situated at the bottom of the anterior median fissure, and is formed of medullated nerve-fibres, which pass between the gray matter of the anterior horn and the anterior and lateral white columns of one side into similar parts on the other side. The fibres are oblique in direction; many which enter at the posterior part of the commissure on the one side leave it at the anterior part of the commissure on the other, and *vice versa*, a decussation taking place in the middle line.

The **Posterior** or **Gray Commissure** (*commissura grisea*), which connects the two crescentic masses of gray matter, is separated from the bottom of the anterior median fissure by the anterior white commissure. It consists of transverse medullated nerve-fibres, with a considerable quantity of neuroglia between them. The fibres when they reach the lateral crescents diverge: some pass backward to the posterior roots; others spread out, at various angles, into the crescent. The portion of the gray commissure in front of the central canal is called the **anterior gray commissure** (*commissura grisea anterior*); the portion behind the central canal is called the **posterior gray commissure** (*commissura grisea posterior*).

Running through the gray commissure of the whole length of the cord is a

minute canal, which is barely visible to the naked eye in the human cord, but is proportionately larger in some of the lower vertebrata. It is called the **central canal** (*canalis centralis*); it opens above into the fourth ventricle, and terminates below in a somewhat dilated extremity, the **inferior rhomboid fossa** (*fossa rhomboidea inferior*). It is surrounded by an area of neuroglia, which, in the recent state, has a gelatinous appearance, and in which there are no nerve-fibres. This is sometimes called the **substantia gelatinosa centralis**. When hardened in alcohol or chromic salts it has a finely reticulated appearance. The canal is lined in the fœtus by columnar ciliated epithelium, but in the adult the cilia have disappeared, and the canal is filled with their remains.

The mode of arrangement of the gray matter, and its amount in proportion to the white, vary in different parts of the cord. Thus, the posterior horns are long and narrow in the cervical region; short and narrower in the dorsal; short, but wider, in the lumbar region. In the cervical region the crescentic portions are small, and the white matter more abundant than in any other region of the cord. In the dorsal region the gray matter is least developed, the white matter being also small in quantity. In the lumbar region the gray matter is more abundant than in any other region of the cord. Toward the lower end of the cord the white matter gradually ceases. The crescentic portions of the gray matter soon blend into a single mass, which forms the only constituent of the extreme point of the cord.

Blood Supply of the Cord.—Spinal branches are given off by the **vertebral, ascending cervical, deep cervical, intercostal, lumbar, lumbar branches of the ilio-lumbar, lateral** and **middle sacral arteries.**[1] Many of these spinal arteries give branches to the cord and the branches reach the cord in the spinal nerve-roots and form three vascular chains in the cord. The **arteries** of the cord are the **anterior spinal** and the **two posterior spinal,** which take origin from the vertebral arteries (pp. 638 and 639). The anterior spinal lies at the surface of the anterior median fissure. The posterior spinal arteries descend on either side of the cord behind the posterior nerve-roots. The central supply of the cord is chiefly from the anterior spinal artery. It sends **sulcal branches** inward in the fissure toward the cord, and branches of these vessels enter the cord. The vessels of the cord are terminal arteries. The gray matter is chiefly supplied by the anterior spinal, partly by the posterior spinal. The white matter is supplied by both vessels. From the interior of the cord blood is brought by **fissural veins** (which emerge from the fissures), **root-veins** (which emerge with the fibres of the anterior and posterior roots), and a few veins which emerge from different parts of the surface of the cord. These vessels unite to form the **medulli-spinal plexus,** which is between the pia mater and the arachnoid membrane. (See Spinal Veins.)

Lymphatics.—There are no lymph-vessels in the cord, but lymph is collected by perivascular lymph-spaces and by spaces about the nerve-fibres.

Minute Anatomy of the Cord.—The cord consists of an outer part, composed of medullated nerve-fibres, which is the **white substance**; and of a central part, the **gray matter,** both supported in a stroma.

The **stroma** is composed of **connective tissue,** which is derived from the pia by ingrowth, and hence is of mesodermic origin, and of **neuroglia.**

The Neuroglia.—The neuroglia consists of a homogeneous transparent matrix, of a network of very delicate fibrillæ, and of small stellate or branched cells, the **neuroglia-cells.**

It takes origin from cells which were derived from the large columnar cells of the wall of the neural canal, and hence is of epithelial origin.

[1] A Manual of Practical Anatomy. By the late Prof. Alfred W. Hughes. Edited and completed by Arthur Keith, M.D.

In addition to forming a ground substance, in which the nerve-fibres, nerve-cells, and blood-vessels are embedded, a considerable accumulation of neuroglia takes place in three situations: (1) on the surface of the cord, beneath the pia mater; (2) around the central canal, the **substantia gelatinosa centralis**; and (3) as a cap over the extremity of the posterior horn, forming the **substantia cinerea gelatinosa.**

The White Substance of the Cord (*substantia alba*).—The white substance of the cord is placed at the periphery and in the anterior commissure. It consists of medullated nerve-fibres, mostly disposed longitudinally, with blood-vessels and neuroglia, sustained by a network of connective tissue from the pia. When stained with carmine it presents a very striking appearance on transverse section. It is seen to be studded all over with minute dots, surrounded by white areas. This is due to the longitudinal medullated fibres seen on section. Each dot is an axis-cylinder, the white area about it is the substance of Schwann. Externally, the neuroglia forms a sheath closely investing the outer surface of the cord immediately beneath the pia mater; from it numerous septa pass inward and separate the respective bundles of fibres and extend between the individual nerve-fibres, acting as a supporting medium, in which they are embedded. There are **transverse, oblique** or **dorso-ventral** and **longitudinal fibres** in the white substance.

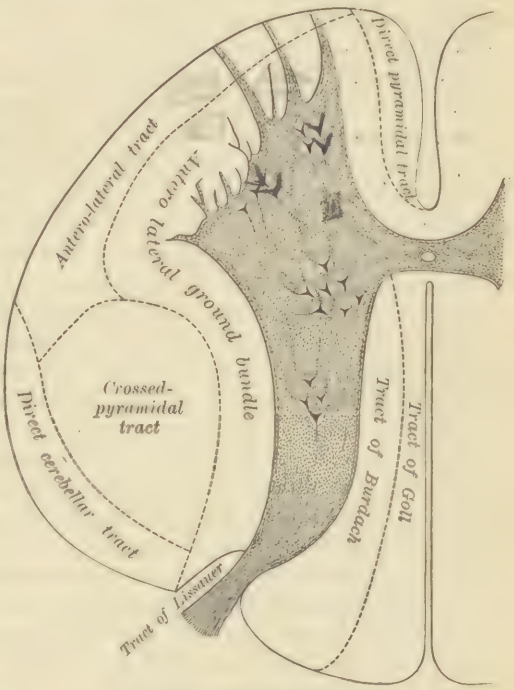

Fig. 539.—Columns of the cord.

Transverse Fibres.—These fibres pass between the longitudinal tracts of the cord and the gray matter. They constitute the anterior or white commissure, which joins the anterior and lateral white columns and the anterior gray horn of one side to like parts of the opposite side.

As previously stated, it is in front of the gray commissure, and is the floor of the anterior median fissure. It contains four sets of fibres: (1) those belonging to the direct pyramidal tract, (2) those belonging to the antero-lateral ground bundle, (3) those belonging to the antero-lateral ascending cerebellar tract, (4) crossed fibres to the anterior spinal nerve-roots.[1]

Oblique or Dorso-ventral Fibres.—These are the anterior root-fibres passing from the anterior gray horn to the periphery of the cord and the posterior root-fibres passing from the periphery of the cord to the posterior gray horn.

Longitudinal Fibres.—They constitute the *conducting tracts* (Fig. 539).

It is impossible to trace the course of the nerve-fibres in their passage through the cord; but the investigation of pathological lesions has shown that the white matter of the cord consists of certain **columns** or **tracts of fibres**; for it has been found that certain lesions are strictly limited to certain well-determined parts of the cord without involving neighboring regions. That these parts or fasciculi correspond to so many distinct anatomical systems, each endowed with special

[1] Santee. The Anatomy of the Brain and Spinal Cord.

functions, seems abundantly proved by the researches of Flechsig and others on the development of the spinal cord during the later periods of utero-gestation and in the newly born infant. By these researches several tracts can be traced along the greater part of the cord and into or from the encephalon (Fig. 539). Thus (1) in the antero-lateral column of the cord, on either side of the anterior median fissure, a portion of the column may be divided off as the **uncrossed** or **direct pyramidal tract** or the **fasciculus of Turck** (*fasciculus cerebrospinalis anterior* [*ventralis*]). This tract is a continuation of the corresponding tract in the medulla. It is only found in the upper part of the cord; it gradually diminishes as it is traced downward, and disappears about the middle of the dorsal region. It consists of centrifugal or descending fibres which can be traced downward from the pyramid of the medulla of the same side, and are derived from the motor area of the cerebral cortex. The fibres of this tract decussate in their course down the cord, passing across the middle line through the anterior white commissure and terminating in the anterior gray horn of the opposite side; this explains the gradual diminution and eventual disappearance of the tract. (2) In the hinder part of the antero-lateral column is a somewhat triangular area, larger than the preceding, which is named the **crossed pyramidal tract** (*fasciculus cerebrospinalis lateralis*). In the cervical and dorsal regions the crossed pyramidal tract is overlaid by the direct cerebellar tract, but in the lumbar cord it is at the surface. This also consists of descending fibres, which are derived from the pyramid of the medulla of the opposite side, and which have crossed in the decussation of the pyramids. After crossing in the medulla the fibres descend and terminate about the cells in the anterior cornu of the same side as the column. The fibres are derived from the motor area of the cerebral cortex of the opposite side. Thus it will be seen that all the fibres from the motor area, which descend through the internal capsule, the crus cerebri, and the pons Varolii to the pyramidal body of the medulla, decussate. Some decussate in the lower part of the medulla, and descend through it as the crossed pyramidal tract. Others do not decussate in the medulla but descend as the direct pyramidal tract and cross through the anterior commissure of the cord to terminate in the anterior gray horn of the opposite side, where the fibres end by forming synapses around its cells. Investigations render it probable that the crossed pyramidal tract contains some fibres from the main pyramidal tract in the medulla, which have descended from the corresponding side of the brain undecussated and terminate about the cells of the gray cornu of the same side of the cord. The **crossed descending tract of the red nucleus** is found within the crossed pyramidal tract at the junction of its lateral and dorsal portions. This tract from the opposite red nucleus reaches the lumbar cord and ends in the gray matter. (3) The **antero-lateral tract** is an extensive crescent-shaped strand which skirts the circumference of the anterior three-quarters of the antero-lateral column of the cord. Behind, where it is thickest, it lies in the angle formed by the direct cerebellar and crossed pyramidal tracts, becoming narrower as it passes forward toward the direct pyramidal tract. It contains two sets of fibres, centripetal or ascending, and centrifugal or descending, and hence is divided into two tracts, the **antero-lateral ascending** and the **antero-lateral descending cerebellar tracts.** (*a*) The **antero-lateral ascending cerebellar tract** or the **column of Gowers** (*fasciculus anterolateralis superficialis ascendens*) is chiefly in the posterior part of the antero-lateral tract, although some of its fibres mingle with the descending tract. The axones which compose this tract arise from cells in the central gray matter and the gray matter of the base of the anterior horn, chiefly from the opposite side of the cord (Santee), most of the fibres crossing soon after their beginning by way of the anterior commissure. The fibres of the column of Gowers pass through the dorsal portion of the lateral region of the medulla (sending nerve fibres to the lateral nucleus) and the formatio reticularis of the pons, turn backward over the superior peduncle of the cerebellum, and

pass into the superior vermis through the valve of Vieussens (Santee, from Hoche). Between the ascending and descending tracts is the **olivary bundle of the cord** or the **triangular tract of Helwig** (*tractus triangularis* [*Helwigi*]). It arises in the lumbar cord and terminates in the olive of the medulla. (*b*) The **antero-lateral descending cerebellar tract** or the **column of Marchi** and **Lowenthal** (*fasciculus anterolateralis superficialis descendens*) is situated chiefly in the anterior portion of the antero-lateral tract, but some of its fibres are scattered among the fibres of Gowers' column. The axones of the descending tract are derived from Purkinjean cells in the cerebellar cortex. The fibres pass through the inferior peduncle of the cerebellum and the lateral region of the medulla and terminate in the anterior gray horn. (4) The **direct cerebellar** or **dorso-lateral cerebellar tract** (*fasciculus cerebellospinalis*) is situated at the circumference of the cord behind the preceding and external to the crossed pyramidal tract, occupying a narrow area which extends backward as far as the postero-lateral fissure or nearly so. It commences at the upper level of the lumbar cord. Below this level it is absent, and where it is absent the crossed pyramidal tract reaches the surface. As the direct cerebellar tract ascends it increases in size. It passes through the restiform body of the medulla and terminates in the superior vermis of the cerebellum. Its fibres are derived from the cells of the **posterior vesicular column of Clarke** in the gray matter of the cord. (5) Close to the point where the posterior roots enter the cord, in the antero-lateral column, is a small collection of fibres, which is known as the **marginal tract of Spitzka and Lissauer** (*fasciculus marginalis*); it is formed by some of the outer fibres of the posterior roots which run upward in the tract for a short distance, and end about the cell-bodies of the substantia gelatinosa (Santee). (6) The rest of the antero-lateral column of the spinal cord is occupied by the **antero-lateral ground bundle** (*fasciculus proprius anterolateralis*). It surrounds the anterior cornu and separates the antero-lateral tract and the crossed pyramidal tract from the gray matter of the cord. Nowhere does it reach the surface of the cord, but at one place it very closely approaches it. The direct pyramidal tract separates it from the antero-median fissure. The fibres are very short and are commissural and associative. The portion of the ground bundle in the anterior column is chiefly commissural, its fibres passing between the anterior cornua. The portion in the lateral column is chiefly for association, its fibres joining different areas of the cord on the same side. It consists of (*a*) longitudinal fibres. An **anterior longitudinal bundle** (*fasciculus longitudinalis medialis*), which ascends to reach the motor nuclei of cranial nerves and the subthalamic region. A **posterior longitudinal bundle** (*fasciculus ventralis*), passing to the posterior corpus quadrigemina and the cilio-spinal and other centres (Santee). Longitudinal commissural fibres, which unite the groups of cells in the gray matter with one another; (*b*) of fibres which pass across the anterior commissure from the gray matter of the opposite side; and (*c*) horizontal fibres belonging to the anterior roots of the nerves, which pass through it before leaving the cord. In the posterior column of the cord there are two definite tracts. They are marked off from each other by the posterior intermediate furrow on the surface of the cord. The part which has been described previously as the posterior median column pretty nearly corresponds to the one tract, the **tract of Goll**, and the remainder of the posterior column corresponds to the other, the **tract of Burdach**. (7) The **postero-median tract** or **tract of Goll** (*fasciculus gracilis*) increases as it ascends, and consists of long, but small, fibres derived from the posterior roots of the spinal nerves, which ascend to the medulla oblongata, the fasciculus gracilis of the medulla, and end in the nucleus gracilis. Some fibres leave the tract and end in the gray matter of the cord. A few fibres pass to the thalamus and a few to the cerebellum. (8) The **postero-lateral tract** or the **tract of Burdach** (*fasciculus cuneatus*) consists of shorter, but larger, fibres than the preceding; they are derived from the posterior roots and from cells in the gray

matter of the cord; some ascend only for a short distance in the tract and then enter the gray matter and come into close relationship with the cells of the posterior vesicular column of Clarke; others incline toward the mesial plane, and, entering Goll's column, can be traced as far as the medulla. The tract of Burdach becomes in the medulla the fasciculus cuneatus and the fasciculus of Rolando. Some of its fibres continue along the interolivary fillet, others along the arciform fibres, and some terminate in the gray matter of the cord (Santee). In the cervical and upper dorsal regions there is contained in the substance of Burdach's column a small strand of fibres, called the **descending comma tract.** It presents, on transverse section, the appearance of a comma, the blunt extremity of which is directed forward. The fibres forming it probably represent in part descending portions of the dorsal nerve-roots, together with descending commissural fibres within the cord itself.

What is known as the **cornu commissural tract** is in the lumbar and lower dorsal regions, between the posterior cornu and the gray commissure. The **septo-marginal tract** is only found in a portion of the lumbar cord. It is between the septum and the dorsal surface of the cord (Santee).

Functions of the Various Tracts in the Cord.—1. The direct pyramidal tract is motor, and conveys impulses chiefly to the arms and trunk. It conducts motor impulses from the cerebral cortex of one side, along the spinal cord of the same side, and to the multipolar nerve-cells of the anterior horn of the opposite side of the cord. A given muscular region is supplied chiefly by the crossed pyramidal tract of the corresponding side of the cord and partly by the direct pyramidal tract of the opposite side of the cord, but both tracts are innervated by the same brain area. It is further to be remembered that there are probably direct or uncrossed fibres in the crossed pyramidal tracts of the cord which convey motor impulse from the cortex to muscles of the same side.

2. The crossed pyramidal tract conveys motor impulses and impulses which control reflex movements. It descends from the cortex, decussates in the lower part of the medulla, and descends in the cord on the side opposite to the brain area from which it arose. It supplies muscles on the same side of the body as the tract is of the cord. This tract also contains a few uncrossed fibres from the same side of the brain. Hence the muscles of one side receive their chief innervation from the opposite side of the brain by way of the crossed and the direct pyramidal tracts, but receive some slight innervation from the same side of the brain by way of the direct fibres in the crossed pyramidal tract. Gowers[1] says: "There is abundant evidence that each hemisphere of the brain is connected with both legs, although chiefly with that of the opposite side. There is also a similar and even more equal connection with the trunk muscles, and a slighter connection with certain muscles of the arm. Such muscles invariably regain some power on the paralyzed side, even with a complete interruption to the motor path, and they are weakened on the unparalyzed side."

3. The antero-lateral descending cerebellar tract is a "segment of an indirect motor path" (Santee). The antero-lateral ascending cerebellar tract conveys impressions of temperature and pain.

4. The direct cerebellar tract conveys impressions of equilibrium, particularly from the viscera.

5. The antero-lateral ground bundle is associative between the anterior cornua and is commissural between different segments of the cord. These commissural and associative connections are of great importance, for if the regular route of nervous conduction is interrupted they may serve to convey the nerve current around the block.

[1] Diseases of the Nervous System.

6. The marginal tract of Spitzka and Lissauer is composed of ascending fibres from the posterior nerve-roots.

7. The postero-lateral tract conveys impressions of common sensation.

8. The postero-median tract conveys impressions of muscular sense.

The Gray Substance of the Cord (*substantia grisea*).—The gray substance of the cord occupies its central part in the shape of two crescentic horns, joined together by the gray commissure. Each of these crescents has an **anterior** or **ventral** and a **posterior** or **dorsal cornu.**

The **Posterior** or **Dorsal Horn** (*columna grisea posterior*) consists of a slightly narrowed portion, at its base, where it is connected with the rest of the gray substance —this is, the **cervix cornu**; from this it gradually expands into the main part of the horn, the **caput cornu,** and tapers to form the **apex cornu**; around its extremity is a lamina or layer of gelatinous material, which covers the head like a cap, and from this it tapers almost to a point, which approaches the surface of the cord at the postero-lateral groove.

The gelatinous substance is a peculiar accumulation of neuroglia (Klein) similar to that found around the central canal, and has been named by Rolando the **substantia cinerea gelatinosa.** It probably takes its origin from the columnar cells which line the posterior part of the embryonic spinal canal.

The **Anterior** or **Ventral Horn of the Gray Substance** (*columna grisea anterior*) in the cervical and lumbar swellings, where it gives origin to the motor nerves of the extremities, is much larger than in any other region, and contains several distinct groups of large and variously shaped cells.

In addition to this, a **lateral horn** (*columna grisea lateralis*) is found projecting outward from the lateral region of the gray matter on a level with the gray commissure in the upper part of the dorsal region of the cord; in the cervical and lumbar regions this lateral horn blends with the anterior horn, which thus becomes broad and expanded. From the concavity of the crescent, between the anterior and posterior horns, processes of gray matter extend into the white substance, where they divide and anastomose to form a network, termed the **formatio reticularis.**

The gray commissure contains the **central canal** (*canalis centralis*), and is situated behind the white commissure, which separates it from the bottom of the anterior median fissure.

The gray substance of the cord is composed of—(1) the **substantia gelatinosa,** which envelops the head of the posterior horn and which encircles the central canal of the cord; (2) the **substantia spongiosa,** which forms the crescentic horns (except the heads of the posterior horns and the envelope of the central canal). Further, it may be stated that the gray matter consists of nerve-fibres of variable but smaller average diameter than those of the white column; (3) nerve-cells of various shapes and sizes, with from two to eight processes; (4) blood-vessels and connective tissue.

The **nerve-fibres** of the gray matter of the posterior horn are for the most part composed of a dense interlacement of minute fibrils, intermingled with nerves of a larger size. This interlacement is formed partly by the axones and dendrites of the cells of the gray matter, and partly by fibres which enter the gray matter and which come from various sources.

The **nerve-cells** of the gray matter are collected into groups as seen on transverse section, but they really form columns of cells placed longitudinally; or else they are found scattered throughout the whole of the gray matter.

In the anterior horn the cells consist of *two* chief groups; one **medial,** the more constant, near the anterior column; the other **lateral,** near the lateral column. The axones of these cells constitute the bulk of the anterior roots of the spinal nerves. The spinal nerves obtain axones from the entire lateral gray column and

from part of the medial gray column of the same side, and also from the gray matter of the medial column of the opposite side by way of the white commissure. The nerve-fibres from these cells are distributed to the muscles of the trunk and extremities. A second lateral group is present in the cervical and lumbar enlargements. In the centre of the gray crescent (*substantia intermedia grisea*) the cells are collected into three groups or columns. The **intermedio-lateral column** runs throughout the length of the cord, but is most distinct in the thoracic region. Its cells are in relation with fibres from the posterior nerve-roots and send off axones to the anterior nerve-roots. It is believed by Morris and others that these fibres are sympathetic and pass to glands and blood-vessels. Other axones enter the antero-lateral ascending cerebellar tract (Santee). The **middle column** is most distinct in the cervical cord. It certainly receives fibres from the posterior roots, and possibly sends fibres to the antero-lateral ascending cerebellar tract. At the base of the posterior horn on its inner side, adjoining the gray commissure, is a group of nerve-cells, called **Clarke's posterior** or **dorsal column** or **Clarke's vesicular column** (*nucleus dorsalis*), which extends from the eighth cervical to the second lumbar nerve. In the cervical and lumbar cord the *nuclei of Stilling* are its representatives, and in the medulla the *accessory cuneate nucleus* represents it. This column

Fig. 540.—Formation of a spinal nerve. (Testut.)

is in relation with the fibres of the posterior nerve-roots, and the axones from the cells of the column compose the direct cerebellar tract, and some, which are sympathetic, enter the anterior roots of the spinal nerves. In the posterior cornu are many cells not definitely arranged, but groups which are named peripheral, central, and basal. The axones of the cells of the posterior cornu enter the ground bundles, the column of Burdach, the anterior cornu of the same side, and the anterior and posterior cornua of the opposite side. Many fibres of the posterior roots are in relation with the cells of the posterior cornu.

At the junction of the anterior and posterior cornua, in the outer portion of the gray matter, is a third group of cells, the **lateral cell column**; this is best seen in the dorsal region. In certain regions of the cord these cells extend in among the fibres of the white matter of the lateral column, and give rise to the lateral horn.

In addition to these groups a few large scattered cells are found in the posterior horn and in the substantia gelatinosa of Rolando.

Origin of the Spinal Nerves (Figs. 538 and 540).—The roots of the spinal nerves are attached to the surface of the cord, opposite the horns of gray matter.

A **Posterior Nerve-root** enters the cord in two bundles, **medial** and **lateral.** The medial strand consists of coarse fibres which enter the outer part of the column of Burdach. The lateral strand is sometimes divided into a middle and an external bundle. The former contains large fibres, and passes through the gelatinous substance of Rolando into the posterior horn. The external bundle consists of fine fibres which assume a longitudinal direction in the Spitzka-Lissauer tract. All the posterior root-fibres divide into ascending and descending branches on entering the cord, and these in their turn give off collaterals (Fig. 541). The fibres and their collaterals terminate by forming arborescences, some around the cells in the posterior horn, and others around the cells of Clarke's column, while the long ascending branches pass up in the columns of Goll and Burdach, and end by arborizing around the cells in the gracile and cuneate nuclei. Some of the fibres, however, pass to the gray matter of the opposite horn, and others to the anterior horn of the same side of the cord.

Anterior Nerve-roots.—The majority of the fibres of the anterior nerve-roots are the continuations outward of the axones of the large or small multipolar cells in the anterior horn of gray matter. Some, however, appear to pass across in the anterior a white commissure to the cells in the anterior horn of the opposite side, while others extend backward to the posterior horn and outward to the lateral column of the same side.

THE MENINGES OR MENINGEAL MEMBRANES OF THE BRAIN (MENINGES ENCEPHALI).

Dissection.—To examine the brain with its membranes, the skull-cap must be removed. In order to effect this, saw through the external table, the section commencing, in front, about an inch above the margin of the orbit, and extending, behind, to a little above the level with the occipital protuberance. Then break the internal table with the chisel and hammer, to avoid injuring the investing membranes or brain; loosen and forcibly detach the skull-cap, when the dura mater will be exposed. The adhesion between the bone and the dura mater is very intimate, and much more so in the young subject than in the adult.

The membranes of the brain are from without inward: the **dura mater, arachnoid membrane,** and the **pia mater.**

The Dura Mater of the Brain (Dura Mater Encephali) (Figs. 543, 544, 545, 547).

The dura mater of the brain is a thick and dense inelastic fibrous membrane which lines the interior of the skull. It is a covering for the brain and is also the internal periosteum. Its outer surface is rough and fibrillated, and adheres closely to the inner surface of the bones by fibrous processes and blood-vessels. The adhesion is most marked on bony projections, opposite the sutures and at the base of the skull. Except at the sutures the adhesions are not dense, and between the fibrous processes which pass to the bone are spaces which are thought to be lymph-spaces, and are called **epidural spaces.** At these points the outer surface of the dura is covered with endothelium. Fibrous tissue passes through the open sutures and joins the outer layer of the dura to the external periosteum. It is known as the **sutural membrane.** The inner surface of the dura limits the **subdural space.** It is smooth and lined by a layer of endothelium. The dura mater sends four processes inward, into the cavity of the skull, for the support and protection of the different parts of the brain, and is prolonged to the outer surface of the skull through the various foramina which

exist at the base, and thus becomes continuous with the pericranium; its fibrous layer forms sheaths for the nerves which pass through these apertures. At the base of the skull it sends a fibrous prolongation into the foramen cæcum; it sends a series of tubular prolongations around the filaments of the olfactory nerves as they pass through the cribriform plate, and also around the nasal nerve as it passes through the nasal slit; a prolongation is also continued through the sphenoidal fissure into the orbit, and another is continued into the same cavity through the optic foramen, forming a sheath for the optic nerve, which is continued as far as the eyeball. In the posterior fossa it sends a process into the internal auditory meatus, ensheathing the facial and auditory nerves; another through the jugular foramen, forming a sheath for the structures which pass through this opening; and a third through the anterior condyloid foramen. Around the margin of the foramen magnum it is closely adherent to the bone, and is continuous with the dura mater lining the spinal canal. The **cavity** or **cave of Meckel** (*cavum Meckeli*) (Fig. 545) is an osteo-fibrous recess near the apex of the petrous portion of the temporal bone, formed by folding of the dura mater in a bony depression. It contains the Gasserian ganglion. In certain situations, as already mentioned (p. 736), the fibrous layers of this membrane separate to form sinuses for the passage of venous blood. Upon the outer surface of the dura mater, in the situation of the longitudinal sinus, may be seen numerous small, whitish bodies, the **glandulae Pacchioni** (p. 854).

Structure (Fig. 542).—The dura mater consists of white fibrous tissue with connective-tissue cells and elastic fibres arranged in flattened laminæ, which are imperfectly separated by lacunar spaces and blood-vessels into two layers, **endosteal** and **meningeal**. The **endosteal layer** is the internal periosteum for the

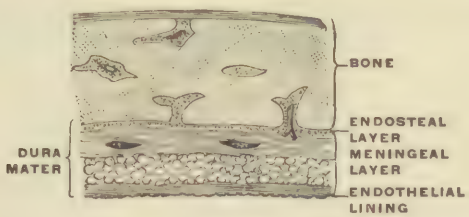

FIG. 542.—The structure of the dura mater. Section through the cranial vault of a child, slightly enlarged. (Poirier and Charpy.)

cranial bones and contains the blood-vessels for their supply. At the margin of the foramen magnum it becomes continuous with the periosteum lining the spinal canal. The **meningeal** or **supporting layer** is lined on its inner surface by a layer of nucleated endothelium, similar to that found on serous membranes; these cells were formerly regarded as belonging to the arachnoid membrane. By its reduplication the meningeal layer forms the **falx cerebri**, the **tentorium** and **falx cerebelli**, and the **diaphragma sellae**. The two layers are connected by fibres which intersect each other obliquely.

The Arteries of the Dura Mater (see section on Arteries).—Its arteries are very numerous, but are chiefly distributed to the bones. Those found in the anterior fossa are the **anterior meningeal branches of the anterior** and **posterior ethmoidal** and **internal carotid**, and a **branch from the middle meningeal**. In the middle fossa are the **middle** and **small meningeal branches of the internal maxillary**, a **branch from the ascending pharyngeal**, which enters the skull through the foramen lacerum medium basis cranii, **branches from the internal carotid**, and a **recurrent branch from the lachrymal**. In the posterior fossa are **meningeal branches from the occipital**, one of which enters the skull through the jugular foramen, and the other through the mastoid foramen; the **posterior meningeal**,

from the vertebral; occasionally **meningeal branches from the ascending pharyngeal**, which enter the skull, one at the jugular foramen, the other at the anterior condyloid foramen, and a **branch from the middle meningeal.**

The Veins of the Dura Mater.—The veins which return the blood from the dura mater (see p. 734), and partly from the bones, anastomose with the diploic veins (see p. 733). These vessels terminate in the various sinuses, with the exception of two which accompany the middle meningeal artery, and pass out of the skull at the foramen spinosum to join the internal maxillary vein; above, the meningeal veins communicate with the superior longitudinal sinus. The *sinuses* are considered on pages 736 to 743 inclusive. On either side of the superior longitudinal sinus, especially near its middle, and also near the lateral and straight sinuses, are numerous spaces in the dura mater which communicate with the sinus, either by a small opening or a distinct venous channel. These spaces are the **parasinoidal sinuses** (*lacunae laterales*) (Fig. 453). Many of the meningeal veins do not open directly into the sinuses, but indirectly through the parasinoidal sinuses. These venous lacunæ are often invaginated by Pacchionian bodies, and they communicate with the underlying cerebral veins, and also with the diploic and emissary veins.

The Lymphatics of the Dura Mater.—The existence of lymphatic vessels is not proved. Some anatomists claim to have injected such vessels along the middle meningeal arteries (Mascagni, Arnold). Perivascular lymph-spaces do exist.

The Nerves of the Dura Mater.—The nerves of the dura mater are filaments from the **fourth**, the **ophthalmic division of the fifth**, the **Gasserian ganglion**, the **pneumogastric**, the **hypoglossal**, and the **sympathetic.**

Processes of the Dura Mater (*processus durae matris*).—The processes of the dura mater, sent inward into the cavity of the skull, are four in number: the **falx cerebri**, the **tentorium cerebelli**, the **falx cerebelli**, and the **diaphragma sellae.**

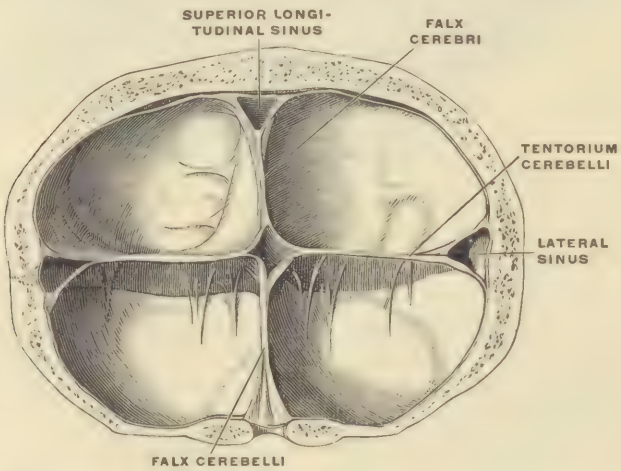

FIG. 543.—Crucial prolongation of the dura mater. Frontal section passing through the tentorium cerebelli. The torcular Herophili is seen in the centre. (Poirier and Charpy.)

The Falx Cerebri (Figs. 543 and 545).—The falx cerebri, so named from its sickle-like form, is a strong arched process of the dura mater, which descends vertically in the longitudinal fissure between the two hemispheres of the brain. It is narrow in front, where it is attached to the crista galli of the ethmoid bone, and broad behind, where it is connected with the upper surface of the tentorium. Its upper margin is convex, and attached to the inner surface of the skull, in the

middle line, as far back as the internal occipital protuberance; it contains the **superior** or **great longitudinal sinus** (*sinus sagittalis superior*). Its lower margin is free, concave, and presents a sharp curved edge, which contains the **inferior longitudinal sinus** (*sinus sagittalis inferior*). The **straight sinus** (*sinus rectus*) is formed by the attachment of the falx cerebri to the tentorium cerebelli.

The Tentorium Cerebelli (Figs. 543, 544, and 545).—The tentorium cerebelli is an arched lamina of dura mater, elevated in the middle and inclining downward

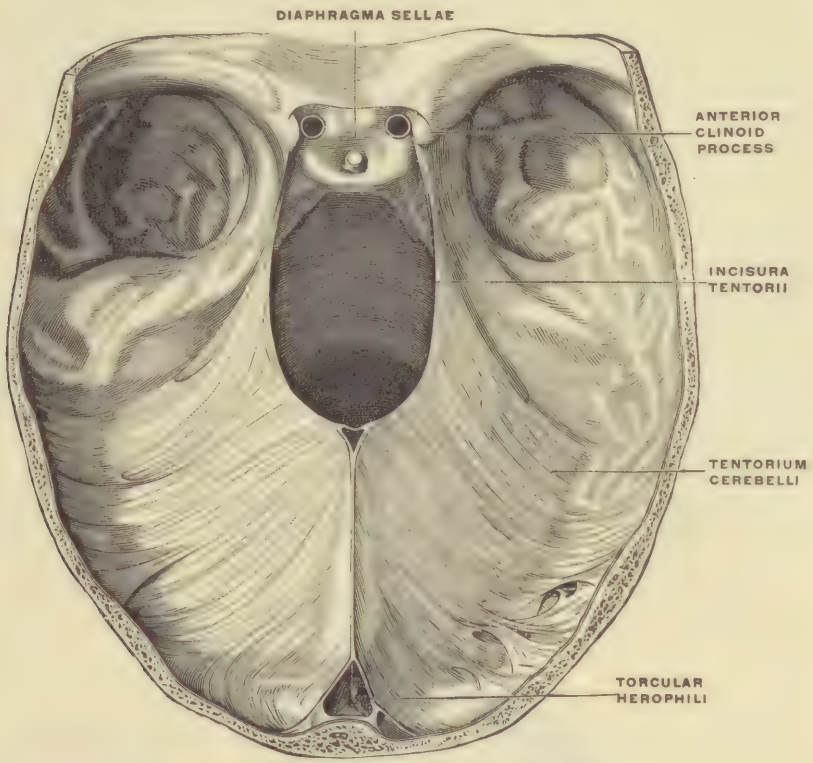

FIG. 544.—The tentorium cerebelli. (Poirier and Charpy.)

toward the circumference. It covers the upper surface of the cerebellum, and supports the occipital lobes of the brain, and prevents them pressing upon the cerebellum. It is attached, behind, by its convex border to the transverse ridges upon the inner surface of the occipital bone, and there encloses on each side the **lateral sinus** (*sinus transversus*); in front, to the superior margin of the petrous portion of the temporal bone on either side, enclosing the **superior petrosal sinus** (*sinus petrosus superior*); and at the apex of this bone the free or internal border and the attached or external border meet, and, crossing one another, are continued forward, to be attached to the anterior and posterior clinoid processes respectively. Along the middle line of its upper surface the posterior border of the falx cerebri is attached, the **straight sinus** being placed at their point of junction. Its anterior border is free and concave, and with the dorsum sellae forms a large oval opening. This opening is called the **incisura tentorii** and transmits the mesencephalon.

The Falx Cerebelli (Fig. 543).—The falx cerebelli is a small triangular process of dura mater received into the indentation between the two lateral lobes of the cerebellum behind. Its base is attached, above, to the under and back part of

the tentorium; its posterior margin, to the lower division of the vertical crest on the inner surface of the occipital bone. As it descends it sometimes divides into two smaller folds, which are lost on the sides of the foramen magnum.

The Diaphragma Sellae (Fig. 544). —The diaphragma sellae is a horizontal process formed by a reduplication of the meningeal layer of the dura mater. It forms a small circular fold, which constitutes a roof for the sella turcica. This almost

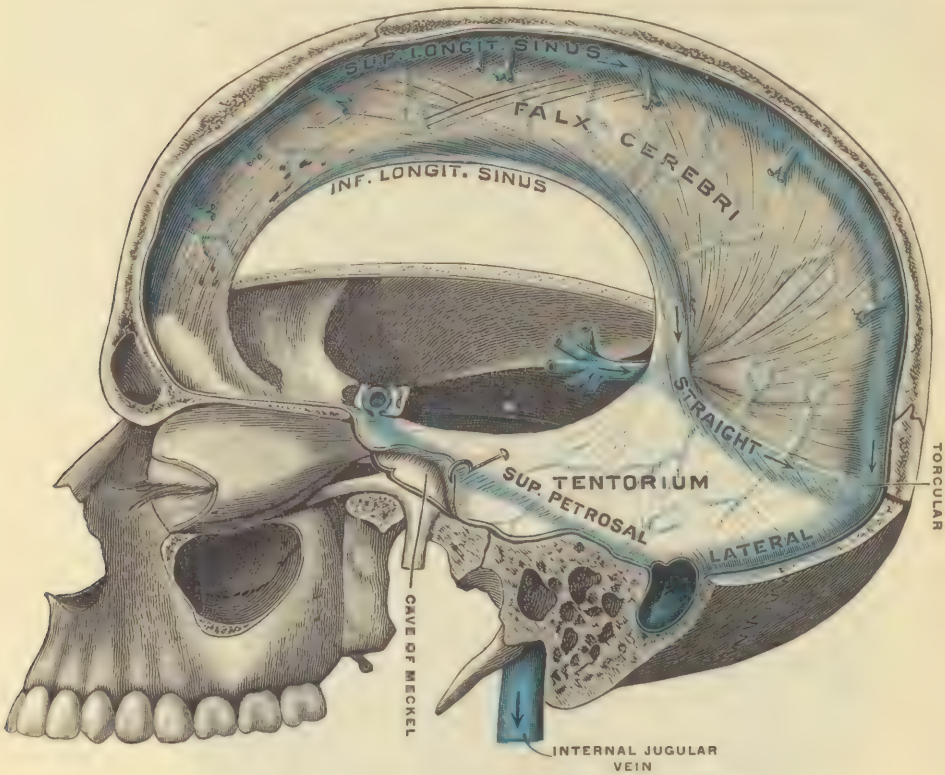

FIG. 545. —Falx cerebri and tentorium, left lateral view. (Testut.)

completely covers the pituitary body, presenting merely a small central opening (*foramen diaphragmatis sellae*) for the infundibulum to pass through.

The Arachnoid Membrane (Arachnoidea Encephali) (Fig. 546).

The term arachnoid is from the Greek ἀράχνη εἶδος, like a spider's web, so named for its extreme thinness. The cranial arachnoid is a delicate membrane which envelops the brain, lying between the pia mater internally and the dura mater externally; from this latter membrane it is separated by a very fine slit or space, the **subdural space** (*cavum subdurale*). The subdural space contains a very minute quantity of fluid of the nature of lymph. This fluid obtains exit by way of the parasinoidal sinuses. The subdural space is prolonged upon emerging nerves and joins the lymph spaces of the nerves. The subdural space does not communicate with the subarachnoid space.

The arachnoid invests the brain loosely, being separated from direct contact with the cerebral substance by the pia mater, and a quantity of loose areolar tissue, the **subarachnoidean areolar** tissue. On the upper surface of the cerebrum the arachnoid is thin and transparent, and may be easily demonstrated by

injecting a stream of air beneath it by means of a blowpipe; it passes over the convolutions without dipping down into the sulci between them, but does pass into the Sylvian and great longitudinal fissures and is prolonged upon the nerves as a sheath. At the base of the brain the arachnoid is thicker, and slightly opaque toward the central part; it covers the orbital surface of the anterior lobes, and extends across between the two temporal lobes so as to leave a considerable interval between it and the brain, the **cisterna basalis**.

The Subarachnoid Space (*cavum subarachnoideale*) (Fig. 547).—The subarachnoid space is the interval between the arachnoid and pia mater. It is not only on

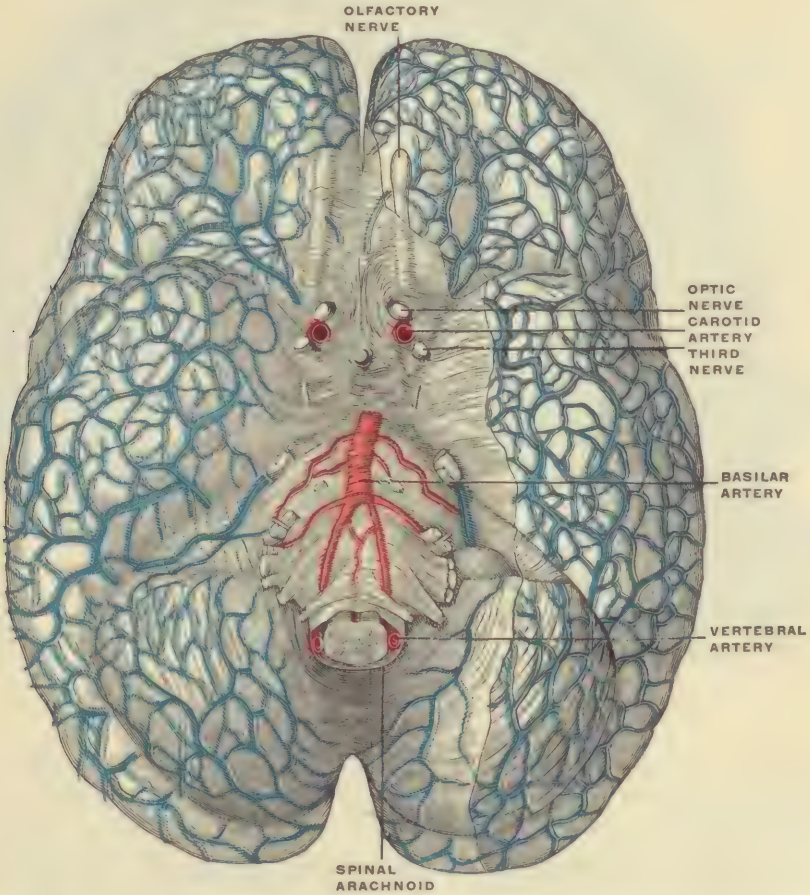

FIG. 546.—The arachnoid upon the base of the brain. On the right the arachnoid has been partly removed to show the cerebrum and cerebellum with their superficial veins. (Poirier and Charpy.)

the surface, but dips between the convolutions. It is not, properly speaking, a *space*, for it is occupied everywhere by a spongy tissue consisting of trabeculæ of delicate connective tissue covered with endothelium, which pass from the pia mater to the arachnoid, and in the meshes of which the subarachnoid fluid is contained. This so-called space is small on the surface of the hemispheres; but at the base of the brain the subarachnoid tissue is less abundant and its meshes larger.

In certain regions the arachnoid and pia are farther apart than was previously indicated, and these spaces are called **subarachnoid cisternae** (*cisternae subarachnoidalis*). The largest space is the continuation of the posterior part of the subarachnoid space of the spinal cord. It is called the **posterior subarachnoid space**

or **cisterna magna** (*cisterna cerebellomedullaris*). It is a space formed by the arachnoid passing across the back and under portions of the medulla and cerebellum. It communicates with the fourth ventricle by three foramina. The largest opening is the **foramen of Majendie** (*apertura medialis ventriculi quarti*). It is in the middle line of the tela choroidea inferior. At the end of each recessus lateralis of the fourth ventricle there is also an opening, and each opening is called the **foramen of Key and Retzius** (*apertura lateralis ventriculi quarti*). The **cisterna pontis** is the continuation upward of the anterior part of the subarachnoid space of the cord. About the medulla it is continuous with the cisterna magna, so this important nerve centre is surrounded by a large subarachnoid space. The **cisterna basalis** (*cisterna interpeduncularis*) is formed by the arachnoid extending between the two temporal lobes, and it contains the arteries forming the circle of Willis. The **anterior subarachnoid space** (*cisterna pontis, interpeduncularis et chiasmatis*) includes the cisterna pontis, the cisterna basalis and the cisterna of the chiasm. There is a cisterna between the inferior edge of the falx cerebri and the superior surface of the corpus callosum which contains the anterior cerebral arteries, a cisterna in the fissure of Sylvius which contains the anterior cerebral artery, and a cisterna between the corpora quadrigemina which contains the vena magna Galeni.

It is stated by Merkel that the lateral ventricles also communicate with the subarachnoid space at the apices of their descending horns.

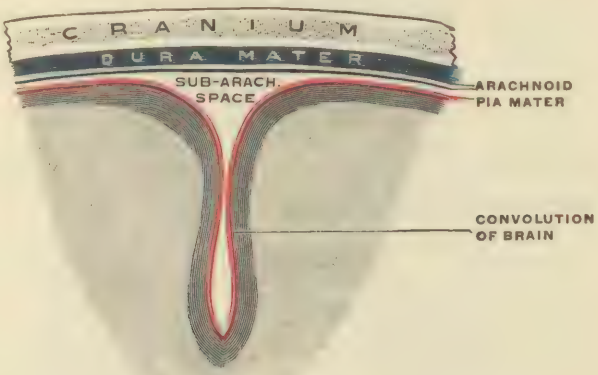

FIG. 547.—The subarachnoid space. (Schematic.) (Poirier and Charpy.)

The **cerebro-spinal fluid** (*liquor cerebrospinalis*) fills the subarachnoid space. It is a clear, limpid fluid, having a saltish taste and a slightly alkaline reaction. According to Lassaigne, it consists of 98.5 parts of water, the remaining 1.5 per cent. being solid matters, animal and saline. It varies in quantity, being most abundant in old persons, and is quickly reproduced. Its chief use is probably to afford mechanical protection to the nervous centres, and to prevent the effects of concussions communicated from without.

Structure.—The arachnoid consists of bundles of connective tissue, the fine fibres of which form one layer and cross each other in every direction. At the level of the large fissures, and especially around the circle of Willis, it is reinforced by thick fibrous tissue. Both surfaces are covered with endothelium. There are no blood-vessels in the arachnoid; the vessels which appear to be in it are really in the pia. There is no positive proof that nerves are present in the arachnoid. It is true that Bochdalek and Luschka long ago described arachnoid nerves, but these observations have never been corroborated.

Glandulae Pacchioni, Luschka's Villi or the Arachnoid Villi (Granulationes Arachnoideales).

The glandulae Pacchioni are numerous small whitish or purplish projections, usually collected into clusters of variable size, which are found in the following situations: 1. Upon the outer surface of the dura mater, in the vicinity of the superior longitudinal sinus, being received into little depressions on the inner surface of the calvarium. 2. On the inner surface of the dura mater. 3. In the superior longitudinal sinus and the other sinuses. 4. On the pia mater, near the margin of the hemispheres.

A hasty examination would lead us to suppose that these bodies spring from the dura, but, as a matter of fact, they originate from the arachnoid. They are not glandular in structure, but are simply enlarged normal villi of the arachnoid. In their growth they appear to perforate the dura mater, and when a group of villi is of large size it causes absorption of the bone, and comes to be lodged in a pit or depression (*foveola granularis* [*Pacchioni*]) on the inner table of the skull. Their manner of growth is as follows: at an early period they project through minute holes in the inner layer of the dura mater, which open into large venous spaces situated in the tissues of the membrane, on either side of the longitudinal sinus and communicating with it. In their onward growth the villi push the outer layer of the dura mater before them, and this forms over them a delicate membranous sheath. In structure they consist of spongy trabecular tissue, covered over by a membrane, which is continuous with the arachnoid. The space between these two coverings, derived from the dura mater and arachnoid respectively, corresponds to and is continuous with the subdural space. The spongy tissue of which they are composed is continuous with the trabecular tissue of the subarachnoid space; so that fluid injected into the subarachnoid space finds its way into the Pacchionian bodies, and through their coverings filters into the superior longitudinal sinus. They are supposed to be a means of getting rid of an excess of cerebro-spinal fluid, when its quantity is increased above normal. Another means of getting rid of cerebro-spinal fluid is absorption by the lymph-spaces of the cranial nerves, which possess sheaths of arachnoid up to the points at which they emerge from the skull.

These bodies are not found in infancy, and very rarely until the third year. They are usually found after the tenth year; and from this period they increase in number as age advances. Occasionally they are wanting.

The Pia Mater of the Brain (Pia Mater Encephali) (Figs. 547, 548).

The pia mater of the brain is a vascular membrane, and derives its blood from the internal carotid and vertebral arteries. It consists of a minute plexus of blood-vessels, held together by an extremely fine areolar tissue. It invests the entire surface of the brain, dipping down between the convolutions and laminæ, and is prolonged into the interior, forming the velum interpositum and the choroid plexuses of the lateral and fourth ventricles.

The Velum Interpositum or the Tela Chorioidea Superior (*tela chorioidea ventriculi tertii*) (Fig. 548).—The velum interpositum is the prolongation of the pia mater into the interior of the brain through the middle of the transverse fissure. It is a double triangular vascular fold, lies between the body of the fornix above and the optic thalami and the epithelial roof of the third ventricle below, and passes forward to the foramen of Monro. At each edge of the velum interpositum is the **choroid plexus** (*plexus chorioideus ventriculi lateralis*) of the corresponding lateral ventricle. In front the two plexuses join behind

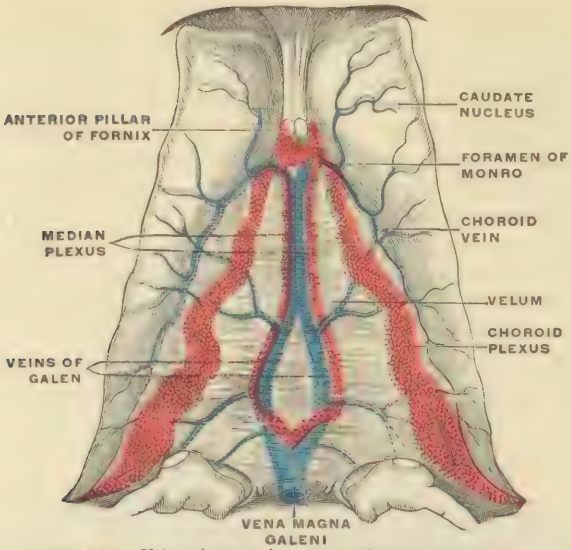

FIG. 548.—Velum interpositum. (Poirier and Charpy.)

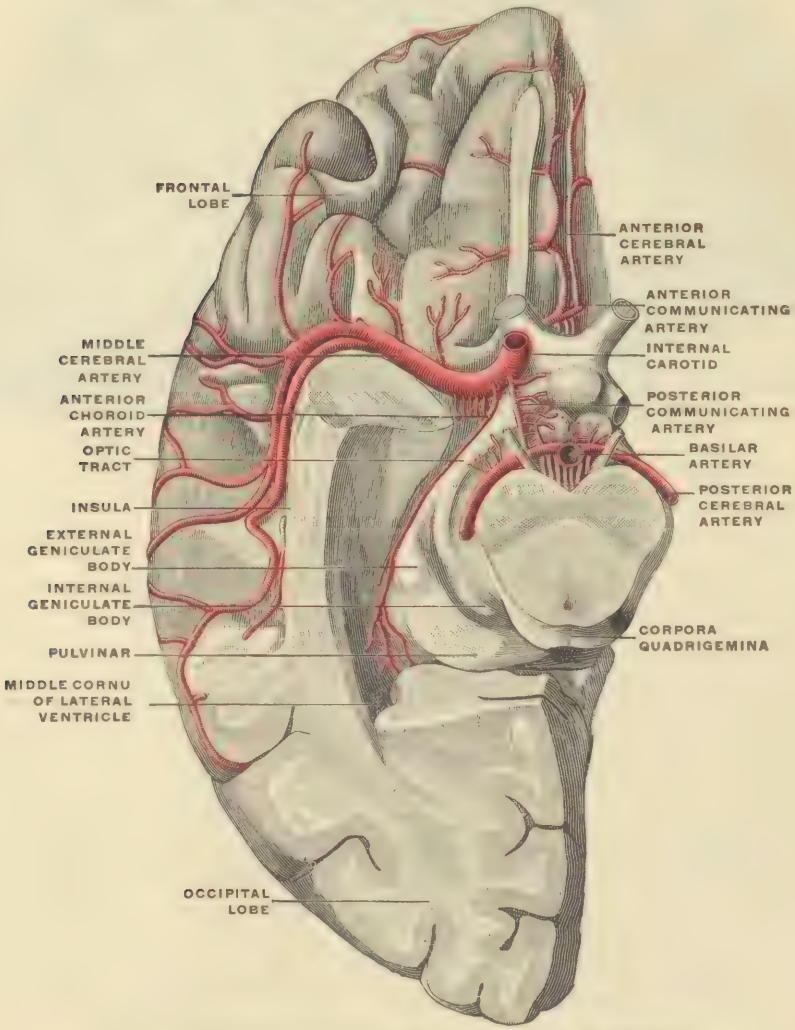

FIG. 549.—The anterior cerebral and choroid arteries. (Spalteholz.)

the foramen of Monro, and at the point of junction two lesser choroid plexuses pass back along the under surface of the velum to the third ventricle, the **median plexus** (*plexus chorioideus ventriculi tertii*). The veins of Galen or the deep cerebral veins (p. 735) are two veins which lie on either side of the middle of the velum interpositum and pass back. Each vein of Galen is formed by the union of the vein from the corpus striatum and the choroid vein from the choroid plexus. The two veins of Galen unite and form the **vena magna Galeni**, which empties into the straight sinus.

The pia mater of the surfaces of the hemispheres, where it covers the gray matter of the convolutions, is very vascular, and gives off from its inner surface a multitude of minute vessels, which extend perpendicularly for some distance into the cerebral substance. At the base of the brain, in the situation of the anterior and posterior perforated spaces, a number of long straight vessels are given off, which pass through the white matter to reach the gray substance in the

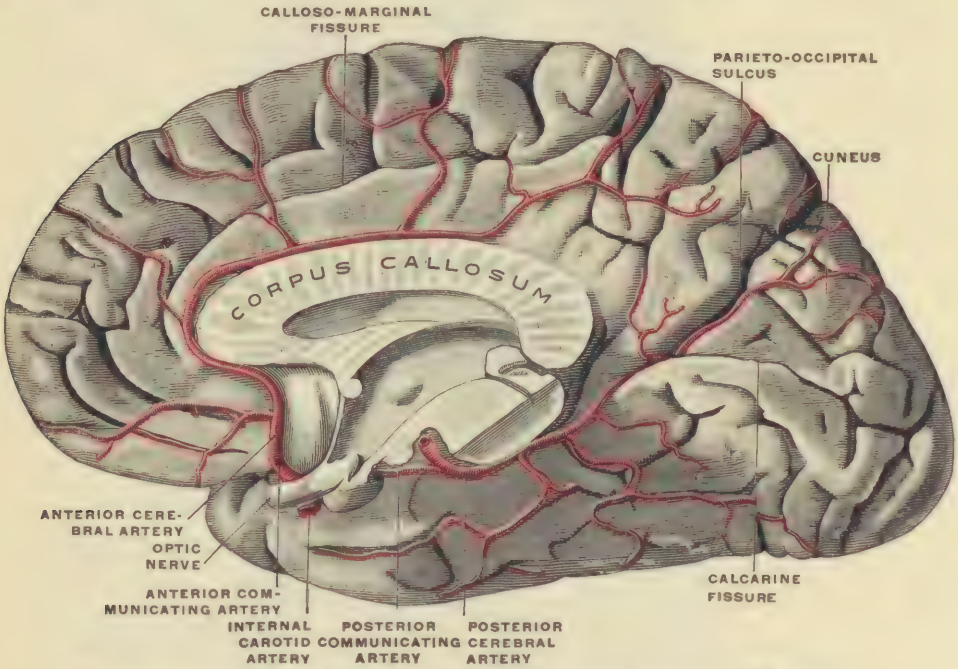

FIG. 550.—The arteries of the medial surface of the right cerebral hemisphere. (Spalteholz.)

interior. On the cerebellum the membrane is more delicate, and the vessels from its inner surface are shorter. The pia mater of the spinal cord is thicker, firmer, and less vascular than that of the brain, and as it is traced upward over the medulla it is seen to preserve these characters. At the upper border of the medulla it is prolonged over the lower half of the fourth ventricle, forming a covering for it called the **tela chorioidea inferior** (*tela chorioidea ventriculi quarti*), before it is reflected on to the under surface of the cerebellum, and which carries the **choroid plexus of the fourth ventricle** (*plexus chorioideus ventriculi quarti*).

The **arteries** of the pia mater (see pp. 626, 627, and 628) (Figs. 549 and 550) are the **anterior cerebrals, middle cerebrals, posterior cerebrals, anterior choroids, posterior choroids,** the **superior cerebellars,** and the **anterior** and **posterior inferior cerebellars.** (The vessels of the cerebral ganglionic system and of the cortical arterial system are considered on pp. 630 and 631.)

The **veins** of the pia mater (see pp. 734, 735, and 736) are the **basilar vein,** the **veins of Galen** (Fig. 548), the veins constituting the **choroid plexuses of the**

third ventricle, the **lateral ventricles**, and the **fourth ventricle**; the **cerebral veins** (Fig. 546) and the **cerebellar veins** (Fig. 546).

The **nerves** of the pia mater accompany the branches of the arteries and are derived from the **sympathetic** and from the **third, fifth, sixth, seventh, ninth, tenth,** and **eleventh cranial nerves.**

According to Folmann, Arnold, and Mascagni, this membrane contains numerous *lymphatic vessels,* but the question is uncertain.

THE BRAIN (ENCEPHALON).

The encephalon or brain is that portion of the cerebro-spinal axis which is contained in the cavity of the cranium.

The Development of the Brain.—The nervous system (brain, ganglia, spinal cord, and nerves) is derived from the ectoderm (the epiblastic layer of the blastodermic vesicle). This, it will be remembered, is an epithelial layer, and nervous structure is composed of epithelial cells variously modified. The embryonal area of the surface of the developing germ is a white spot, which at first is round, but becomes pear-shaped and develops a transverse ridge, the **terminal ridge,** on its posterior margin. From the embryonal layer, and from this alone, the new individual is developed.

About the twelfth or the thirteenth day of the development of the human embryo, cell-proliferation occurs at a certain portion of the under surface of the ectoderm. This proliferation gives rise to a white, longitudinal streak in the embryonal area, known as the **primitive streak** or **axis plate.** The head process of the primitive streak appears somewhat later, and is situated directly in front of the anterior end of the streak.

At the anterior end of the primitive streak is a group of epiblastic cells known as **Hensen's node.** The epiblastic cells of the head-process of the primitive streak enlarge and become columnar, and the cells at each side of the streak become flat (Heisler). Thus is formed from the ectoderm the medullary plates; and the turning up of the edge of the medullary plates forms the spinal or medullary furrow or groove. As the curling up of the edges of the medullary plates continues the groove deepens, finally becoming a tube known as the **medullary** or **neural tube or canal.**

The neural tube lies beneath the ectoderm; is finally separated from it; runs from one end of the body to the other; forms the primitive nervous system, and gives origin to the entire nervous system. The constricted portion between the hind-brain and the mid-brain is known as the **isthmus rhombencephali.**

It is thus seen that the medullary or neural groove is converted into a canal, the **neural canal.** Its cephalic end dilates into a sac, from which the brain is developed, and the remainder forms the spinal cord. In consequence of the curve that the cephalic portion of the embryo undergoes, a marked bend in the canal takes place forward, so that the plane of the ventricles is placed almost at a right angle with the long axis of the central canal of the cord. The rudimentary brain consists of a hollow sac—the rudimentary cord of a hollow canal. The sac and the canal communicate freely with each other.

The sac elongates, and in it appear two constrictions, which partially divide it into three portions, namely, the anterior, middle, and posterior primitive cerebral vesicles, or the **fore-brain** (*prosencephalon*), the **mid-brain** (*mesencephalon*), and the **hind-brain** (*rhombencephalon*) (Fig. 551). Subsequently the anterior and the posterior vesicles become constricted, each into two, while the middle remains undivided (Figs. 553 and 554). It will thus be seen that at the anterior extremity of the medullary canal there are five dilatations, separated from each

other by constrictions, through which, however, they freely communicate with one another. These five vesicles are the fundamental or primitive divisions of the adult brain. They are named, from before backward, the **fore-brain** (*prosencephalon*), the **inter-brain** (*thalamencephalon*, formed from the prosencephalon), the **mid-brain** (*mesencephalon*), the upper portion of the **hind-brain** (*metencephalon*),

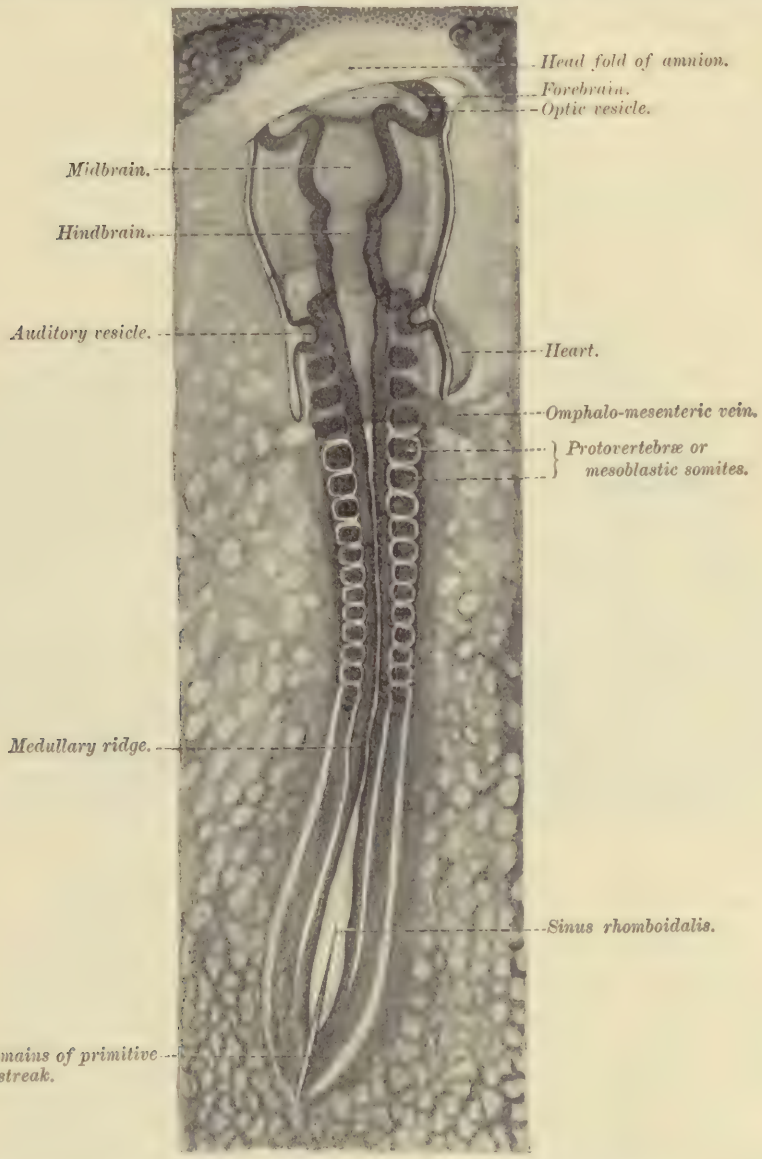

FIG. 551.—Chick embryo of thirty-three hours' incubation, viewed from the dorsal aspect. × 30. (From Duval's Atlas d'Embryologie.)

and the lower portion of the **hind-brain** (*myelencephalon*). The constricted portion between the hind-brain and the mid-brain is known as the **isthmus rhombencephali.**

These five vesicles are at first fairly uniform in size and in shape, but they soon begin to grow at different rates and to assume different forms. The changes are most marked in the first vesicle.

The **first secondary vesicle** sends out two hollow protrusions, one on each side, from the forepart of its lateral surface. These grow rapidly, spread out, and extend forward, laterally, and backward, over the sides of the first and second ventricles, forming large cavities, which become the **lateral ventricles** (Fig. 552, *G*). From each protrusion three prolongations take place: one forward and outward; the second backward and inward, and the third at first backward, outward, and downward, and then forward and inward. These prolongations form the horns of the lateral ventricles, and they far exceed in size the original vesicle from which they have taken origin, which does not increase to any great extent, but remains as the anterior part of the third ventricle. The communication between it and the future lateral ventricle persists as the foramen of Monro (Fig. 552).

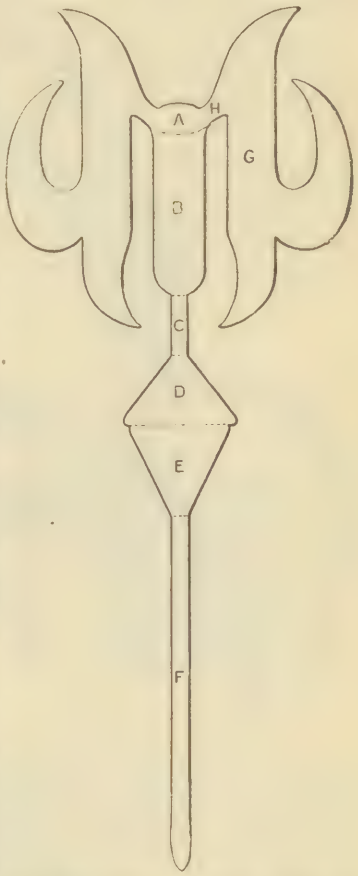

FIG. 552. Plan showing the mode of formation of the ventricles of the brain and the central canal of the spinal cord. *A*. Prosencephalon. *B*. Thalamencephalon. *C*. Mesencephalon. *D*. Metencephalon. *E*. Myelencephalon. *F*. Central canal of cord. *G*. Lateral ventricle. *H*. Foramen of Monro. (After Gerrish.)

The **second vesicle** or **thalamencephalon** becomes elongated from before backward and compressed laterally, so as to form the greater part of the third ventricle (Fig. 552, *B*). From each side of that part of the fore-brain, which ultimately becomes the lateral ventricle, is budded off a hollow projection, the **primary optic vesicle**, that is developed eventually into the optic nerve and the retina. It will be considered later.

The constriction between the first and the second vesicle disappears, so as to throw the whole cavity of the future third ventricle, formed by the remains of the first ventricle and the whole of the second vesicle, into one.

The **third vesicle** or **mesencephalon** forms a very insignificant part of the brain of the adult. It constitutes a stem of junction between the parts that take origin from the rhombencephalon and those that arise from the prosencephalon. The wall of the mesencephalon is completely converted into nerve-tissue, and forms the **corpora quadrigemina**, the two **crura cerebri**, and the **aqueduct of Sylvius**, which join the third ventricle with the fourth.

The **metencephalon** gives origin to the **cerebellum** and the **pons Varolii**. The cerebellum takes origin from a thickening of the superior wall of the vesicle, while the pons takes origin from a thickening of the lateral and inferior walls of the vesicle.

The **myelencephalon** gives origin to the **bulb** or **medulla oblongata**, chiefly by a thickening of the lateral walls of the vesicle. The original hind-brain remains in the brain of the adult as the fourth ventricle.

As already stated, these vesicles do not remain in the same plane. The formation of certain definite flexures alters the position of the vesicles with regard to one another (Fig. 554). The **cephalic flexure** is opposite the base of the mid-brain, which becomes sharply bent upon itself over the end of the notochord. This bending causes the mid-brain to become the most prominent part of the encephalon on the convexity of the curve. The **pontine** or **pontal flexure** is a curve in the hind-brain, in the opposite direction to that of the cephalic flexure. At the junction of the

hind-brain with the spinal cord is the **cervical** or **nuchal flexure.** In the development of the brain the cephalic flexure remains permanent, but the other two flexures completely disappear.

The manner in which the different parts of the encephalon are formed from the walls of this greatly altered medullary canal will now be considered, it being remembered that the ventricles are developed, as previously described, from the five secondary vesicles.

The first vesicle, or prosencephalon, sends out two hollow protrusions, which spread rapidly, and in the walls of these nervous matter is developed, which constitutes the cerebral hemispheres (Fig. 554, *II*), the cavities remaining as the lateral ventricles. As these hemispheres extend they grow forward in front of the anterior extremity of the primitive brain, and lie side by side, separated by the longitudinal fissure; they also grow upward, and again lying side by side are separated by another portion of the same fissure, containing a thin layer of mesoblast, which forms the falx cerebri; behind and laterally they overlap the roof and sides of the other cerebral vesicles, so that by the seventh month they project

(From Mihalkovics.)

behind them In the floor of each of these hemispheres there occurs a local thickening, which forms the **corpus striatum,** which is continuous behind with the optic thalamus presently to be described. The surface of the hemisphere is at first smooth, but about the fifth month a sulcus or groove appears in either hemisphere just external to the corpus striatum; this is the **fissure of Sylvius**: subsequently other fissures appear on the surface, three of which are of sufficient depth to cause a projection into the lateral ventricle. These are the **hippocampal fissure,** corresponding to the hippocampus major of the lateral ventricle, the **collateral fissure,** corresponding with the bend of the posterior horn of the ventricle; and the **calcarine fissure,** corresponding with the projection of the calcar avis.

The remainder of the first vesicle and the second, as we have seen, form the third ventricle, in its normal walls a thickening takes place, which forms the **optic thalamus.** From the floor of this ventricle a hollow protrusion passes downward, and is intimately connected with a diverticulum from the stomodæum, to form part of the **pituitary body** (*hypophysis cerebri*) (Figs. 553, 554, and 555). The greater part of the roof of the third ventricle is very thin, and with the pia mater

forms the **velum interpositum**; from its posterior part an outgrowth of cells forms the **pineal body** (*epiphysis cerebri*). Where the cerebral hemispheres are not separated in the middle line by the falx, in front and for some distance backward over the roof of the third ventricle their mesial surfaces come in contact, and to a certain extent fuse together, leaving, however, a small portion where no union takes place, and thus a slit-like cavity is left; this is termed the **fifth ventricle**, though it will be at once seen that its development is quite different from that of the other ventricles. Its lateral walls form the **septum lucidum**. The roof of this cavity becomes thickened, and nerve-fibres pass across from the one hemisphere to the other to form the **corpus callosum**, while in its floor longitudinal fibres are developed to form the **fornix**.

The third vesicle, the cavity of which forms the **iter a tertio ad quartum ventriculum**, develops in its roof four well-marked thickenings, which together form

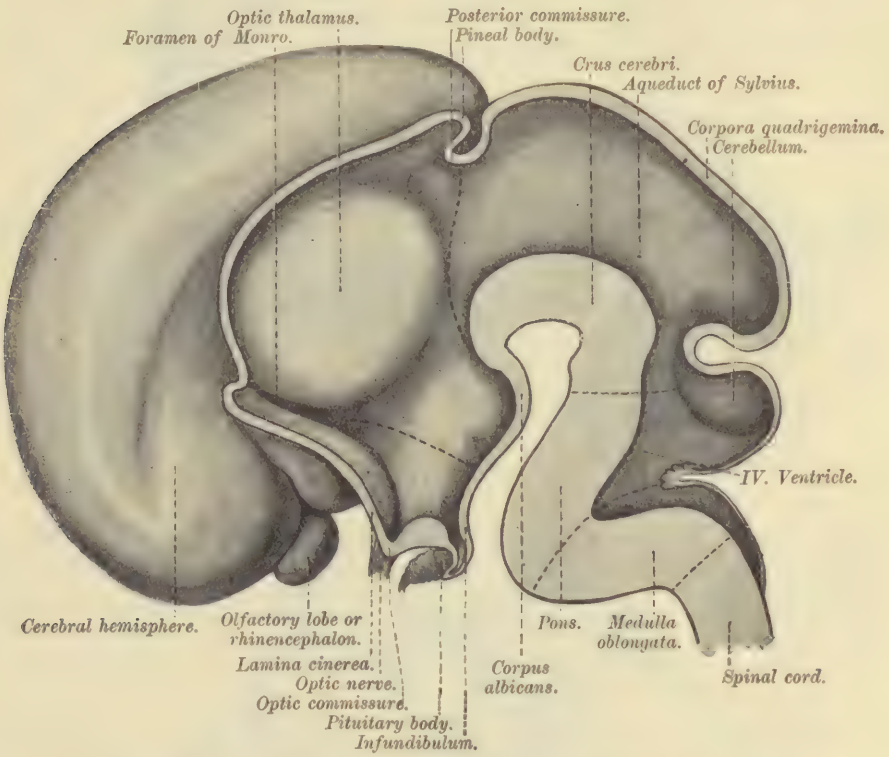

FIG. 555.—Median section of brain of human fœtus during the third month. (After His.)

the **corpora quadrigemina**, while its lateral regions become thickened to form the **crura cerebri** (Fig. 555).

The dorsal surface of the fourth vesicle forms the covering of the fourth ventricle, and in it a thickening occurs which is developed into the **cerebellum**; its ventral and lateral regions form the **pons** (Fig. 555).

In the fifth vesicle the lateral parts increase and grow downward on each side toward the middle line, forming the **medulla**, while the dorsal surface assists in forming the roof of the fourth ventricle.

On making a transverse section of the lower part of the fourth ventricle, the alar and basal laminae, already referred to as being present in the cord, are readily recognized, while the thin roof-plate is seen to be greatly expanded laterally. The dorsal part of the alar lamina becomes folded outward and downward, form-

ing what is termed the **rhomboid lip** (Fig. 556). This is at first separated by a groove from the lateral aspect of the alar lamina, but ultimately fuses with it. As the central canal of the cord opens out to form the fourth ventricle, the alar and basal laminae come to occupy the floor of the ventricle—the basal lamina lying nearest the mesial plane.

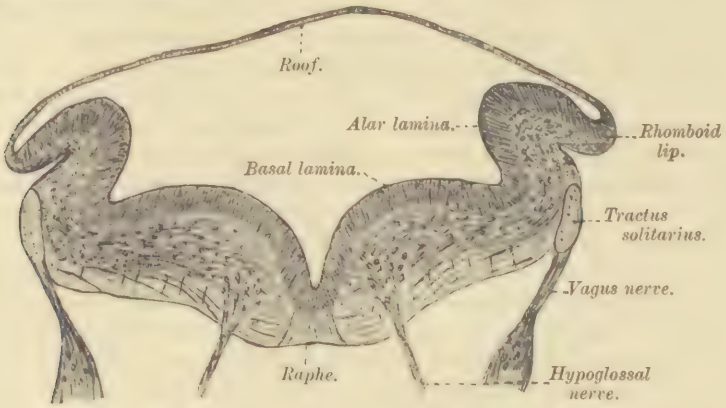

FIG. 556.—Transverse section of medulla oblongata of human embryo. (After His.)

The Communications of the Parts of the Brain.—In the posterior fossa of the cranium lies the medulla oblongata, the pons Varolii, and the cerebellum, and between these structures and the cerebrum is the tentorium cerebelli. The pons, medulla, and cerebellum surround the fourth ventricle. The greater portion of the fibres of the medulla are continued into the pons, but some fibres from the dorsal aspect of the medulla (the restiform bodies) pass into the cerebellum and

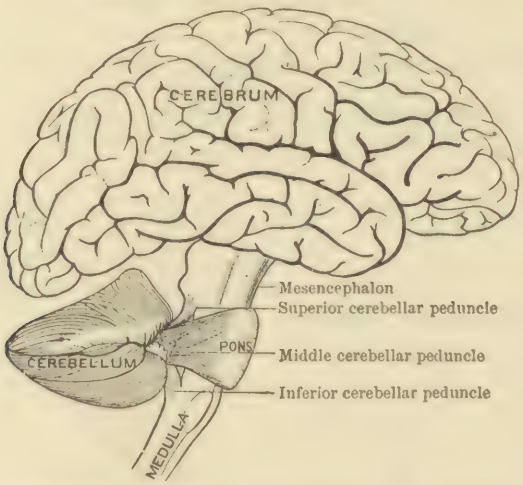

FIG. 557.—Scheme showing the connections of the several parts of the brain. (Cunningham.)

become the **inferior cerebellar peduncles** (Fig. 557). On each side of the pons a thick strand of transverse fibres passes to the cerebellum. These strands are the **middle cerebellar peduncles** (Fig. 557).

The cerebral hemispheres are joined together by the **corpus callosum**, a commissure lying within the depths of the great longitudinal fissure. Between and beneath the cerebral hemispheres is the **inter-brain** (*thalamencephalon*), composed chiefly of the **optic thalami**. In the interior of each hemisphere is a space called

the **lateral ventricle.** Between the optic thalami is the third ventricle. The **foramen of Monro** connects the third ventricle with the lateral ventricles.

The mid-brain connects the cerebrum with the pons, medulla, and cerebellum. It is composed of the **crura cerebri,** which join together the pons and the cerebrum; the **corpora quadrigemina,** and the **superior cerebellar peduncles** (Fig. 557), which connect together the cerebrum and the cerebellum. In the mid-brain the **aqueduct of Sylvius** joins the third ventricle and the fourth ventricle.

General Considerations and Divisions.—For the purposes of description the brain may be divided into five parts, as follows: (1) the two **cerebral hemispheres**; (2) the **inter-brain** (*thalamencephalon*); (3) the **mid-brain** (*mesencephalon*); the **hind-brain** (*rhombencephalon*), which includes (4) the **pons Varolii** and **cerebellum**; and (5) the **medulla oblongata.** If the student will refer to the section on the Development of the Brain he will find that these five portions correspond fairly accurately to the five secondary cerebral vesicles, of which the brain at an early period of embryonal life consisted; the prosencephalon, or *first* vesicle, by means of a protrusion from its front part on either side, forms the cerebral hemispheres and the lateral ventricles; the remainder of the prosencephalon, together with the *second* vesicle, the thalamencephalon, form the inter-brain and third ventricle; the *third* vesicle, the mesencephalon, forms the mid-brain, or that portion which connects the inter-brain and hemispheres above with the pons Varolii below, and the cavity of the vesicle forms the aqueduct of Sylvius, or iter a tertio ad quartum ventriculum; the *fourth* vesicle, the metencephalon, becomes the future pons Varolii and cerebellum, and its cavity forms the upper half of the fourth ventricle; and, finally, the *fifth* vesicle, the myelencephalon, develops into the medulla oblongata, and its cavity forms the lower half of the fourth ventricle. It will thus be seen that the five divisions of the encephalon mentioned above correspond to the five secondary cerebral vesicles, with the exception of the first two, which together form the cerebral hemispheres and the inter-brain. In consequence of this these two portions of the brain are sometimes grouped together as the **cerebrum.**

I. The Hemispheres of the Cerebrum (Hemisphaeria Cerebri).

General Considerations.—The two hemispheres constitute the largest portion of the encephalon, and, together with the parts derived from the **inter-brain** (*thalamencephalon*) form what is called by some writers the **fore-brain** (*prosencephalon*). They occupy the whole of the vault of the skull, and consist of a central cavity, in either hemisphere, surrounded by exceedingly thick and convoluted walls of nervous tissue. The under surface or base of the cerebrum is of an irregular form, resting in front on the anterior and middle fossæ of the skull and behind upon the tentorium cerebelli. The upper surface is of an ovoid form, broader behind than in front and convex in general outline. The **frontal pole** (*polus frontalis*) is the most prominent portion of the anterior end of the hemisphere. The most prominent portion of the posterior end is the **occipital pole** (*polus occipitalis*). The most prominent part of the temporal lobe below the fissure of Sylvius is the **temporal pole** (*polus temporalis*). The upper surface is divided into two lateral halves or hemispheres, the **right** and **left,** by the **great longitudinal fissure** (*fissura longitudinalis cerebri*), which extends throughout the entire length of the cerebrum in the middle line, reaching down to the base of the brain in front and behind, but interrupted in the middle by a broad transverse commissure of white matter, the **corpus callosum,** which connects the two hemispheres together.

The Constituent Parts of the Hemisphere.—The hemisphere is composed of three distinct parts: the **brain-mantle** (*pallium*), the chief mass of the hemisphere; the **olfactory brain** or **lobe** (*rhinencephalon*), composed of the olfactory

bulb, anterior perforated space, a portion of the uncinate gyrus, the hippocampus, the septum lucidum, etc., and the **corpus striatum.**

The Surface of the Cerebrum.—Each hemisphere presents an **outer convex surface** (*facies convexa cerebri*), filling the concavity of the corresponding half of the vault of the cranium; an **inner, flattened surface** (*facies medialis cerebri*), which is vertical and directed toward the corresponding surface of the opposite hemisphere (the two inner surfaces forming the sides of the longitudinal fissure); and an **under surface** or **base** (*basis cerebri*), of irregular form, which rests in front on the anterior and middle fossæ of the base of the skull, and behind upon the tentorium cerebelli. The hemispheres are composed of an outer stratum of gray matter (*substantia grisea*), called the **cortical substance** or the **cerebral cortex**, and in the interior of a mass of white matter (*substantia alba*) called the **medullary centre.** The cortex is thrown into a number of creases or infoldings, which are termed **fissures** and **sulci** (*sulci cerebri*), and these separate the surface into a number of irregular eminences, named **convolutions** or **gyri** (*gyri cerebri*).

The infoldings or creases are of two kinds, **complete fissures** and **incomplete fissures** or **sulci.** The **complete fissures** (*fissurae*) are of large size, and appear early in fœtal life; they are few in number, nearly constant in their arrangement, and are produced by infoldings of the entire thickness of the wall of the cerebrum, producing corresponding elevations in the interior of the ventricle, and hence are termed **complete fissures.** They comprise (*a*) the **hippocampal** or **dentate fissure**; (*b*) the **anterior part of the calcarine fissure**; (*c*) the **collateral fissure.** The **sulci** are vastly more numerous than the complete fissures; they are superficial depressions of the gray matter, which is folded inward and only indents the central white substance. They produce no corresponding elevations in the interior of the ventricle, and are therefore spoken of as **incomplete fissures.** They are fairly constant in their arrangement, and have received names indicative of their position and direction, but at the same time vary, within certain limits, in different individuals. They are similar, without being absolutely identical, on the two sides of the brain. It therefore follows that the **gyri** or **convolutions** (*gyri cerebri*) which lie between these sulci are fairly constant in their general arrangement. The gyri upon the surface are called **superficial gyri.** Within the sulci, adjacent superficial gyri are joined by **deep gyri** (*gyri profundi*). Short gyri, superficial or deep which connect two gyri of greater length are called **annectant** or **transitional gyri** (*gyri transitivi*).

The number and extent of the convolutions, as well as the depth of the intervening sulci, appear to bear a close relation to the intellectual power of the individual, as is shown in their increasing complexity of arrangement as one ascends from the lowest mammalia up to man, where they present a most complex arrangement. Again, in the child, at birth, before the intellectual faculties are exercised, the convolutions are simpler, and the sulci between them shallower, than in the adult. In old age, when the mental faculties have diminished in activity, the gyri and sulci become less prominently marked. By their arrangement the convolutions are adapted to increase the amount of gray matter without occupying much additional space, while they also afford a greater extent of surface for the termination of white fibres in gray matter.

It will be convenient in the first instance to describe the fissure which separates the two hemispheres from each other, and those which divide each hemisphere into its larger divisions.

Fissures and Sulci of the Outer Surface of the Hemispheres. The Longitudinal Fissure (*fissura longitudinalis cerebri*) (Fig. 560).—This great fissure separates the cerebrum into two hemispheres, and reaches from the front to the back of the organ; it contains a vertical process of the dura mater, the **falx cerebri** (p. 849). In front and behind the longitudinal fissure extends from the top (dorsal surface) to

the bottom (ventral surface) of the cerebrum, and completely separates the two hemispheres, but its middle portion only separates the hemispheres for about half their vertical extent, the floor of this part of the fissure being formed by the great central white commissure, the **corpus callosum** (Figs. 567 and 571), which connects the two hemispheres together.

The remaining fissures are situated in one or other of the two hemispheres, with the exception of the **transverse fissure,** one-half of which is contained in each hemisphere.

Sylvian Fissure (*fissura cerebri lateralis* [*Sylvii*]) (Figs. 558, 561, 565, and 570).—This fissure is a well-marked cleft on the base and side of the hemisphere. Starting at the base of the brain in a depression, the **vallecula Sylvii,** in which is situated the **anterior perforated space** (Fig. 570). The fissure passes outward between the frontal and temporal lobes, along the lesser wing of the sphenoid

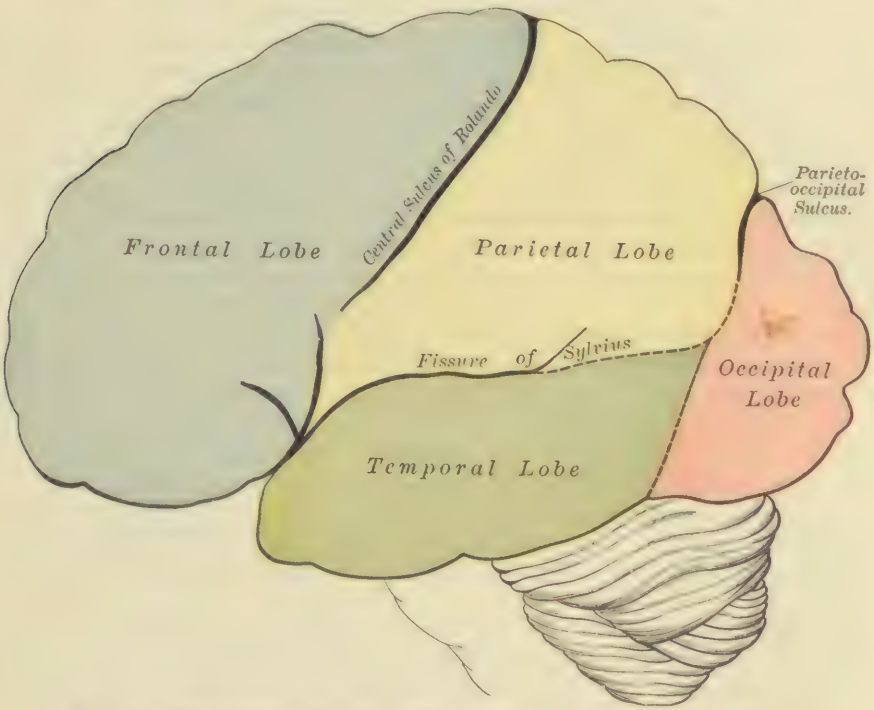

FIG. 558.—Chief fissures and lobes on the external surface of the cerebral hemispheres.

bone to the external surface of the hemisphere. The point at which it reaches the external surface is called the **Sylvian point.** It here gives off a short **anterior horizontal limb** (*ramus anterior horizontalis*), which passes forward, and a short **ascending** or **vertical limb** (*ramus anterior ascendens*), which passes upward into the inferior frontal convolution. It also gives off the **posterior horizontal limb** (*ramus posterior*), which is the most distinct of the three branches. The posterior horizontal limb lies under the middle third of the lateral surface of the hemisphere and above the temporal lobe. It passes backward and slightly upward for about two and a half inches and terminates by an upward inflexion in the parietal lobe, which is called the **ascending terminal portion.** The anterior horizontal and the vertical limbs are separated by the **frontal operculum** (*pars triangularis*), which is the foot of the inferior frontal convolution. A portion of the same convolution below the anterior limb is called the **orbital operculum** (*pars orbitalis*). Between the vertical and posterior horizontal limbs is the **fronto-parietal operculum** (*pars opercularis*).

Limiting Sulcus of Reil (*sulcus circularis Reili*) (Fig. 566).—If the lips of the posterior horizontal limb of the Sylvian fissure are widely separated, the **island of Reil** (*insula*) (Figs. 566 and 568) is seen in the depths, surrounded by the limiting sulcus. The upper or external portion of the sulcus separates the island from the parietal and frontal lobes, the lower or posterior portion from the temporal lobe, and the anterior portion from the frontal lobe.

The Central Sulcus of Rolando or the Fissure of Rolando (*sulcus centralis* [*Rolandi*]) (Figs. 558, 559, 561, 565, and 574).—The fissure of Rolando is situated about the middle of the outer surface of the hemisphere, and, coursing obliquely downward and forward, divides the surface of the hemisphere into approximately equal parts. It is between the frontal and parietal lobes. It commences as a rule on the mesial surface of the longitudinal fissure, runs forward a short distance, and ascends to the superior mesial border, which it reaches a little behind its mid-point, that is at a point half an inch behind the middle of a line drawn from the nasal eminence to the external occipital protuberance. It then runs sinuously downward and forward, to terminate a little above the hori-

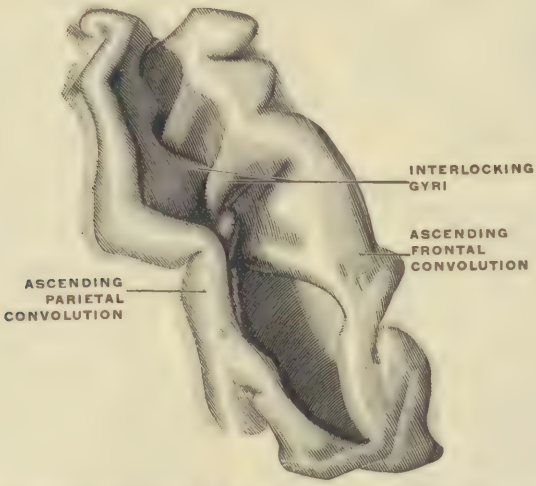

FIG. 559.—Sulcus of Rolando fully opened up, so as to exhibit the interlocking gyri and deep annectant gyrus behind it. (Cunningham.)

zontal limb of the fissure of Sylvius, and about half an inch behind the ascending limb of the same fissure. The angle made by the fissure of Rolando and the mesial plane is known as the **Rolandic angle**, and it varies in the adult between 69 degrees and 74 degrees (Cunningham). It forms two chief curves: the upper or **superior curve** or **genu** is concave forward and upward, while the lower or **inferior curve** or **genu** has its concavity directed backward. If the lips of the Rolandic fissure are opened, we will see in the depths frontal gyri interlocked with parietal gyri (Fig. 559). Two of these gyri are often fused, and this fused gyrus is named the **deep annectant gyrus** (Fig. 559).

The Parieto-occipital Sulcus (*sulcus occipitoparietalis*) (Figs. 558, 562, 564, and 565).—The parieto-occipital sulcus is only seen to a slight extent on the outer surface of the hemisphere, being situated for the most part on its mesial aspect. The portion on the outer surface is called the **external parieto-occipital sulcus**, to distinguish it from the part continued on to the internal surface, which is termed the **internal parieto-occipital sulcus**. The external parieto-occipital sulcus commences about midway between the posterior extremity or occipital pole of the brain and the central sulcus of Rolando, and runs downward and outward for about half an inch, and is ended by an arch-shaped convolution (*arcus parieto-*

occipitalis). The internal parieto-occipital sulcus is vertical in direction, is very distinct, and passes into the calcarine fissure. When its lips are fully separated, deep annectant gyri come into view.

Besides the three fissures which have been discussed, the following must be mentioned (the situation of each is shown in Fig. 561). On the outer surface of the hemisphere there are the three frontal sulci, the **sulcus frontalis superior, medius,** and **inferior.** The **sulcus paramedialis,** the **superior** and **inferior precentral sulci, sulcus diagonalis,** the **superior** and **inferior temporal sulci,** the **superior** and **inferior post central sulci,** the **ramus occipitalis,** the **sulcus occipitalis transversus,**

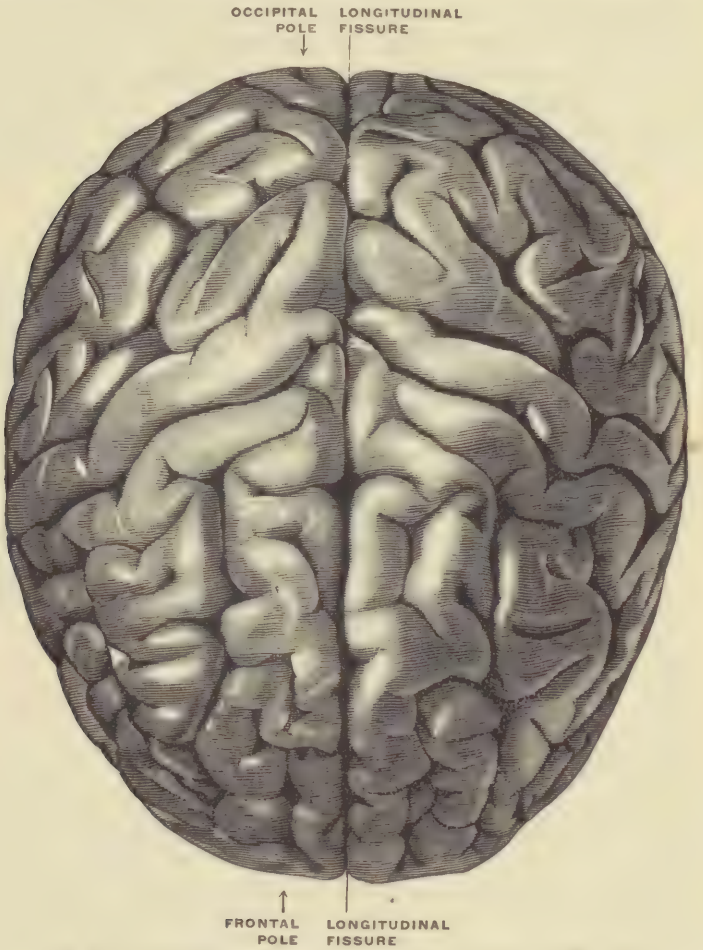

FIG. 560.—The cerebral hemispheres viewed from above. (Spalteholz.)

the **ramus horizontalis,** the **calloso-marginal sulcus,** the **inferior transverse furrow** (Fig. 561). The **sulcus interparietalis** (of Turner) is a group of four sulci: the **sulcus post-centralis inferior,** the **sulcus post-centralis superior,** the **ramus horizontalis,** and the **ramus occipitalis.** The first two are usually joined; the last two remain distinct and separate. When the lips of the intraparietal sulcus are widely opened, deep annectant gyri come into view.

The fissures of Sylvius, of Rolando, and the parieto-occipital sulcus divide the external surface of the hemisphere into four lobes: the **frontal,** the **parietal,** the **occipital,** and the **temporal lobes.** To these must be added (1) the **central lobe** or **island of Reil,** which is situated deeply in the Sylvian fissure, and (2) the **olfactory**

lobe, which is found at the base of the brain and was formerly described under the name of the olfactory nerve.

The Lobes on the External Surface.—The lobes on the external surface have received their names from the bones of the skull with which they are most nearly in relation, but it must be borne in mind that they do not correspond in shape or limit with the bone after which they are named. The division is, moreover, to a certain extent artificial, as will be seen from the following description. If a line is drawn in continuation of the external parieto-occipital sulcus downward and outward to the lower border of the hemisphere, it will impinge on a slight notch, the **pre-occipital notch**, and if a second line is prolonged backward from the horizontal part of the fissure of Sylvius to join the first line, the division of the outer surface of the hemisphere into four lobes will be accomplished (Fig. 558). The portion in front of the central sulcus of Rolando is the **frontal lobe**; that behind the central sulcus of Rolando and above the fissure of Sylvius is the **parietal lobe**; the

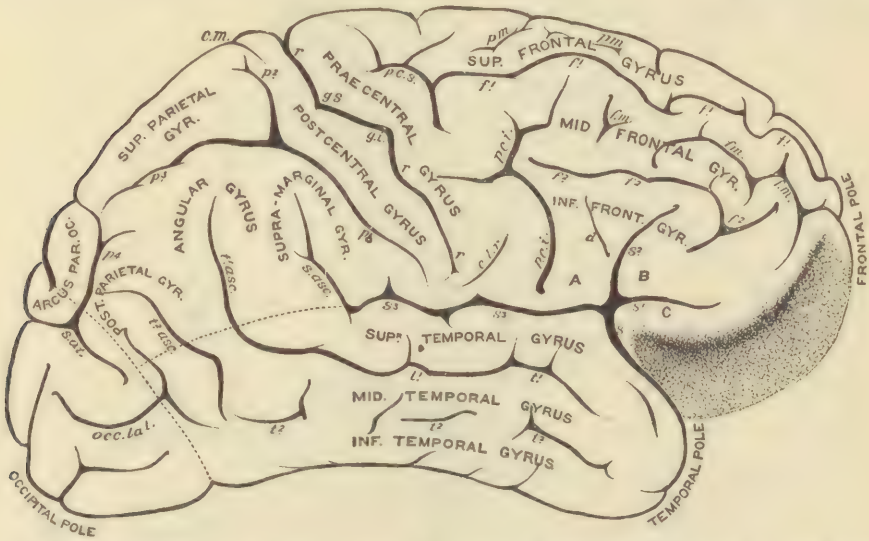

FIG. 561.—Gyri and sulci on the outer surface of the cerebral hemisphere. f^1, sulcus frontalis superior; f^2, sulcus frontalis inferior; *f.m.*, sulcus frontalis medius; *p.m.*, sulcus paramedialis; *A*, pars basilaris; *B*, pars triangularis; *C*, pars orbitalis; *S*, Sylvian fissure; s^1, anterior horizontal limb (Sylvian fissure); s^2, ascending limb (Sylvian fissure); s^3, posterior horizontal limb (Sylvian fissure); *p.c.i.*, inferior precentral sulcus; *p.c.s.*, superior precentral sulcus; *r*, fissure of Rolando; *g.s.*, superior genu; *g.i.*, inferior genu; *d*, sulcus diagonalis; t^1, superior temporal sulcus (parallel); t^2, inferior temporal sulcus; p^1, inferior post-central sulcus; p^2, superior post-central sulcus; p^3, ramus horizontalis; p^4, ramus occipitalis; *s.o.t.*, sulcus occipitalis transversus; *c.m.*, calloso-marginal sulcus; *c.t.r.*, inferior transverse furrow. (Cunningham).

portion behind the parieto-occipital sulcus and its imaginary line of continuation to the pre-occipital notch is the **occipital lobe**; and the part below the fissure of Sylvius and in front of the occipital lobe is the **temporal lobe**.

The Fissures, Sulci, and Lobes of the Mesial and Tentorial Surfaces.—The mesial surface of the cerebrum can only be fully viewed by dividing the corpus callosum and the structures beneath it longitudinally in the middle line; in order to expose the tentorial surface, the pons Varolii, cerebellum, and medulla must be removed, by division of the crus cerebri on either side. The diagram (Fig. 562) and the section (Fig. 564) show these fissures and sulci. The parts in the centre, below the corpus callosum, belong to the interior of the brain, and will be disregarded for the present, while the lobes and fissures of the remaining portion of the hemisphere are considered. The fissures and sulci are ten in number on each side, in addition to a small part of the fissure of Sylvius, the commencement of which is seen separating the frontal and temporal lobes and the beginning and end of the great longitudinal fissure. These fissures and sulci are named the **olfactory**

sulci, the **orbital sulci**, the **inferior** and **middle temporal sulci**, the **occipito-temporal sulci**, the **calloso-marginal** and the **internal parieto-occipital sulci**, the **calcarine**, the **collateral**, and the **dentate** or **hippocampal fissures.**

The Olfactory Sulcus (*sulcus olfactorius*) (Figs. 563 and 566).—The olfactory sulcus is a straight furrow which lodges the olfactory tract and bulb.

The Orbital Sulcus (*sulcus orbitalis*) (Figs. 563 and 566).—The orbital sulcus is usually shaped somewhat like the letter H, and is then composed of an external limb (*sulcus orbitalis externus*), an internal limb (*sulcus orbitalis internus*), and a transverse portion (*sulcus orbitalis transversus*). The parts of the orbital sulcus are often complicated and irregular, and are sulci rather than parts of a sulcus.

The Inferior Temporal Sulcus (*sulcus temporalis inferior*).—The inferior temporal sulcus is shown in Fig. 563.

The Occipito-temporal Sulcus (Fig. 563).—The occipito-temporal sulcus is in the tentorial base of the occipital lobe. It is external to the collateral fissure, is not limited purely to the temporal lobe, and bounds the occipito-temporal gyrus externally. It often consists of two or more portions.

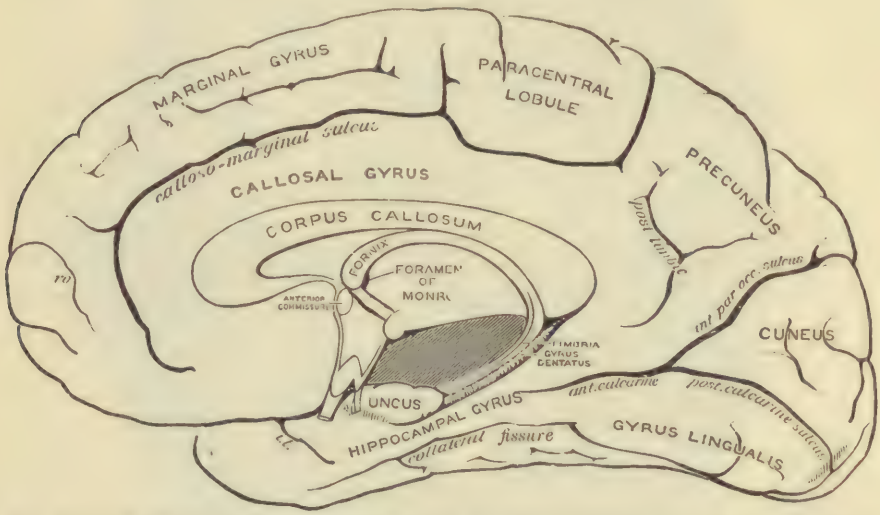

FIG. 562.—The gyri and sulci on the mesial aspect of the cerebral hemisphere: *r*, fissure of Rolando; *r.o.*, rostral sulcus; *i.t.*, incisura temporalis. (Cunningham.)

The Calloso-marginal Sulcus (*sulcus cingulus*) (Figs. 562, 564, and 567).—The calloso-marginal sulcus commences below the anterior extremity of the corpus callosum; it at first runs forward and upward, parallel with the rostrum of the corpus callosum, and, winding round in front of the genu of that body, it continues from before backward, between the upper margin of the hemisphere and the convolution of the corpus callosum, to about midway between the anterior and posterior extremities of the brain, where it ascends to reach the upper margin of the hemisphere, a short distance behind the superior extremity of the fissure of Rolando.

The Internal Parieto-occipital Sulcus (*sulcus parietooccipitalis*) (Figs. 562, 564, and 567).—The internal parieto-occipital sulcus extends in an oblique direction downward and forward to join the calcarine fissure, on a level with the hinder end of the corpus callosum.

The Calcarine Fissure (*fissura calcarina*) (Figs. 562, 564, and 567).—The calcarine fissure commences, usually by two branches, close to the posterior extremity of the hemisphere. These soon unite, and the fissure runs nearly horizontally forward, and is joined by the parieto-occipital fissure, and continues as far as the

posterior extremity of the corpus callosum, a little below the level of which it terminates in the limbic lobe. Its anterior part causes the prominence in the interior of the brain known as the **hippocampus minor** or **calcar avis.**

The Collateral Fissure (*fissura collateralis*) (Figs. 562, 563, 564, and 567).—The collateral fissure is situated on the tentorial surface, below and external to the preceding, being separated from it by the **subcollateral** or **uncinate gyrus.** It runs forward, from the posterior extremity of the brain, nearly as far as the tip of the temporal lobe. It lies below the posterior and descending horns of the lateral ventricle, and its middle part causes the prominence in the interior of the brain known as the **eminentia collateralis.**

The Dentate or Hippocampal Fissure (*fissura hippocampi*) (Figs. 563, 564, and 567).—The dentate or hippocampal fissure commences immediately behind

FIG. 563.—Gyri and sulci on the tentorial and orbital aspects of the cerebral hemisphere. (Cunningham.)

the posterior extremity of the corpus callosum, and runs forward to terminate at the recurved part of the hippocampal gyrus. It causes the prominence of the **hippocampus major** in the descending horn of the lateral ventricle.

In addition to these fissures, which are constant, there is frequently an irregular broken fissure, which is sometimes an independent sulcus, but which often appears to be a continuation backward of the posterior part of the calloso-marginal fissure, before it ascends to reach the upper edge of the hemisphere. This has been termed the **post-limbic fissure** (Fig. 562). The fissures of the internal and tentorial surfaces map off portions of the hemisphere, which form parts of the lobes found on the external surfaces. That portion which lies in front and above the calloso-marginal fissure belongs almost entirely to the frontal lobe; its posterior extremity, which extends for a short distance behind the upper end of the

fissure of Rolando, forms a small part of the parietal lobe; that portion which lies above the internal parieto-occipital fissure and behind the calloso-marginal fissure forms a part of the parietal lobe; that between the parieto-occipital fissure above and the calcarine fissure below is a portion of the occipital lobe; and all the region below the calcarine fissure behind and the collateral fissure in front belongs to the temporal lobe. The remainder of the mesial and tentorial surfaces of the hemisphere constitute what Broca termed the **limbic lobe,** which is subsequently referred to (p. 878).

The surface of the hemisphere has thus been divided by large sulci and fissures into its different parts—viz., the frontal, the parietal, the occipital, the temporal, the limbic, the olfactory lobes, and the island of Reil. Each of these lobes is further subdivided into convolutions or gyri by smaller fissures, which, though less constant in their arrangement than the larger fissures, have a fairly definite course.

1. **The Frontal Lobe** *(lobus frontalis)* (Figs. 558, 561, 562, 563, 564, 565, and 566). —It is the largest of the lobes of the cerebrum. Its outer surface is bounded behind

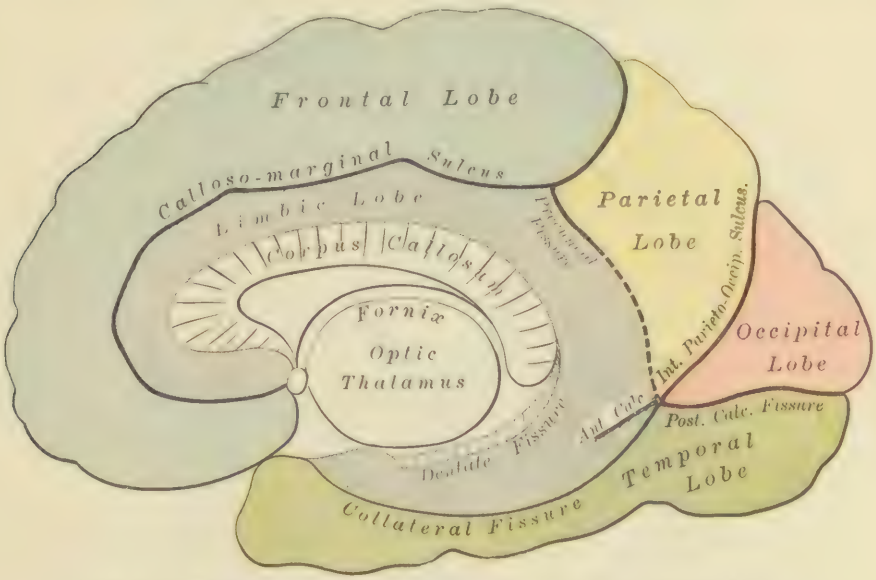

FIG. 564.—Fissures and lobes on the internal surface of the cerebral hemispheres.

by the central sulcus of Rolando and below by the posterior horizontal limb of the fissure of Sylvius. On the orbital surface the fissure of Sylvius bounds it posteriorly. On the mesial surface it is bounded by the calloso-marginal sulcus.

External Surface.—On its external surface the frontal lobe presents three sulci and four gyri or convolutions. The sulci are the precentral, the superior frontal, and the inferior frontal.

The **Precentral Sulcus** *(sulcus praecentralis)* is divided into two parts: The **inferior precentral sulcus** *(sulcus praecentralis inferior)* is composed of two parts (Figs. 561 and 565): one part (the vertical) is placed before the Rolandic fissure; the other part (the horizontal) passes upward and to the front into the middle frontal convolution. The **superior precentral sulcus** *(sulcus praecentralis superior)* is vertical in direction and is placed in front of the upper part of the Rolandic fissure. The other frontal sulci are shown in the diagrams.

The **ascending frontal convolution** or **praecentral gyrus** *(gyrus centralis anterior* or *gyrus frontalis ascendens)* (Figs. 561 and 565), one of the chief motor areas of the

cortex, is a simple convolution, and is limited in front by the precentral sulcus and behind by the fissure of Rolando. It extends from the upper margin of the hemisphere above to a little behind the bifurcation of the fissure of Sylvius below. From it two sulci, the **superior** and **inferior frontal sulci** (*sulcus frontalis superior* and *sulcus frontalis inferior*), run forward and downward, and divide the remainder of the outer surface of the lobe into three parallel principal convolutions, named respectively the **superior, middle,** and **inferior frontal convolutions** (Figs. 561 and 565).

The **superior** or **first frontal convolution** (*gyrus frontalis superior*) (Figs. 561 and 565) is situated between the margin of the longitudinal fissure and the superior frontal sulcus. It extends above on to the inner aspect of the hemisphere, forming the greater part of the **marginal convolution** (Figs. 562, 564, and 567), and in front on to the orbital surface, forming the **internal orbital convolution** (Figs. 563 and

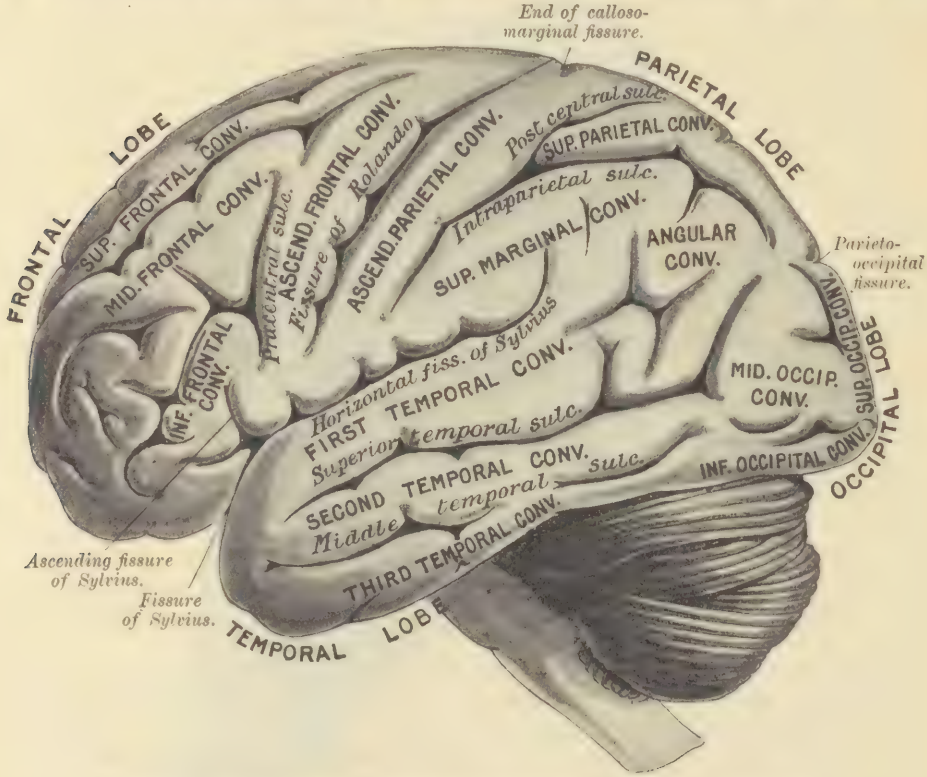

FIG. 565.—Convolutions and sulci on the external surface of the cerebral hemisphere.

566). It is usually more or less completely subdivided into two (*pars superior* and *pars inferior*) by several depressions of trivial length, the aggregation being called by Cunningham the **sulcus paramedialis.** It is frequently interrupted and broken into several parts by bridging convolutions.

The **second** or **middle frontal convolution** (*gyrus frontalis medius*) (Figs. 561 and 565) is situated between the superior and inferior frontal sulci, and extends from the precentral sulcus on to the orbital surface of the lobe, where it forms the anterior orbital convolution (Figs. 563 and 566). The middle frontal convolution is frequently subdivided into two (*pars superior* and *pars inferior*) by a sagittally directed sulcus, the **sulcus frontalis medius** of Eberstaller.

The **third** or **inferior frontal convolution** (*gyrus frontalis inferior*) (Figs. 561 and 565) is situated below the inferior frontal sulcus, and extends forward from the lower part of the precentral sulcus, on to the under surface of the lobe, where it forms the pos-

terior orbital convolutions (Figs. 563 and 566). The inferior frontal convolution is subdivided by the anterior and ascending limbs of the fissure of Sylvius into three parts—viz.: (1) **anterior part** or the **orbital operculum** (*pars orbitalis*), below the anterior limb of the fissure of Sylvius; (2) **middle part** or "**cap**" **of Broca** or the **frontal operculum** (*pars triangularis*), between the anterior horizontal and the vertical limbs of the fissure of Sylvius; and (3) **posterior part** or the **fronto-parietal operculum** (*pars basilaris*), behind the posterior horizontal and vertical limbs of the fissure of Sylvius. In the basilar part is the **sulcus diagonalis** (*d* in Fig. 561). The left inferior frontal convolution is, as a rule, more highly developed than the right, and is named the **convolution of Broca**, from the fact that in 1861 Broca declared that it was the centre for speech. It is now known that the region of speech comprises the posterior part of the inferior frontal convolution and the fronto-parietal operculum.

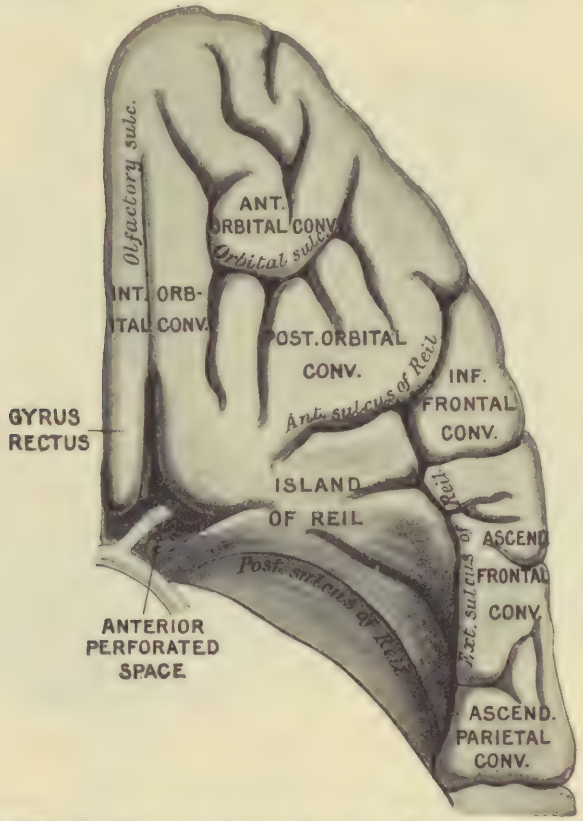

FIG. 566.—Convolutions and sulci on the under surface of the anterior lobe.

Under Surface (Figs. 563 and 566).—The under surface of the frontal lobe rests on the orbital plate of the frontal bone, and is sometimes named the **orbital lobe.** It is divided into three convolutions by a well-marked sulcus, the **orbital** or **tri-radiate sulcus** (*sulci orbitales*). These convolutions are named, from their position, the **internal, anterior,** and **posterior orbital convolutions,** and are the continuations respectively of the superior, middle, and inferior frontal convolutions of the external surface. The internal orbital convolution presents a well-marked antero-posterior groove or sulcus, the **olfactory sulcus** (*sulcus olfactorius*), for the olfactory bulb and tract; and the portion internal to this is named the **gyrus rectus,** and is continuous with the marginal gyrus, presently to be described.

Mesial or Internal Surface (Figs. 562 and 567).—The mesial or internal surface of the frontal lobe is occupied by a single curved convolution, which from its

situation is termed the **marginal gyrus** (*gyrus marginalis*). It commences in front of the anterior perforated space, runs along the margin of the longitudinal fissure on the mesial surface of the orbital lobe, where it is continuous with the internal orbital convolution; it then ascends, and runs backward to the point where the calloso-marginal fissure turns upward to reach the superior border of the hemisphere. An oval portion at the posterior part of this convolution is sometimes marked off by a vertical fissure, and is distinguished as the **paracentral lobule** (*lobulus paracentralis*), because it is continuous with the convolutions in front and behind the central fissure or fissure of Rolando. In the anterior portion of the marginal gyrus are two sulci named the **sulci rostrales**.

2. **The Parietal Lobe** (*lobus parietalis*) (Figs. 558, 561, 562, 564, 565, and 567).—This lobe includes a considerable portion of the surface of the hemisphere,

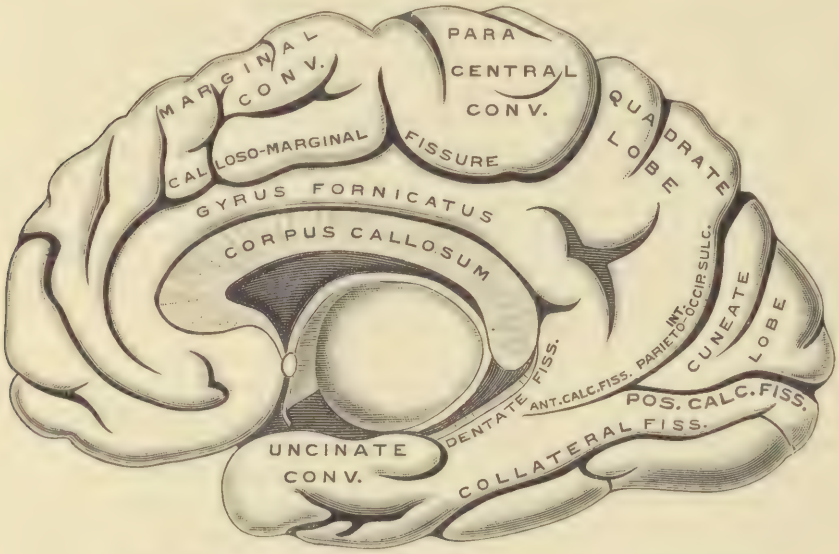

FIG. 567.—Convolutions and sulci on the internal surface of the cerebral hemispheres.

and it also occupies the portion of the mesial surface known as the **quadrate lobule** or **cuneus**. It is bounded in front by the central sulcus of Rolando. Posteriorly it is partly separated from the occipital lobe by the external parieto-occipital sulcus. Below it is partly limited by the posterior horizontal limb of the fissure of Sylvius.

External Surface.—On its external surface the parietal lobe presents for examination one sulcus (which is divided into four parts) and three convolutions.

The **Intraparietal Sulcus of Turner** (*sulcus intraparietalis*) (Figs. 561 and 565), according to Prof. Cunningham, is a group of four sulci—viz., the **superior post-central sulcus** (*sulcus postcentralis superior*), the **inferior post-central sulcus** (*sulcus postcentralis inferior*), the **horizontal ramus** (*ramus horizontalis*), and the **occipital ramus** (*ramus occipitalis*). The first named lies back of the upper portion of the central sulcus of Rolando; the second lies back of the lower portion of the same sulcus. In front of the post-central sulci is the **ascending parietal** (**post-central**) **convolution** (*gyrus centralis posterior*). The superior and inferior post-central sulci are usually continuous. The upper end of the inferior post-central sulcus is prolonged upward and backward as the ramus horizontalis between the superior and inferior parietal gyri. The ramus occipitalis may or may not be joined to the ramus horizontalis. It is the external boundary of the arcus parieto-occipitalis.

The **ascending parietal convolution** or the **post-central gyrus** (*gyrus ascendens parietalis* or *gyrus postcentralis*) (Figs. 561 and 565) is usually regarded as one of the chief motor areas of the cortex, although Mills, Sherrington and others are of the opinion that the motor areas are all in front of the central sulcus of Roland. The ascending parietal convolution is bounded in front by the central sulcus of Rolando, behind by the superior and inferior post-central sulci. It extends from the great longitudinal fissure above to the posterior horizontal limb of the fissure of Sylvius below. It lies parallel with the ascending frontal convolution, with which it is connected below, and also, sometimes, above the termination of the central sulcus of Rolando.

The **superior parietal convolution** (*lobulus parietalis superior*) (Figs. 561 and 565), still regarded by some as a part of the motor area of the cortex, is bounded in front by the superior post-central sulcus, which lies between it and the previous convolution, but with which it is usually connected above the upper extremity of the sulcus; behind, it is joined to the occipital lobe by a narrow convolution, the **first annectant gyrus** (*arcus parietooccipitalis*); below, it is separated from the inferior parietal convolution by the horizontal portion of the intraparietal sulcus; and above, it is continuous on the inner surface of the hemisphere with the quadrate lobe.

The **inferior parietal convolution** (*lobulus parietalis inferior*) (Figs. 561 and 565) is that portion of the parietal lobe which is situated between the ascending portion of the intraparietal sulcus in front, the horizontal portion of the same sulcus above, the horizontal limb of the fissure of Sylvius below, and the posterior boundary of the parietal lobe behind. It is divided into three convolutions: the supramarginal, the angular, and the post-parietal. One, the **supramarginal convolution** (*gyrus supramarginalis*), lies behind the ascending part of the intraparietal sulcus and above the horizontal limb of the fissure of Sylvius, over the extremity of which it arches. It is connected in front with the ascending parietal convolution below the intraparietal sulcus, and behind with the first or superior temporal convolution around the posterior extremity of the fissure of Sylvius (Fig. 561). The **angular convolution** or the **angular gyrus** (*gyrus angularis*) is united anteriorly with the foregoing, while posteriorly it is continuous with the middle or second temporal convolution by a process which curves around the superior temporal or parallel sulcus (Fig. 561). The **post-parietal convolution** or the **second annectant gyrus** passes around the posterior end of the middle temporal convolution and into the inferior temporal convolution. It joins the inferior parietal convolution to the occipital lobe.

The Internal or Mesial Surface (Figs. 562 and 564).—The internal or mesial surface of the parietal lobe is continuous with the external surface over the upper edge of the hemisphere. It is of small size, and forms one square-shaped convolution, which from its shape is termed the **quadrate lobe**. From its situation above the cuneate lobe it is named the **precuneus** (*praecuneus*). The **post-limbic sulcus** imperfectly separates the precuneus from the limbic lobe.

3. **The Occipital Lobe** (*lobus occipitalis*) (Figs. 558, 561, 562, 563, 564, 565, and 567).—The occipital lobe is indefinitely separated from the temporal and parietal lobes. It is defined by Cunningham as the portion of "the hemisphere which encloses the posterior horn of the lateral ventricle." In form it is pyramidal, and it possesses an apex, the **occipital pole** (*polus occipitalis*), and three surfaces. The inferior surface is directly continuous with the temporal and limbic lobes. On the outer surface the external parieto-occipital fissure partly separates it from the parietal lobe. On the mesial surface the internal parieto-occipital fissure separates it from the precuneus.

External Surface (Figs. 561 and 565).—The occipital lobe is divided on its external surface into three convolutions by two indistinct sulci, the **superior** and **middle occipital sulci** (*sulcus occipitalis transversus* and *sulcus occipitalis lateralis*). They are directed backward across the lobe, being frequently small and ill marked; the superior is sometimes continuous with the horizontal portion of the intraparietal sulcus.

The **superior occipital convolution** (*gyrus occipitalis superior*) is situated above the superior sulcus, and is connected to the superior parietal convolution by the **first annectant gyrus.**

The **middle occipital convolution** (*gyrus occipitalis medius*) is situated between the superior and middle occipital sulci, and is connected to the angular convolution by the **second annectant gyrus**, and to the middle temporal convolution by the **third annectant gyrus.**

The **inferior occipital convolution** (*gyrus occipitalis inferior*) is situated below the middle occipital sulcus, and is sometimes separated from the external occipito-temporal convolution on the under surface of the hemisphere by an inconstant sulcus, the **inferior occipital sulcus** (*sulcus occipitalis inferior*). The inferior occipital convolution is connected to the inferior temporal convolution by the **fourth annectant gyrus.**

Internal or Mesial Surface (Figs. 562, 564, and 567).—The internal or mesial surface of the occipital lobe presents a triangular convolution, which is known as the **cuneate lobule** (*cuneus*). I is situated between the internal parieto-occipital sulcus and the calcarine fissure, which, as already mentioned, meet some distance behind the posterior extremity of the corpus callosum.

The **lingual gyrus** or **subcalcarine convolution** (*gyrus lingualis*) is between the calcarine and collateral fissures, and runs forward into the hippocampal portion of the limbic lobe. A portion of the gyrus lingualis is on the mesial aspect and a portion on the inferior aspect of the occipital lobe (Fig. 563).

Inferior Surface (Fig. 563).—The inferior or **tentorial surface** of the occipital lobe possesses one convolution, the **occipito-temporal gyrus,** which is continuous with the temporal lobe and the **limbic lobe** (p. 878), and is bounded externally by the occipito-temporal sulcus.

The centre for visual memory is in the external surface of the occipital lobe and the angular gyrus.

4. **The Temporal Lobe** (*lobus temporalis*) (Figs. 558, 561, 562, 563, 564, 565, and 567).—The temporal lobe is sometimes called the **temporo-sphenoidal lobe.** This lobe lies behind the junction point and below the posterior horizontal limb of the Sylvian fissure. On its inferior (tentorial) surface the collateral fissure separates it from the hippocampal portion of the limbic lobe. The apex of the temporal lobe projects in front of the Sylvian junction. The lobe presents an outer and an inferior surface.

Outer Surface (Figs. 561 and 565).—The outer surface is subdivided by two sulci, named respectively the **first** and **second temporal sulci.**

The **First Temporal Sulcus** (*sulcus temporalis superior*) is well marked, and runs from before backward through the temporal lobe parallel with, but some little distance below, the posterior horizontal limb of the fissure of Sylvius; hence it is often termed the **parallel sulcus.**

The **Second Temporal Sulcus** (*sulcus temporalis medius*) takes the same direction as the first, but is situated at a lower level, and is often interrupted by one or more bridging convolutions. These two sulci subdivide this surface of the temporal lobe into three convolutions.

The **first** or **superior temporal convolution** (*gyrus temporalis superior*) is situated between the posterior horizontal limb of the fissure of Sylvius and the first temporal sulcus, and is continuous behind with the supramarginal convolution.

The **second** or **middle temporal convolution** (*gyrus temporalis medius*) lies between the first and second temporal sulci, and is continued behind into the angular and middle occipital convolutions.

The **third** or **inferior temporal convolution** (*gyrus temporalis inferior*) is placed below the second temporal sulcus; it is connected posteriorly with the inferior occipital convolution, and is also prolonged on to the under or tentorial surface

of the temporal lobe (Fig. 563), where it is limited internally by the third temporal sulcus, about to be described.

Inferior Surface (Fig. 563).—The inferior or tentorial surface presents two fissures—viz., the **third temporal sulcus** and the **collateral fissure**—the latter fissure has already been described (p. 871).

The **Third Temporal Sulcus** (*sulcus temporalis inferior*) extends from near the occipital pole behind to near the anterior extremity of the temporal lobe in front, but is, however, frequently subdivided by bridging gyri.

The convolution on the inferior surface is the **fourth temporal** or **subcollateral** or the **occipito-temporal convolution.** It is situated between the third temporal sulcus and the collateral fissure.

5. **The Central Lobe or Island of Reil (Insula)** (Figs. 566, 568, 576, and 577).—The central lobe or island of Reil lies deeply in the Sylvian fissure, and can only be seen when the lips of that fissure are widely separated, since it is overlapped and hidden by the convolutions which bound the fissure. These convolutions are termed the **opercula of the insula** (*opercula insulae*) (operculum, a lid); they are separated from each other by the three limbs of the Sylvian fissure, and are named the **orbital, frontal, fronto-parietal,** and **temporal opercula** (p. 866). The insula

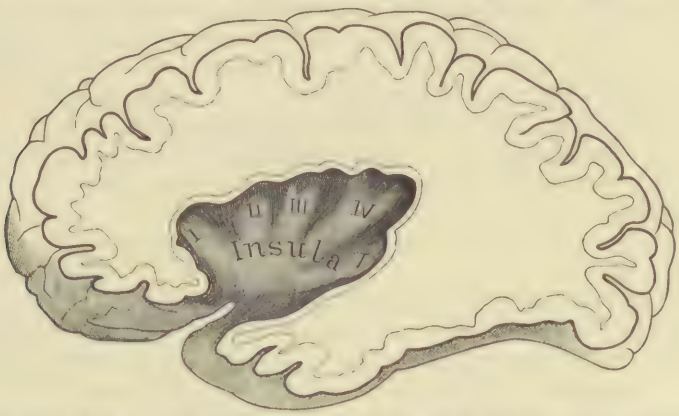

Fig. 568.—The island of Reil. Left side. The overlapping parts of the hemisphere have been removed. 1, 2, 3. Gyri breves. 4, 5. Gyrus longus, bifurcated at its upper extremity. (Dalton.)

is almost surrounded by a deep limiting sulcus, the **limiting sulcus of Reil** (*sulcus circularis Reili*) (Fig. 566 and p. 867), which separates it from the frontal, parietal, and temporal lobes. When the opercula have been removed, the insula presents the form of a triangular eminence; its apex is directed downward and inward toward the anterior perforated space, and is continuous in front with the posterior orbital convolution. At the apex of the insula the limiting sulcus does not exist, and the gray matter passes into the anterior perforated space. This point is called the **limen insulae.** The insula is continuous behind with the **hippocampal convolution.** It is divided into a **pre-central** and a **post-central lobe** by the sulcus centralis, which runs backward and upward from the apex of the insula. The pre-central lobe is further subdivided by shallow sulci into three or four short convolutions, the **gyri breves insulae,** while the post-central lobe is named the **gyrus longus insulae,** and is often bifurcated at its upper extremity. The gray matter of the insula is continuous with that of the different opercula, while its mesial surface corresponds with the external surface of lenticular nucleus of the corpus striatum, from which it is separated by the external capsule and claustrum.

6. **Limbic Lobe** (Figs. 564 and 569).—The term limbic lobe or *grande lobe limbique* was introduced by Broca in 1878, and under it he included two convolutions—viz., the **callosal** and **hippocampal convolutions,** which together arch around

the corpus callosum and the hippocampal fissure. These he separated on the morphological ground that they are well developed in animals possessing a keen sense of smell (osmatic animals), such as the dog and fox. To the lobe thus defined the following parts must be added—viz., the laminae of the septum lucidum, together with the fornix and its fimbriae, which may be regarded as forming an inner or deep arch; the peduncles and longitudinal striae of the corpus callosum, together with the gyrus dentatus, which form a middle arch, while the outer arch is constituted by the callosal and hippocampal convolutions; the first two arches are separated from each other by the corpus callosum.

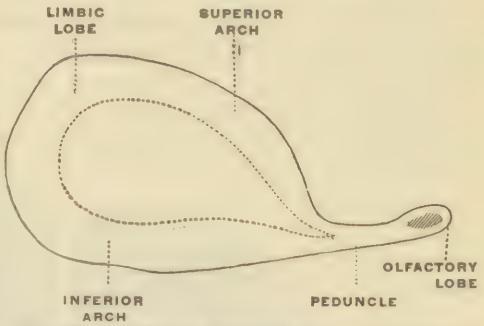

FIG. 569.—Scheme of the limbic lobe. (Poirier and Charpy.)

Convolutions of the Limbic Lobe.—(1) The **callosal convolution** (*gyrus fornicatus* or *gyrus cinguli*) (Figs. 562 and 567) is an arch-shaped convolution, lying in close relation to the superficial surface of the corpus callosum, from which it is separated by a slit-like sulcus, the **callosal sulcus** (*sulcus corporis callosi*). It commences below the rostrum of the corpus callosum. The inner root of the olfactory tract enters the beginning of the convolution. The callosal convolution curves around in front of the genu, extends along the upper surface of the body, and finally turns downward behind the splenium, where it becomes narrow because the calcarine fissure cuts it. The narrow portion is the **isthmus** (*isthmus gyri fornicati*). The isthmus connects the callosal convolution with the **gyrus hippocampi**. The callosal convolution is separated from the marginal convolution by the calloso-marginal sulcus, from the precuneus by the post-limbic sulcus, and from the lingual gyrus by the anterior portion of the calcarine fissure.

(2) The **hippocampal convolution** (*gyrus hippocampi*) (Figs. 562 and 563) is bounded above by the hippocampal or dentate fissure, and below by the anterior part of the collateral fissure. Behind, it is continuous superiorly, through the isthmus, with the callosal convolution, and inferiorly with the subcalcarine or lingual convolution. Its anterior extremity is recurved in the form of a hook, and is named the **uncinate convolution** or **uncus** (Fig. 567). Running in the substance of the callosal and hippocampal convolutions, and connecting them together, is a tract of arched fibres, named the **fillet of the gyrus fornicatus** or the **cingulum**. The outer root of the olfactory tract passes into the anterior extremity of the hippocampal convolution, and the inner root into the commencement of the callosal convolution, so that these two convolutions, with the addition of the olfactory tract, present a racquet-like appearance—the olfactory tract constituting the handle and the two convolutions the circumference of the blade.

(3) The **dentate convolution** (*gyrus dentatus*) (Figs. 562 and 581), also called the **dentate fascia** (*fascia dentata hippocampi*). It is situated above the gyrus hippocampi, from which it is separated by the **hippocampal** or **dentate fissure** (*fissura hippocampi*) (Figs. 562, 564, and 567). The dentate convolution is covered by the **fimbria**, a prolongation of the posterior pillar of the fornix, and is a narrow, elongated convolution, the free surface of which presents a notched or toothed appearance, hence its name. Posteriorly it is prolonged as a delicate lamina, the **fasciola cinerea**, around the splenium of the corpus callosum, and becomes continuous on the upper surface of that body with its mesial and lateral longitudinal striae. Anteriorly it is prolonged into the notch produced by the recurving of the uncus, where it forms a sharp curve; from here it can be traced as a delicate band, the **band of Giacomini**, over the uncus, on the outer surface of which it is lost.

The remaining structures which contribute to the formation of the limbic lobe will be subsequently described.

7. **The Olfactory Lobe or Rhinencephalon** (*lobus olfactorius*) (Figs. 555 and 569).—The olfactory lobe is situated on the under surface of the frontal lobe. It is rudimentary in man and some other mammals, but in vertebrates generally it is well developed, and consists of a distinct extension of the cerebral hemisphere, enclosing a portion of the anterior horn of the lateral ventricle. In man it is long and slender, and may be described as consisting of two parts, the **anterior** and **posterior olfactory lobules.**

The Anterior Olfactory Lobule.—The anterior olfactory lobule is made up of: (1) the **olfactory bulb**; (2) the **olfactory tract**; (3) the **trigonum olfactorium**; (4) the **area of Broca.**

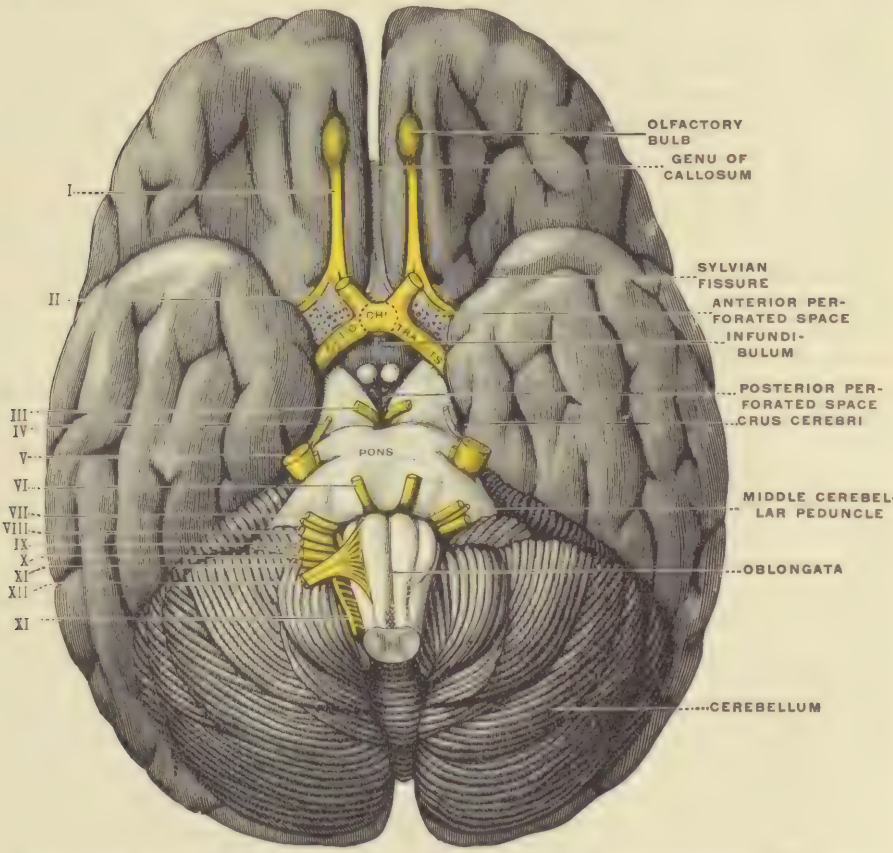

FIG. 570.—Under surface of the brain, showing the superficial origins of the cranial nerves. The Roman numerals indicate the nerves. (Testut.)

(1) The **Olfactory Bulb** (*bulbus olfactorius*) (Fig. 570) is an oval mass of reddish-gray color, which rests on the cribriform plate of the ethmoid bone below and the olfactory sulcus of the orbital surface of the frontal lobe above. It forms the anterior expanded extremity of the olfactory tract. Its under surface receives the olfactory nerves, which pass upward through the cribriform plate from the olfactory region of the nose. Its minute structure will be subsequently described.

(2) The **Olfactory Tract** (*tractus olfactorius*) (Fig. 570), often called the **olfactory nerve** or **first cranial nerve,** is a band of white matter, triangular on section, the apex being directed upward. It lies in the olfactory sulcus on the under surface of the frontal lobe. Traced backward, it is seen to divide into two roots, an outer

and an inner. Some have called the olfactory tubercle a middle root. The *outer root* passes across the outer part of the anterior perforated space to the **nucleus amygdalae** and the anterior part of the **gyrus hippocampi**. The *inner root* turns sharply inward, and ends partly in **Broca's area** and partly in the **callosal convolution**; in other words, the inner root is continuous with one extremity and the outer root with the other extremity of the limbic lobe (Fig. 569).

(3) The **Trigonum Olfactorium** or **Olfactory Tubercle** is situated between the diverging roots of the olfactory tract, and is sometimes described at the *middle* or *gray root* of the tract. It is part of an area of gray matter, which forms the base of the anterior olfactory lobule; another portion of it is termed (4) the **area of Broca** (*area parolfactoria*), the portion of gray matter between the internal root and the peduncle of the corpus callosum; and a third portion, of no special significance, is situated external to the outer root of the olfactory tract. This area of gray matter is bounded internally and posteriorly by a sulcus, the **fissura prima** (*sulcus parolfactorius posterior*), which separates it from the peduncle of the corpus callosum and from the posterior olfactory lobule. The area of Broca is continuous with the gyrus fornicatus, and receives fibres from the inner or mesial root.

The Posterior Olfactory Lobule.—The posterior olfactory lobule corresponds to the portion of the hemisphere called the **anterior perforated space** (*locus perforatus anticus* or *substantia perforata anterior*) (Figs. 566 and 570). It is marked off from the anterior lobule by the **sulcus parolfactorius posterior**, and is situated at the commencement of the fissure of Sylvius. Internally, it is bounded by the peduncle of the corpus callosum, and is continuous with the lamina cinerea. Posteriorly it is bounded by the optic tract, and it is partially concealed by the temporal lobe which overlaps it. It has received the name of **anterior perforated space** from its being perforated by numerous openings, which transmit blood-vessels to the interior of the brain, and it corresponds to the under surface of the lenticular nucleus.

Under Surface or Base of the Encephalon (*facies basalis encephali*) (Fig. 570).—Having considered the surface of the hemispheres, the student should direct his attention to the base of the brain, before commencing the study of the component parts which make up the two hemispheres.

The base of the brain presents for examination the under surfaces of the frontal and temporal lobes; the structures contained in the interpeduncular space, with the crura cerebri or cerebral peduncles; the under surfaces of the pons Varolii, cerebellum, and medulla oblongata; and the superficial origins of the cranial nerves.

The various objects exposed to view (with the exception of the superficial origins of the cranial nerves, which will be considered in another section), in the middle line and on either side of the middle line, are here arranged in the order they are met with from before backward.

In the Middle Line.	*On Each Side of the Middle Line.*
Longitudinal fissure.	Frontal lobe.
Rostrum and peduncles of corpus callosum.	Olfactory lobe.
Lamina cinerea.	The anterior perforated space.
Optic commissure.	Fissure of Sylvius.
Tuber cinereum.	Optic tracts.
Infundibulum.	Crura cerebri.
Pituitary body.	Temporal lobe.
Corpora albicantia.	Hemisphere of cerebellum.
Posterior perforated space.	
Pons Varolii.	
Medulla oblongata.	

The Longitudinal Fissure (*fissura longitudinalis cerebri*) (p. 865).—The longitudinal fissure partially separates the two hemispheres from each other. It divides completely the anterior portions of the two frontal lobes; and on raising the cerebellum and pons it will be seen to separate completely the two occipital lobes; of these two portions of the longitudinal fissure, that which separates the occipital lobes is the longer. The intermediate part of the fissure is filled up by the great transverse band of white matter, the **corpus callosum**. In the fissure between the two frontal lobes the anterior cerebral arteries ascend on the corpus callosum.

The Corpus Callosum.—The corpus callosum, the transverse commissure which joins the two cerebral hemispheres, is described on p. 886. It terminates at the base of the brain by a concave margin, which is connected with the tuber cinereum through the intervention of a thin layer of gray substance, the **lamina cinerea**. This may be exposed by gently raising and drawing back the optic commissure. A white band may be observed on each side, passing backward from the under surface of the corpus callosum, across the posterior margin of the anterior perforated space to the hippocampal gyrus, where it meets the corresponding outer root of the olfactory tract; this band is called the **peduncle of the corpus callosum** or the **gyrus subcallosus** (*pedunculus corporis callosi*). The band may be traced upward around the genu to become continuous with the striae longitudinales on its upper surface. Laterally, this portion of the corpus callosum extends into the frontal lobe.

The Lamina Cinerea.—The lamina cinerea is a thin layer of gray substance, extending upward in the anterior portion of the great longitudinal fissure from the optic commissure to join the rostrum of the corpus callosum. It is continuous on each side with the gray matter of the anterior perforated space, and forms the anterior part of the inferior boundary of the third ventricle. The portion of the lamina cinerea which is turned upward is called the **lamina terminalis**.

The Optic Commissure or Optic Chiasma (*chiasma opticum*).—The optic commissure is situated in the middle line, immediately in front of the tuber cinereum and below the lamina cinerea; that is to say, the commissure is superficial to the lamina in the order of dissection when the base is uppermost. It is the point of junction between the two optic tracts, and will be described with the cranial nerves. Immediately behind the diverging optic tracts, and between them and the **peduncles of the cerebrum** (*crura cerebri* or *pedunculi cerebri*), is a lozenge-shaped interval, the **interpeduncular space** (*fossa interpeduncularis* [*Tarini*]). The **posterior recess** (*recessus posterior*) of this space passes for a little way underneath the anterior margin of the pons; the **anterior recess** (*recessus anterior*) passes between the corpora albicantia. The floor of the interpeduncular space is the **substantia perforata posterior**, and in the space are found the following parts: the tuber cinereum, infundibulum, pituitary body, corpora albicantia, and the posterior perforated space.

The Tuber Cinereum.—The tuber cinereum is an eminence of gray matter, situated between the optic tracts, and extending from the corpora albicantia to the optic commissure, to which it is attached; it is connected with the surrounding parts of the cerebrum, forms part of the floor of the third ventricle, and is continuous with the gray substance in that cavity. From the middle of its under surface a conical tubular process of gray matter, about two lines in length, is continued downward and forward to be attached to the posterior lobe of the pituitary body. This is the **infundibulum**, and its canal, which is funnel-shaped, communicates with the third ventricle.

The Pituitary Body (*hypophysis cerebri*).—The pituitary body is a small, reddish-gray, vascular mass, weighing from five to ten grains, and of an oval form, situated in the sella turcica, where it is retained by a process of dura mater, named the **diaphragma sellae** (Fig. 544). This process of the dura covers in the sella turcica,

and has a small hole in its centre through which the infundibulum passes, the **foramen diaphragmatis sellae** (Fig. 544).

Structure.—The pituitary body is very vascular, and consists of two lobes, separated from one another by a fibrous lamina. Of these, the anterior and the larger is of an oblong form, and somewhat concave behind, where it receives the posterior lobe, which is round. The two lobes differ both in development and structure. The **anterior lobe**, of a dark, reddish-brown color, is developed from the epiblast of the buccal cavity, and resembles to a considerable extent, in microscopic structure, the thyroid body. It consists of a number of isolated vesicles and slightly convoluted tubules, lined by epithelium and united together by a very vascular connective tissue. The epithelium is columnar and occasionally ciliated. The alveoli sometimes contain a colloid material, similar to that found in the thyroid body, and their walls are surrounded by a close network of lymphatic and capillary blood-vessels. The **posterior lobe** is developed as an outgrowth from the embryonic brain, and during fœtal life contains a cavity which communicates through the infundibulum with the cavity of the third ventricle. In the adult it becomes firmer and more solid, and consists of a sponge-like connective tissue arranged in the form of reticulating bundles, between which are branched cells, some of them containing pigment. In the lower animals the two lobes are quite distinct, and it is only in the mammalia that they become fused together. The pituitary body is believed to be a *ductless gland*, which furnishes an internal secretion. In many cases of acromegaly the gland is enlarged or otherwise diseased.

The Corpora Albicantia or Corpora Mamillaria.—The corpora albicantia or mamillaria are two small, round, white masses, each about the size of a pea, placed side by side immediately behind the tuber cinereum, and connected with each other across the mesial plane. They are mainly formed by the anterior crura or pillars of the fornix, which, after descending to the base of the brain, are twisted upon themselves to form loops, and constitute the white covering of the corpora albicantia. A second fasciculus, the **bundle of Vicq d'Azyr** (*fasciculus thalamomamillaris*) (Figs. 574 and 586), converges from the optic thalamus, and enters the anterior part of each body on its dorso-mesial surface. The corpora albicantia are composed externally of white substance, and internally of gray matter; the nerve-cells of the gray matter are arranged in two sets, inner and outer, the cells of the former set being the smaller. Each corpus is connected to the tegmentum by a small bundle of fibres, the **peduncle of the mamillary body** (*pedunculus corporis mamillaris* (Fig. 586). At an early period of fœtal life the corpora albicantia are blended together into one large mass, but become separated about the seventh month. In most vertebrates there is only one median corpus albicans.

The Posterior Perforated Space or Lamina or the Pons Tarini (*locus perforatus posticus, substantia perforata posterior*).—The posterior perforated space corresponds to a whitish-gray fossa placed between the corpora albicantia in front, the pons Varolii behind, and the crus cerebri on either side. It is in reality a visible portion of the substantia nigra and forms the floor of the interpeduncular fossa. It forms the posterior part of the floor of the third ventricle, and is perforated by numerous small orifices for the passage of the postero-median ganglionic branches of the posterior cerebral and posterior communicating arteries. Slender white bands are observed in some subjects coming from the gray matter of the posterior perforated space, passing around the crura cerebri, and entering into the pons Varolii. The bands bear the name of the **taenia pontis**.

The Pons Varolii (p. 922).—The pons Varolii is situated immediately behind the two crura of the cerebrum. It consists of a broad band of white fibres, which pass transversely from one cerebellar hemisphere to the other; the band becoming

narrower as it enters the cerebellum. In the middle line on its under surface a narrow groove runs from before backward and accommodates the basilar artery.

The Medulla Oblongata, Medulla Spinalis or Bulb (p. 938).—The medulla oblongata emerges from the posterior border of the pons Varolii; it is pyramidal in form, and is continuous below with the cervical portion of the spinal cord. It is marked on its ventral surface by a median fissure, continuous below with the anterior median fissure of the cord, and on either side by secondary fissures and columns, which will be described in the sequel.

The Frontal Lobe.—The under surface of the frontal lobe, sometimes named the **orbital lobe,** is seen on the anterior part of the base of the brain on either side of the median line. It has already been described (p. 874).

The Olfactory Lobe (p. 880).

The Anterior Perforated Space (p. 881).

The Fissure of Sylvius (*fissura lateralis cerebri*).—The fissure of Sylvius at the base of the brain separates the frontal from the temporal lobe, and lodges the middle cerebral artery. It has also been described (p. 866).

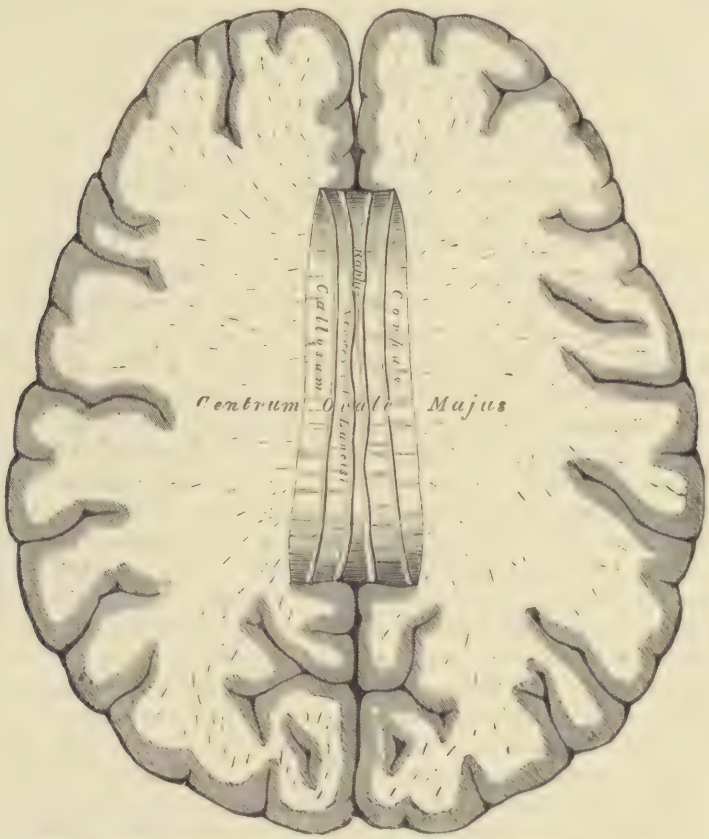

FIG. 571.—Section of the brain. Made on a level with the corpus callosum.

The Optic Tracts.—The optic tracts are well-marked, flattened bands of fibres, which run obliquely across the crus cerebri on either side, and unite anteriorly to form the optic commissure. They will be described in connection with the cranial nerves.

The Crura Cerebri or the Peduncles of the Cerebrum (*pedunculi cerebri*) (p. 906).—The crura cerebri are two thick cylindrical bundles of white matter, which appear

in front of the anterior border of the pons, and diverge as they pass forward and outward to enter the under surface of each hemisphere. They compose the chief portion of the mesencephalon. Each crus is about three-quarters of an inch in length, and is about the same in breadth anteriorly, but somewhat less posteriorly. They are marked upon their surface with longitudinal striae, and each is crossed, just before entering the hemisphere, by the fourth nerve and the optic tract, the latter of which is adherent by its upper surface to the peduncle. Each crus is composed of two parts, a **superior** or **dorsal part**, and an **inferior, ventral**, or **pedal part**. The dorsal part is known as the **tegmentum of the crus cerebri** (*tegmentum*), the fibres (p. 908) of which pass up into the region beneath the optic thalamus, a region known as the **subthalamic tegmental region**. The ventral portion is known as the **crusta** (*basis pedunculi*), the fibres of which (p. 907) pass up external to the optic thalamus and into the **internal capsule**. On the surface of the crus are two grooves which mark the separation between the tegmentum and the crusta. One groove is on the inner (mesial) surface; it is called the **sulcus nervi oculo-motorii**, and from it comes the third or motor oculi nerve. The other groove on the outer (lateral) surface is called the **sulcus lateralis mesencephali**. It passes down into the interval between the superior and middle cerebellar peduncles. From the outer surface of the tegmentum some slender fibres, called the **lateral fillet** (*lemniscus lateralis*), pass to the inferior quadrigeminal body. If a transverse section of the crus is made, the **substantia nigra** is seen between the tegmentum and the crusta. It is a band of pigmented gray matter which begins somewhat below the upper margin of the pons and ascends into the subthalamic area.

The Temporal Lobe (Fig. 878).—The under surface of the temporal lobe is visible at the base of the brain, on either side of the crura and the structures contained in the interpeduncular space. It is separated anteriorly from the frontal lobe by the fissure of Sylvius, and behind is limited by the anterior border of the lateral hemispheres of the cerebellum. The fissures and lobes on its surface have already been described (p. 877).

The Hemispheres of the Cerebellum (*hemisphaeria cerebelli*) (p. 929).—The hemispheres of the cerebellum are situated on either side of the middle line, and cover the occipital lobes of the cerebrum, when viewed from the base. The cerebellum differs much in appearance from the rest of the encephalon, being of a darker color, while its convolutions are smaller and narrower, are arranged like the leaves of a book, and hence are called **folia**.

General Arrangement of the Parts Composing the Cerebrum.—Each hemisphere, as already stated, consists of a central cavity, the **lateral ventricle**, surrounded by thick and convoluted walls of nervous tissue.

Interior of the Cerebrum.—If the upper part of either hemisphere is removed with a knife, about half an inch above the level of the corpus callosum, its internal white matter will be exposed. It is an oval-shaped centre, of white substance, surrounded on all sides by a narrow convoluted margin of gray matter, which presents an equal thickness in nearly every part. This white central mass has been called the **centrum ovale minus**. Its surface is studded with numerous minute red dots (*puncta vasculosa*), produced by the escape of blood from divided blood-vessels. In inflammation or great congestion of the brain these are very numerous and of a dark color. If the remaining portion of one hemisphere is slightly separated from the other, a broad band of white substance will be observed, connecting them at the bottom of the longitudinal fissure; this is the **corpus callosum**. The margins of the hemispheres which overlap this portion of the brain are called the **labii cerebri**. Each labium is part of the **callosal convolution** already described; and the space between it and the upper surface of the corpus callosum is termed the **callosal sulcus** (*sulcus corporis callosi*) (Figs. 562 and 567). The hemispheres should now be sliced off to a level with the upper surface of the corpus callosum,

when the white substance of that structure will be seen connecting the two hemispheres. The large expanse of medullary matter now exposed, surrounded by the convoluted margin of gray substance, is called the **centrum ovale majus of Vieussens** (Fig. 571).

The Corpus Callosum (Figs. 571, 574, and 586).—The corpus callosum is a thick stratum of transversely directed nerve-fibres, by which probably almost every part of one hemisphere is connected with the corresponding part of the other hemisphere (Figs. 572 and 573). It connects not only corresponding but also non-corresponding portions of the cortices. The fibres of this body, when they pass from it into the hemispheres radiate in various directions (*radiatio corporis callosi*) between the fibres of the corona radiata, to terminate in the gray matter of the periphery. According to Cajal the termination is in the layer of small pyramidal cells of the cortex. The corpus callosum thus connects the two hemispheres of the brain, forming their great transverse commissure, and at the same time roofs in the lateral ventricles (Fig. 575). The best conception of its size and form is

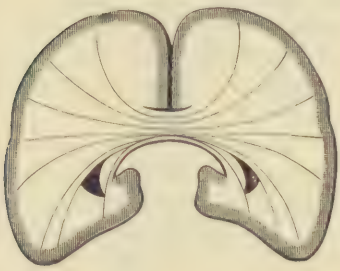

Fig. 572.—Diagram of coronal section of cerebrum to show course of fibres of callosum. (Testut.)

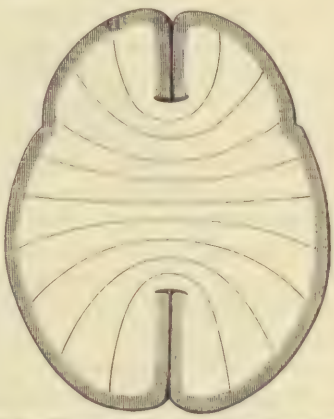

Fig. 573.—Diagram of horizontal section of cerebrum to show course of fibres of callosum. (Testut.)

obtained by making an anterior posterior vertical section through the centre of the brain (Figs. 574 and 586). It is then seen to be a long, thick, irregularly flattened arch, **body of the corpus callosum** (*truncus corporis callosi*); in front taking a sharp bend, the **genu** (*genu corporis callosi*) (Fig. 577), and dipping downward and backward to the base of the brain by a reflected portion, the **beak** or **rostrum** (*rostrum corporis callosi*), which is connected with the lamina cinerea; behind it terminates by a rounded end, which is folded over and is named the **splenium** (*splenium corporis callosi*) (Fig. 577). The corpus callosum is about four inches in length, and extends to within an inch and a half of the anterior and two inches and a half of the posterior extremity of the cerebrum. It is somewhat broader behind than in front, and is thicker at either end than in its central part. The reflected anterior portion of the corpus callosum is called the **beak** or **rostrum**; it becomes gradually thinner as it descends, and is attached by its lateral margins to the frontal lobes. At its termination, in addition to joining the lamina cinerea, the corpus callosum gives off on each side a band of white substance, the **peduncle of the corpus callosum** (*gyrus subcallosus* or *pedunculus corporis callosi*), already described (p. 882).

Posteriorly, the corpus callosum forms a thick rounded fold, called the **pad** or **splenium**, which is free for a little distance as it curves forward, and is then continuous by its under surface with the fornix. The splenium overlaps the mesencephalon, but is separated from it by the pia mater, which is prolonged forward to

form the velum interpositum (Fig. 548). On the upper surface of the corpus callosum the structure is very apparent, the fibres being collected into coarse transverse bundles (Fig. 571). Along the middle line is a longitudinal depression, the so-called **raphé,** bounded laterally on each side by two or more slightly elevated longitudinal bands (Fig. 571). The internal band on each side is called the **stria longitudinalis medialis** or **nerve of Lancisi.** The external band is the **stria longitudinalis lateralis** or **taenia tectae.** The external band is beneath the convolution of the corpus callosum. There is an attenuated sheet of gray matter with the external and internal striae, and it, with the striae, constitutes the so-called **gyrus supra-callosus** (pp. 882 and 886). On each side of the middle line the under surface of the corpus callosum forms the roof of the lateral ventricle, while in the mesial plane it is continuous behind with the fornix, being separated from it in front by the septum lucidum, which forms

FIG. 574.—Vertical median section of the encephalon, showing the parts of the middle line.

a vertical partition between the two ventricles (Figs. 574 and 586). On each side the fibres of the corpus callosum extend into the substance of the hemispheres, connecting them together. The greater thickness of the two extremities of this commissure is explained by the fact that the fibres from the anterior and posterior parts of each hemisphere cannot pass directly across, but have to take a curved direction. The part of the corpus callosum which curves forward on each side from the genu into the frontal lobe and covers the front part of the anterior cornu of the lateral ventricle is called the **forceps anterior** or **forceps minor.** The part which

curves backward from each side of the splenium into the occipital lobe is known as the **forceps posterior** or **forceps major**. Between these two parts on each side is a collection of fibres, which cover in the body of the lateral ventricle. These constitute the **tapetum** or **mat**. The tapetum helps to form the roof and outer wall of the posterior horn of the lateral ventricle and the outer wall of the posterior portion of the descending horn of the ventricle. These fibres were formerly regarded as fibres of the callosum, but in reality are the fibres of the **fasciculus occipito-frontalis** which diverge posteriorly. The corpus callosum contains a few projection fibres, but is chiefly composed of association fibres and branches from both association and projection fibres.

An incision should now be made through the corpus callosum, on either side of the raphé, when two large irregular cavities will be exposed, which extend through a great part of the length of each hemisphere. These are the lateral ventricles.

The Lateral Ventricle (*ventriculus lateralis*) (Fig. 575).—The lateral ventricle is an irregular cavity situated in the lower and inner parts of the cerebral hemisphere.

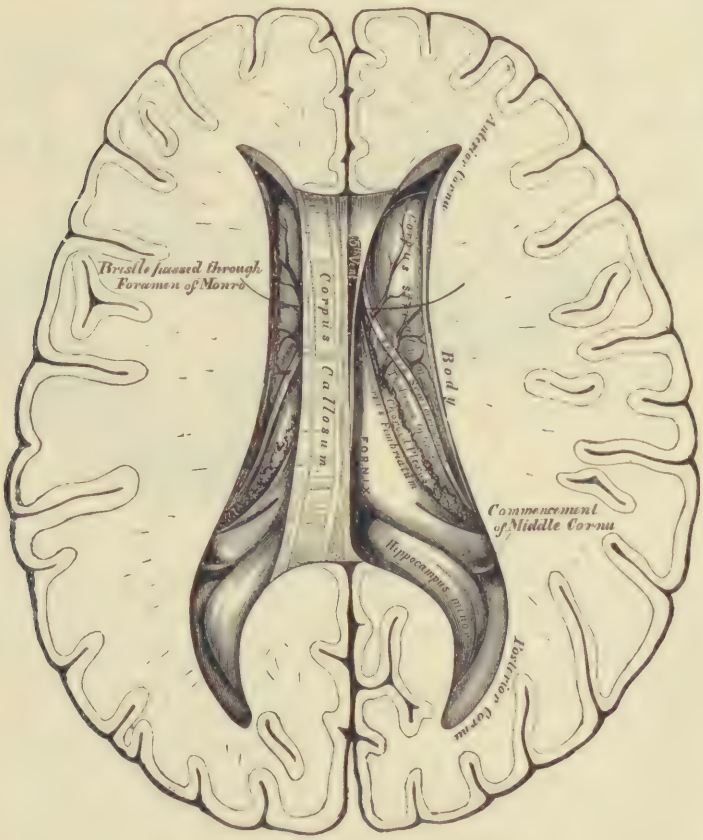

FIG. 575.—The lateral ventricles of the brain.

There are two lateral ventricles, one being placed on either side of the middle line. They are separated from each other by a mesial vertical partition, the **septum lucidum** (Figs. 574 and 586), but communicate with the third ventricle and indirectly with each other through the **foramen of Monro** (Figs. 548, 574, and 575). They are lined by a thin, diaphanous membrane, the **ependyma**, which is neuroglia covered by ciliated epithelium. The layer of neuroglia is absent over the optic thalamus and the choroid plexus. The lateral ventricles communicate with each other and with

the third ventricle, and are moistened by the cerebro-spinal fluid, which, even in health, may be secreted in considerable amount. Each lateral ventricle consists of a **central cavity** or **body** and three prolongations from it, termed **cornua.** The *anterior* cornu curves forward and outward into the frontal lobe; the *posterior* backward and inward into the occipital lobe; and the *middle* descends into the *temporal* lobe.

The **Septum Lucidum** (*septum pellucidum*) (Figs. 574, 586, and 587) is composed of two thin, vertical laminae, which lie in the median line with their mesial surfaces almost in contact. These sheets are triangular and can be separated, and the cavity thus shown is called the **fifth ventricle** (*cavum septi pellucidi*) (Fig. 575). It contains a little fluid, but does not communicate with the general ventricular cavity. Each lamina of the septum lucidum bears the name of the **lamina septi pellucidi.** The front part of the septum lucidum lies behind the genu of the corpus callosum, and below it passes toward the base of the brain between the fornix and the posterior margin of the rostrum, to terminate in the subcallosal gyrus. Posteriorly, the septum lucidum passes back between the fornix and the body of the corpus callosum, being attached to each structure.

The **Central Cavity** or **Body** of the lateral ventricle (*ventriculus lateralis* [*pars centralis*]) (Fig. 575) is situated in the lower part of the parietal lobe. It is an irregularly curved cavity, triangular in shape on transverse section, and presents a **roof,** a **floor,** an **inner wall,** and an **outer wall.** Its **roof** is formed by the under surface of the corpus callosum; its **mesial wall** is the septum lucidum, which separates it from the opposite ventricle and connects the under surface of the corpus callosum with the fornix; its **external wall** is the internal capsule; its **floor** is formed by the following parts, enumerated in their order of position, from before backward; the caudate nucleus of the corpus striatum, taenia semicircularis, the epithelial covered optic thalamus, the epithelial covered choroid plexus, the superior surface of the body of the fornix and part of its posterior pillar.

The **Anterior Cornu** or **Frontal Horn** (*cornu anterius*) (Fig. 575) passes forward and outward, with a slight inclination downward, from the foramen of Monro into the frontal lobe, curving round the anterior extremity of the caudate nucleus. Its roof is the forceps minor of the corpus callosum, and its floor the upper surface of the reflected portion of the corpus callosum, the **rostrum.** It is bounded mesially by the anterior portion of the septum lucidum, and externally by the head of the caudate nucleus of the corpus striatum. Its apex reaches the posterior surface of the genu of the corpus callosum.

The **Foramen of Monro** (*foramen interventriculare*) (Figs. 548, 574, 575, and 587) extends from the anterior and superior extremity of the third ventricle and the point of junction of the anterior horn with the central cavity of the lateral ventricle. It lies between the anterior pillar of the fornix and the anterior margin of the optic thalamus This foramen connects the third ventricle with the two lateral ventricles.

The **Posterior Cornu** or **Occipital Horn** (*cornu posterius*) (Fig. 575) curves backward into the substance of the occipital lobe, its direction being backward and outward, and then inward; its concavity is therefore directed inward. Its **roof** is formed by the tapetum of the corpus callosum passing to the temporal and occipital lobes, which also helps to bound this horn externally. On its **mesial wall** is seen a longitudinal eminence, which is in an involution of the ventricular wall produced by the calcarine sulcus; this is called the **hippocampus minor** (*calcar avis*). Just above this the forceps major of the splenium, sweeping around to enter the occipital lobe, causes another projection, which is known as the **bulb of the posterior horn** (*bulbus cornu posterius*). The hippocampus minor and bulb of the posterior horn are extremely variable in their degree of development, being in some cases ill defined, while in others they are unusually prominent. The balance of the posterior horn is bounded by the white substance of the occipital lobe.

Between the middle and posterior cornu is a triangular area, called the **trigonum ventriculi** (see Descending Horn).

The **Middle** or **Descending Cornu** or **Temporal Horn** (*cornu inferius*) (Figs. 575, 581, and 583), the largest of the three traverses the temporal lobe of the brain, forming in its course a remarkable curve around the back of the optic thalamus. It passes at first backward, outward, and downward, and then curves around the crus cerebri, forward and inward, to within an inch of the apex of the temporal lobe, its direction being fairly well indicated on the surface of the brain by that of the parallel sulcus. Its **antero-external boundary** or **roof** is formed by the under surface of the tapetum of the corpus callosum, the pulvinar of the optic thalamus, and the inferior layer of the internal capsule. The tail of the nucleus caudatus of the corpus striatum and the taenia semicircularis are also prolonged into it, and extend forward in the roof of the descending horn to its extremity, where they end in a mass of gray matter, the **amygdaloid nucleus** (*nucleus amygdalae*); this nucleus is merely a localized thickening of the adjacent gray cortex. The **posterior boundary** or **floor of the lateral ventricle** presents for examination the following parts: the **hippocampus major** (*hippocampus*), **pes hippocampi** (*digitationes hippocampi*), **eminentia collateralis** or **pes accessorius, corpus fimbriatum** (*fimbria hippocampi*), prolonged from the **posterior pillar of the fornix,** and the **choroid plexus.** Along the medial aspect of the descending cornu there is a cleft-like opening, the **choroid fissure**, which is the lower part of the transverse fissure, through which the choroid plexus of the pia mater is invaginated into the ventricle, but covered by the epithelium of the ependyma, which is pushed in before it. Upon the inner wall are also noted the **epithelial covering,** the **pulvinar,** and the **dentate convolution** or **fascia** (*fascia dentata hippocampi*) (Figs. 562 and 581), which is the irregular and free cortical margin.

FIG. 576. Horizontal section of left hemisphere through the basal ganglia, viewed from above. *C.N.*, caudate nucleus. (Testut.)

The **Corpus Striatum** (Figs. 575, 576, 577, 580, and 584), the basal ganglion of the hemisphere, has received its name from the striped appearance which its section presents, in consequence of diverging white fibres being mixed with the gray matter which forms the greater part of its substance. It is situated to the front and to the outside of the optic thalamus. The corpus striatum measures about two inches in its antero-posterior diameter and one and a quarter inches transversely.[1] The larger portion of this body is embedded in the white substance of the hemisphere, and is therefore external to the ventricle. It is termed the **extra-ventricular portion** or the **lenticular nucleus**

[1] Anatomy of the Brain and Spinal Cord. By Harris E. Santee.

(*nucleus lentiformis*); a part, however, is visible in the ventricle and its anterior cornu; this is the **intra-ventricular portion** or the **caudate nucleus** (*nucleus caudatus*). These two portions are separated by the **internal capsule.**

The **caudate nucleus** (*nucleus caudatus*) (Figs. 576, 577, 579, and 580) is a pear-shaped, highly arched mass of gray matter; its broad anterior extremity, the **bulb** or **head** (*caput nuclei caudati*), is directed forward into the forepart of the body and anterior cornu of the lateral ventricle; its narrow posterior end, the **tail** or **surcingle** (*cauda nuclei caudati*), is directed outward and backward on the floor of the body of the lateral ventricle and on the outer side of the optic thalamus, from which structure it is separated by the **taenia semicircularis** (Fig. 577); it is continued downward into the descending cornu of the lateral ventricle and

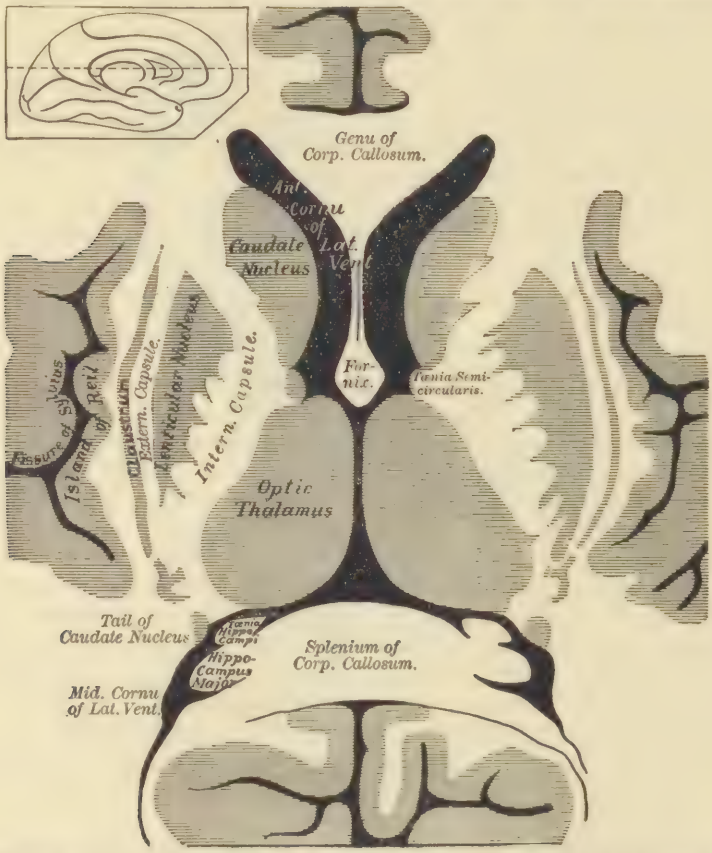

FIG. 577.—Middle part of a horizontal section through the cerebrum at the level of the dotted line in the small figure in one hemisphere. (From Ellis, after Dalton.)

is continued forward in the roof to terminate in the **amygdaloid nucleus,** a collection of gray matter in the apex of the temporal lobe. It is covered by the lining of the ventricle, and crossed by some veins of considerable size. It is separated from the extra-ventricular portion, in the greater part of its extent, by a lamina of white matter which is called the **internal capsule,** but the two portions of the corpus striatum are united in front.

The **lenticular nucleus** (*nucleus lentiformis*) (Figs. 576, 577, 579, and 580) is a mass of gray matter which lies external to the caudate nucleus and the thalamus, and is only seen in sections of the hemisphere. The laminae of the internal capsule separate it from the ventricle. If a coronal section is made through the anterior portion of the lenticular nucleus, it is seen to be continuous below with the head of the caudate nucleus (Fig. 578). Above strands of gray matter join the two nuclei,

and these bands pass through the anterior part of the white internal capsule and give it a striated appearance; hence the term corpus striatum, which is applied to the mass of which the two nuclei are parts. When divided horizontally, it presents, to some extent, the appearance of a biconvex lens, while a vertical transverse section of it gives a somewhat triangular outline. It does not extend as far forward or backward as the nucleus caudatus. It is bounded externally by a lamina of white matter called the **external capsule** (*capsula externa*) (Figs. 576, 577, 578, and 579), on the outer surface of which is a thin layer of gray matter termed the **bulwark** or **claustrum** (Figs. 576, 577, 578, and 579). The claustrum presents ridges and furrows on its outer surface, corresponding to the convolutions and sulci of the island of Reil, from which it is separated by a thin white lamina (Figs. 576, 577, and 578).

Upon making a transverse vertical section through the middle of the lenticular nucleus, it is seen to present two white lines, **external** and **internal medullary laminae** (*laminae medullare externa et interna*) (Fig. 579), parallel with its lateral border, which divide it into three zones, of which the outer and largest is of a reddish color, and is known as the **putamen,** while the two inner are paler and of a yellowish tint, and constitute the **globus pallidus** (Figs. 578 and 579). All three zones are marked by fine radiating white fibres, which are most distinct in the putamen. The gray matter of the corpus striatum is traversed by nerve-fibres, some of which are believed to originate in it. The cells of the corpus striatum are multipolar, both large and small; those of the lenticular nucleus containing yellow pigment.

The **internal capsule** (*capsula interna*) (Figs. 576, 577, 578, 579, and 580) is formed by fibres of the crusta of the crus cerebri, supplemented by fibres derived from the corpus striatum and optic thalamus on each side. Sagittal section exhibits a **superior lamina** and an **inferior lamina,** continuous with each other behind, but separated in front by the Sylvian fissure. The inferior lamina is thin and its fibres terminate in the parietal and temporal lobes. The superior lamina is thick, contains most of the crusta, and the term internal capsule as usually employed is synonymous with it. In horizontal section (Figs. 576, 577, 578, and 579) the internal capsule is seen to be somewhat abruptly curved, with its convexity inward; the prominence of the curve is called the **knee** or **genu of the internal capsule** (*genu capsule internal*) (Fig. 578), and projects between the caudate nucleus and the optic thalamus. The portion in front of the genu is termed the **frontal portion,** the **anterior limb** or the **lenticulo-striate division** (*pars frontalis capsulae internae*), and separates the lenticular from the caudate nucleus; the portion behind the genu is the **occipital portion,** the **posterior limb** or the **lenticulo-optic division** (*pars occipitalis capsulae internae*), and separates the lenticular nucleus from the optic thalamus.

Fibres of the Internal Capsule (Figs. 578 and 579). **Inferior Lamina.**—The fibres of the inferior lamina of the internal capsule pass externally under the lenticular nucleus, over the amygdala and descending horn of the lateral ventricle, and reach the parietal lobe and the temporal lobe. The **motor fibres** constitute a portion of the **motor temporo-pontal tract** which extend from the temporal cortex to the nucleus pontis. The **sensory fibres** consist of a portion of the **acustic radiation,** which passes from the corpus geniculata interna to the auditory cortex in the temporal lobe, and **ansa peduncularis,** a tract of common sensation which passes from the optic thalamus to the sensory region of the cortex. Some of the fibres of the **median fillet** join the ansa peduncularis and pass through the inferior lamina.

Superior Lamina.—This portion is often spoken of as though it were the entire internal capsule. It contains the greater part of the crusta and enters the corona radiata. The **pyramidal tract** is in the knee of the internal capsule. Its fibres come from the cortical region about the central sulcus of Rolando and

pass through the knee of the internal capsule; most of them, by way of the middle of the crusta, to reach the spinal cord (p. 907); some of them end in the pons and medulla. The anterior segment of the superior lamina of the internal capsule contains motor fibres which come from the prefrontal region of the cortex and pass by way of the inner one-fifth of the crusta to the nucleus pontis

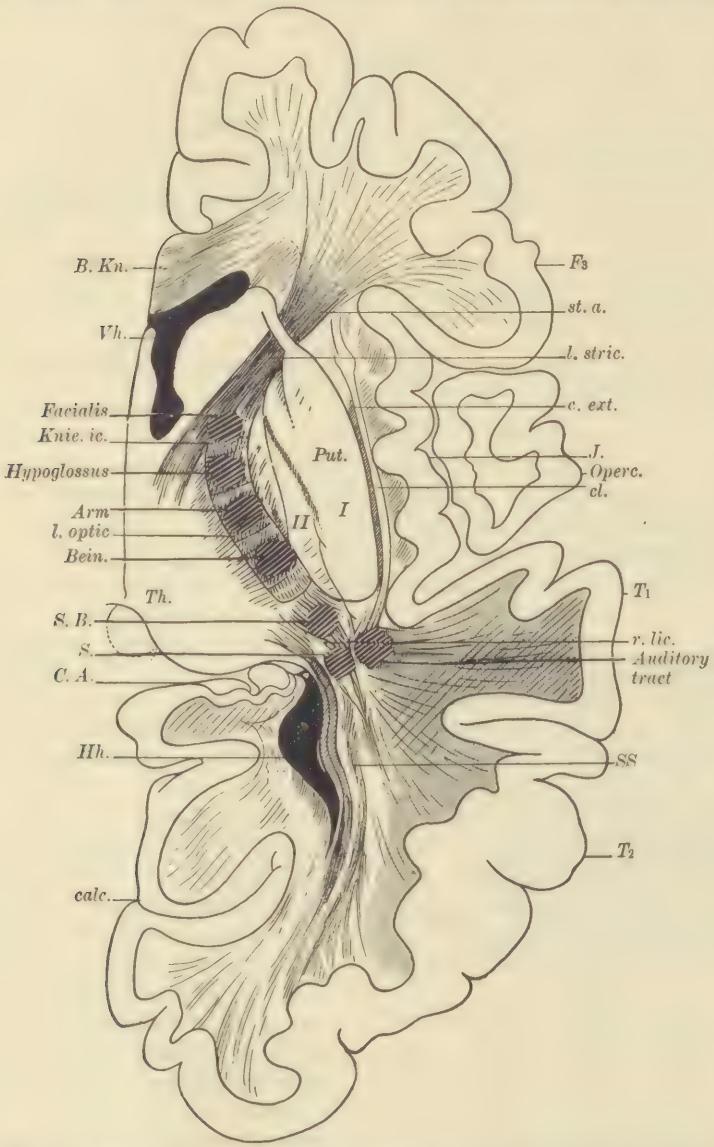

FIG. 578.—Horizontal section through the right hemisphere. *B. kn*, knee of corpus callosum; *Vh*, anterior horn of lateral ventricle; F_3, inferior part of third frontal convolution; *l. stric*, lenticulo-striate division of internal capsule; *Knie. ic*, knee of internal capsule; *l. optic*, lenticulo-optic division of internal capsule; *Th*, optic thalamus; *J*, island of Reil; *cl*, claustrum; *Operc*, operculum; T_1, first temporal convolution; *r. lic*, retrolenticular region of internal capsule; *C.A.*, hippocampus major; *calc*, calcarine fissure; *Hh*, posterior horn of lateral ventricle; *SS*, optic radiation of Gratiolet; T_2, second temporal convolution; *Facialis*, position in capsule of motor tract to the face; *Hypoglossus*, position of tract to the tongue; *Arm*, position of tract to the arm; *Bein*, position of tract to the leg; *S.B.*, sensory fibres; *S*, visual tract; *A*, auditory tract. (M. Allen Starr, after von Monakow.)

and nuclei of cranial nerves. These fibres constitute the **fronto-pontal tract** (*tractus cerebrocorticofrontalis pontalis*). In the posterior segment of the superior lamina of the internal capsule is a part of the tract from the temporal cortex to the nucleus pontis and the nuclei of cranial motor nerves, the balance

of which tract is in the inferior lamina. This path occupies the outer one-fifth of the crusta, and is the **temporo-pontal tract** (*tractus cerebrocorticopontalis temporalis*).

The **sensory fibres** include common sensory fibres and fibres of special sense. Fibres of common sensation exist in both the anterior and posterior segments, and these fibres pass from the optic thalamus to the sensory region of the cortex, and are known as the **cortical fillet**. The fibres of special sense are found where the superior lamina joins the inferior lamina.

The **optic radiations of Gratiolet** (*radiatio occipitothalamica* [*Gratioleti*]) are in the portion back of the lenticular nucleus, and pass from the optic thalamus and corpus geniculatum externum to the cuneus.

The **auditory radiations** (*radiatio temporothalamica*) are also back of the lenticular nucleus and pass from the corpus geniculatum externum to the temporal cortex.

Numerous fibres of the internal capsule give off collaterals which reach the opposite hemisphere by way of the corpus callosum, none of them reaching the cortex.

NOTE.—The above description of the fibres of the internal capsule is largely taken from the *Anatomy of the Brain and Cord*, by Harris E. Santee, M.D.

As the fibres of the internal capsule ascend to reach the various convolutions of the cerebral hemisphere they spread out like an open fan. This expansion is the **corona radiata**. The constituent parts and fibre-groups of the internal capsule are shown in Figs. 578 and 579.

The **external capsule** (*capsula externa*) (Figs. 576, 577, 578 and 579) is a lamina of white matter, situated on the outer side of the lenticular nucleus, between it and the claustrum, and is continuous with the internal capsule in front of and behind the putamen. It is made up of fibres derived partly from the anterior white commissure (Fig. 580) and partly from the subthalamic region.

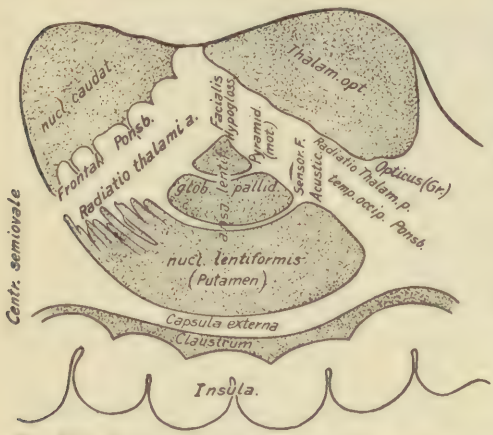

FIG. 579. Scheme of the internal capsule. (Jakob.)

The **Claustrum** (Figs. 576, 577, 578, and 579) is a thin layer of gray matter, situated on the outer surface of the external capsule. On transverse section it is seen to be triangular, with its apex directed upward and its base downward. Its inner surface, which is contiguous to the external capsule, is smooth, but its outer surface presents ridges and furrows which correspond with the convolutions and sulci of the island of Reil, with which it is in close relationship. The claustrum is regarded as a detached portion of the gray matter of the island of Reil, from which it is separated by a layer of white fibres, the **band of Baillarger** (*capsula extrema*) (Figs. 576 and 577). The cells of the claustrum are small and spindle-shaped, and contain yellow pigment; they are similar to those found in the deepest layer of the cortex.

The **Taenia Semicircularis** (*stria terminalis*) (Figs. 575, 577, and 584) is a narrow, whitish band of medullary substance, situated in the depression between the caudate nucleus and the optic thalamus. Anteriorly its fibres are partly continued into the anterior pillar of the fornix; some, however, pass over the anterior commissure to the gray matter between the caudate nucleus and septum lucidum, while

others penetrate the caudate nucleus. Posteriorly it is continued into the roof of the middle or descending horn of the lateral ventricle, at the extremity of which it enters the amygdaloid nucleus, an oval mass of gray matter, situated in the roof of the lower extremity of the descending horn. Like the corpus striatum, it is formed by a localized thickening of the gray matter of the cortex cerebri. Superficial to it is a large vein, **vena corporis striati,** which receives numerous small veins from the surface of the corpus striatum and optic thalamus; it unites with the choroid vein to form the vein of Galen (p. 856). On the surface of the vein of the corpus striatum is a narrow band of white fibres, named the **lamina cornea.**

The remains of the corpus callosum should now be removed in order to expose the fornix.

The Fornix (Figs. 574, 575, 576, 577, 580, 582, 583, 586, and 587).—The fornix is a longitudinal, arch-shaped lamella of white matter, situated beneath the corpus callosum, with which it is continuous behind, but from which it is separated in front by the septum lucidum. It may be described as consisting of two symmetrical halves, one for either hemisphere. The two portions are not united to each other in front and behind, but their central parts are joined together in the middle line. The two anterior, separated parts are called the **anterior pillars**; the intermediate united portions constitute the **body of the fornix**; and the posterior parts, which are also separated from each other, are called the **posterior pillars.**

The **Body of the Fornix** (*corpus fornicis*) is triangular, narrow in front, broad behind. Its *upper surface* is connected, in the median line, to the septum lucidum in front, and the corpus callosum behind; laterally this surface forms part of the floor of each lateral ventricle. Its *under surface* rests upon the velum interpositum, which separates it from the third ventricle and the inner portion of the upper surface of the optic thalami. Its outer edge, on each side, is free, and is connected with the choroid plexuses.

The **Anterior Pillars of the Fornix** (*columnae fornicis*) arch downward toward the base of the brain and are separated from each other by a narrow interval. They are composed of white fibres, which descend immediately behind the anterior commissure, where each anterior pillar passes through the inner part of the optic thalamus of that side. At the base of the brain each pillar becomes twisted upon itself to form a loop, somewhat resembling the figure 8. The lowest part of the loop constitutes the white matter of the corresponding **corpus albicans,** from which the fibres can apparently be traced upward and backward, as the **bundle of Vicq d'Azyr,** into the substance of the corresponding optic thalamus (Figs. 574 and 586). It must be stated, however, that there is probably no direct continuity between this bundle and the anterior pillar of the fornix—the latter possibly ending in the gray matter of the corpus albicans. The anterior pillars of the fornix are joined in their course by the **peduncles of the pineal gland** and the superficial fibres of the taenia semicircularis, and receive fibres from the septum lucidum. Zuckerkandl describes an **olfactory fasciculus,** which becomes detached from the main portion of the anterior pillar of the fornix, and passes downward, in front of the anterior commissure, to the base of the brain, where it divides into two bundles, one joining the inner root of the olfactory tract; the other, the peduncle of the corpus callosum, and through it reaching the hippocampal convolution.

Between the anterior pillars of the fornix and the anterior extremity of the optic thalamus an oval aperture is seen on each side; this is the **foramen of Monro** (*foramen interventriculare*) (Figs. 548, 574, 575, and 587). The two openings descend toward the middle line, and lead into the upper part of the third ventricle. Through this foramen the lateral ventricles communicate with the third ventricle, and consequently with each other; through it also the two choroid plexuses become joined with each other across the middle line. The boundaries of the

opening are, above and in front, the anterior pillars of the fornix; behind, the anterior extremity of the optic thalamus.

The **Posterior Pillars of the Fornix** (*crura fornicis*) are the backward prolongations of the two halves of the body of the fornix. They are flattened bands, and, at their commencement, are intimately connected by their upper surfaces with the corpus callosum. Diverging from one another, each curves round the posterior extremity of the optic thalamus, and then passes downward and forward into the descending horn of the lateral ventricle. Here it lies along the concavity of the hippocampus major, on the surface of which some of its fibres are spread out, the **alveus**, while the remainder are continued, as the **fimbria**, the **corpus fimbriatum**, the **taenia fornicis** or the **taenia hippocampi** (for it bears these different names) (Figs. 562, 575, 577, and 583), into the **hook** or **uncus** of the hippocampal convolution. Upon examining the under surface of the fornix, between its diverging posterior pillars, a triangular portion of the under surface of the corpus callosum may be seen. On it are a number of curved or oblique lines passing between the two pillars of the fornix. This portion has been termed the **lyra** or **psalterium** (Fig. 583), from the fancied resemblance it bears to a harp. It is also called the **commissura hippocampi**. In some cases there is a small space intervening between the lyra and the under surface of the corpus callosum known as **Verga's ventricle**.

The Anterior Commissure of the Cerebrum (*commissura anterior cerebri*) (Figs. 580, 584, and 587).—The anterior commissure of the cerebrum is a bundle of white fibres, in the anterior wall of the third ventricle, placed in front of the anterior pillars of the fornix, behind the rostrum of the corpus callosum, and resting upon the lamina terminalis. The anterior commissure connects the two hemispheres, and in vertebrates possessing a corpus callosum is an extremely important structure. On transverse section it is oval in shape, its largest diameter being vertical in direction and measuring about one-fifth of an inch. Its fibres pass backward and downward through the globus pallidus and below the putamen on each side, from which point most of the fibres radiate to the cortex, but some go to the external capsule. The fibres of the anterior commissure are divisible into two groups: 1. An **anterior group** (*pars anterior* or *pars olfactoria*), the fibres of which join the limbic lobes and connect each limbic lobe to the olfactory tract of the opposite side. The fact that the pars anterior contains fibres from the olfactory tract of the opposite side may serve to explain the condition of crossed anosmia, *e. g.*, where there is a lesion in one temporal lobe with a loss of smell in the olfactory area of the opposite side of the nose. 2. A **posterior group** (*pars posterior* or *pars occipitotemporalis*), the fibres of which pass to the cortex of the temporal lobe and of the lower part of the occipital lobe.

FIG. 580.—Anterior commissure, left half, viewed from above. (Testut.)

The Septum Lucidum (*septum pellucidum*) (Figs. 574, 586, and 587).—The septum lucidum is a thin, double, vertically placed partition, which forms the internal boundary of the body and anterior horn of the lateral ventricle. It consists of two distinct laminae, separated in part of their extent by a narrow chink or interval,

called the **fifth ventricle**. It is a thin, semitransparent septum, attached, above, to the under surface of the corpus callosum; in front to the reflected portion of the corpus callosum; below it passes between the fornix and the posterior margin of the rostrum to terminate in the sub-callosal gyrus; posteriorly it is between the fornix and body of the corpus callosum, being attached to each. It is triangular in form, broad in front and narrow behind; its inferior angle corresponds with the upper part of the anterior commissure. The outer surface of each lamina is directed toward the lateral ventricle, and is covered by the ependyma of that cavity, while its medial surface bounds the cavity of the fifth ventricle (p. 889).

Fifth Ventricle (*cavum septi pellucidi*).—The fifth ventricle was originally a part of the great longitudinal fissure, which was shut off by the union of the hemispheres in the formation of the corpus callosum above and the fornix below. Each half of the septum is therefore formed by the medial wall of the hemisphere, and consists of an internal layer of gray matter, derived from the gray matter of the cortex, and an external layer of white substance continuous with the white matter of the cerebral hemispheres. The fifth ventricle differs from the other ventricles of the brain, inasmuch as it is not developed from the cavity of the cere-

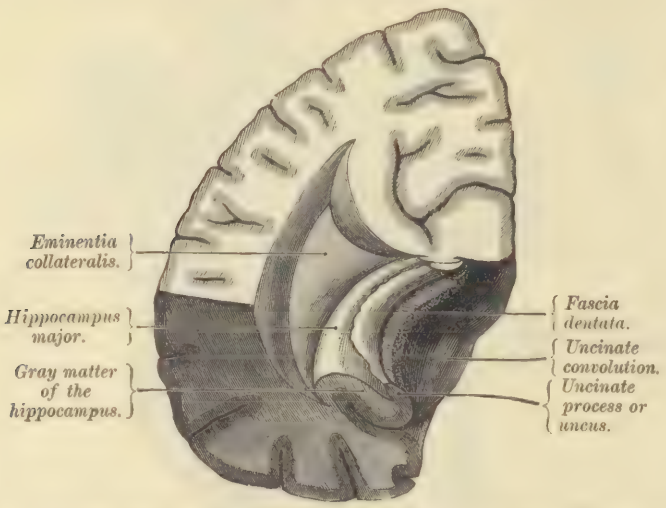

FIG. 581.—Transverse section of the middle horn of the lateral ventricle. (From a drawing by Mr. F. A. Barton.)

bral vesicles, it is not lined by ciliated epithelium but by altered pia mater, and it does not communicate with the general ventricular cavity; further, the fluid it contains is not cerebro-spinal fluid but is of the nature of lymph.

The structures on the floor of the descending horn of the lateral ventricle will now be described.

The **Hippocampus Major** or **Cornu Ammonis** (Figs. 581 and 583) is a white eminence, about two inches in length, of a curved elongated form, extending throughout the entire length of the floor of the descending horn of the lateral ventricle. At its lower extremity it becomes enlarged, and presenting two or three rounded elevations with intervening depressions, it resembles the paw of an animal, and is called the **pes hippocampi** (*digitationes hippocampi*) (Fig. 583). If a transverse section is made through the hippocampus major, it will be seen that this eminence is produced by the folding of the cortex of the brain to form the **dentate** or **hippocampal sulcus** (Figs. 562, 563, 564, and 567). The dentate fissure is separated from the choroid fissure by the **dentate gyrus** or **dentate fascia** (*fascia dentata*) (Figs. 562 and 581). The hippocampal gyrus and the fifth temporal gyrus together constitute the **uncinate convolution** (Figs. 567 and 581). The **uncus** (Fig. 581) is the

hook-like anterior extremity of the hippocampal or uncinate gyrus. To the outer side and parallel with the hippocampus major an elongated eminence, the **eminentia collateralis,** is frequently recognized (Fig. 581). It corresponds with the middle part of the collateral fissure, and its size depends on the direction and depth of this fissure. The main mass of the hippocampus major consists of gray matter, but on its ventricular surface is a thin layer of white matter, known as the **alveus,** which is continuous with the corpus fimbriatum of the fornix and is covered by the ependyma of the ventricle. Dr. J. G. Macarthy, of McGill University, Montreal, has shown[1] that, if the alveus and superficial strata of gray matter be reflected from the surface of the hippocampus by an incision carried along its convexity, the "core" of the hippocampus, as he terms it, presents in many cases a corrugated or crimped appearance.

The **Corpus Fimbriatum, Taenia Fornicis,** or **Fimbria** (*taenia hippocampi* or *taenia fimbriae*) (Figs. 562, 575, 577, and 583) has already been mentioned as a part of the posterior pillar of the fornix. It consists of a narrow white band, which is placed immediately below the choroid plexus, and is attached by its deep surface to the

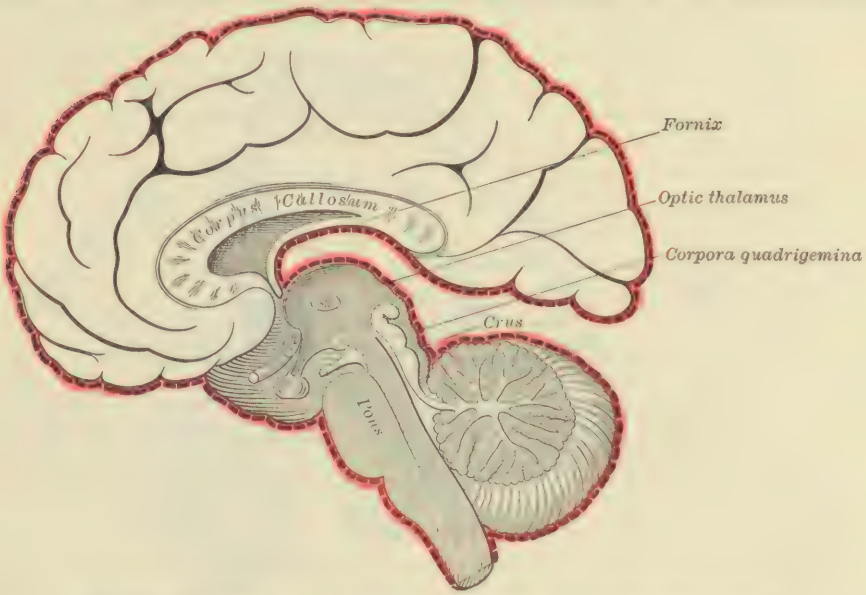

FIG. 582.—Diagram showing the mode of formation of the velum interpositum.

white matter or **alveus** of the hippocampus major as it courses through the descending cornu of the lateral ventricle. It can be traced as far as the uncus or hook of the hippocampal gyrus. Its inner margin is free, and rests upon the dentate fascia, from which it is separated by a slit-like fissure, the **fimbrio-dentate fissure.** The groove between the fimbria and the hippocampal convolution is the defile of the dentate fissure. Its outer margin is attenuated and irregular, and forms the line along which the ependyma is reflected over the choroid plexus as the latter is invaginated through the inferior part of the transverse fissure. When the choroid plexus is pulled away it carries the ependyma with it, and the descending horn opens on to the surface of the brain through the transverse fissure. If now the inner border of the corpus fimbriatum be raised, a notched band of gray matter, which is a free border of cortex, and is called the **dentate fascia** (*fascia dentata hippocampi*) (Figs. 562 and 581), will be exposed; this has already been described as forming part of the limbic lobe (p. 879).

[1] Journal of Anat. and Phys., 1899, vol. xxiii.

The **Choroid Plexus** (*plexus chorioideus*) (Figs. 548, 575, and 583) is a highly vascular, fringe-like structure, which is situated partly in the body and partly in the descending cornu of the lateral ventricle. It will be desirable to consider these two portions separately, in order to get a just conception of how they are formed.

The portion in the body of the ventricle is the vascular, fringed border of a triangular fold of pia mater, the **velum interpositum** (*tela chorioidea superior* or *tela chorioidea ventriculi tertii*), which lies on the under surface of the fornix and forms the roof of the third ventricle. The developing brain vesicles are covered by pia mater. As the prolongation from the first vesicle, which is to form the cerebral hemispheres, increases in size, it grows backward and downward and covers the other vesicles, with the result that the pia mater covering the hemisphere comes in

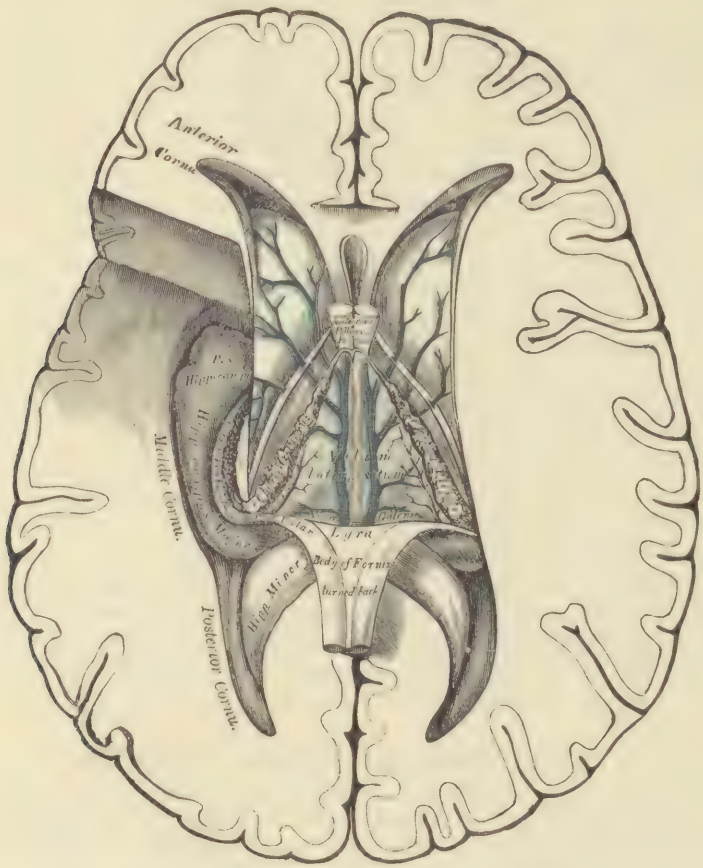

FIG. 583.—The fornix, velum interpositum, and middle or descending cornu of the lateral ventricle.

contact with that covering the upper surface of the second vesicle. Portions of the two layers which are in contact form the velum interpositum. Immediately above is the body of the fornix, which is formed by the fusion of the cerebral hemispheres in the middle line, and below is the cavity of the second vesicle (the third ventricle), with the optic thalamus on either side. Just beyond the free lateral border of the fornix, between it and the taenia semicircularis, is a portion of the first cerebral vesicle, which is not developed into nervous matter, but is made up only of ependyma covered by pia mater. The vessels of this portion of the highly vascular pia mater become dilated and prolonged, and grow into the ventricle, pushing the

ependyma before them, and forming an irregular congeries of vessels, apparently encroaching on the cavity of the lateral ventricle, but in reality being external to it, because they are separated from it by the lining membrane of the cavity, the ependyma. This vascular structure is the **choroid plexus of the body of the ventricle.**

The part of the choroid plexus seen in the descending cornu is formed in exactly the same way—viz., by an ingrowth of the vessels of the pia mater into the cavity, pushing the ependyma before it, at a part of the wall of the horn where there is a similar absence of nervous tissue and where it consists simply of pia mater and ependyma in close contact. This portion lies between the corpus fimbriatum in the floor and the taenia semicircularis in the roof of the descending horn. This area, destitute of nervous matter, is continuous with the area in the body of the ventricle, from which the choroid plexus of this region originated, and in it the vessels of its pia mater increase, and, invaginating the ependyma, appear in the descending horn as its choroid plexus. In the body of the ventricle the choroid plexus is really the vascular fringed margin of the velum; beyond the posterior margin of the velum the plexus of the descending horn is continuous with the pia mater on the surface of the gyrus hippocampi; the two portions of the plexus are, however, directly continuous with each other, and constitute the **choroid plexus of the lateral ventricle** (*plexus chorioideus ventriculi lateralis*). The gap or cleft through which the invagination of the pia mater takes place is called the **choroid fissure.**

In front the choroid plexus of the lateral ventricle is small and tapering, and communicates with the plexus of the opposite side through the foramen of Monro. In structure it consists of minute and highly vascular villous processes, containing an afferent and efferent vessel, and covered by a single layer of flattened epithelium, the cells of which often contain yellowish fat molecules. The **anterior choroidal artery** is derived from the internal carotid, and enters the ventricle at the extremity of the descending cornu, and, after ramifying in the plexus, sends branches into the adjacent parts of the brain. The **posterior choroidal arteries,** one or two in number on each side, are derived from the posterior cerebral artery, and reach the plexus by passing forward under the splenium of the corpus callosum. The veins of the choroid plexus unite to form a prominent vein, the **choroid vein,** which courses from behind forward to the foramen of Monro. On each side of the foramen of Monro a **deep cerebral vein** or **vein of Galen** is formed by the union of the choroid vein and the vein of the corpus striatum. The veins of Galen pass back in the velum interpositum, unite to form the **common vein of Galen** or the **vena magna Galeni** (*v. cerebri magna*), which empties into the straight sinus (p. 735).

The **Transverse Fissure** or **Fissure of Bichat** (*fissura cerebri transversa*), separates the cerebrum from the cerebellum. This fissure passes forward and ends in the cerebrum as the lateral part of the transverse fissure or the **choroid fissure** (*fissura chorioidea*). The posterior part of the transverse fissure is occupied by the **tentorium.** Posteriorly the transverse fissure has above it the mass of the cerebral hemisphere and below it the upper surface of the cerebellum, the corpora quadrigemina, and the pineal gland. The transverse fissure is a complete fissure, but it is filled by the invagination of the pia mater, forming laterally the velum interpositum and the choroid plexuses, which invagination is covered by the lining of the ventricular cavities. If this involution of pia mater is pulled out, the ventricular lining will necessarily be torn away with it, and a cleft-like space will be left on either side, extending from the foramen of Monro to the bottom of the descending horn of the lateral ventricle. The upper part of the cleft, that is to say, the part nearest the foramen of Monro, is between the lateral border of the body of the fornix and the optic thalamus; below this, at the commencement of the middle horn, it is between the commencing corpus fimbriatum

of the fornix and the pulvinar of the optic thalamus; and lower still, in the descending horn, between the corpus fimbriatum on the floor and the taenia semicircularis in the roof of the cornu. The course of the choroid fissure from the foramen of Monro is backward, downward, and forward, to near the apex of the temporal lobe. The choroid fissures of the two sides are continuous between the fornix and the roof of the third ventricle.

The **Velum Interpositum** or **Tela Chorioidea Superior** (*tela chorioidea ventriculi tertii*) (Fig. 548) is a vascular membrane, and is a prolongation of the pia mater into the interior of the brain through the middle part of the transverse fissure. It is of a triangular form, and separates the under surface of the body and posterior pillars of the fornix from the cavity of the third ventricle. Laterally it covers the inner part of the upper surface of the optic thalamus. Its posterior border or base lies beneath the splenium of the corpus callosum above, and the optic thalamus, the corpora quadrigemina, and pineal body below. The upper layer of the base is continuous with the pia mater of the occipital lobe, and the lower layer of the base is continuous with the pia mater of the dorsal aspect of the cerebellum and mid-brain. Its anterior extremity or *apex* ends just behind the anterior commissure, where it receives the anterior extremities of the choroid plexuses, which are here united through the foramen of Monro, and are then prolonged backward on the under surface of the velum as the **choroid plexus of the third ventricle** (*plexus chorioideus ventriculi tertii*). The inferior layer of the velum which carries the choroid plexus of the third ventricle is called the **superior choroid tela** (*tela chorioidea ventriculi tertii*). The external portion of the inferior layer of the velum interpositum covers the inner half of the superior surface of the optic thalamus. In front the plexuses of the third ventricle lie close to the middle line, but diverge from each other behind. Each lateral margin of the velum interpositum constitutes the choroid plexus of the corresponding lateral ventricle. It is supplied by the anterior and posterior choroidal arteries, already described. The veins of the velum interpositum, the **venae Galeni** (*vv. cerebri internae*), two in number, run between its layers, each being formed by the union of the **vein of the corpus striatum** (*v. corporis striata*) with the **choroid vein** (*v. chorioidea*). The venae Galeni unite posteriorly into a single trunk, the **vena magna Galeni** or the **common vein of Galen** (*v. cerebri magna*), which terminates in the straight sinus (Fig. 548). The portion of the pia mater prolonged over the lower half of the fourth ventricle is known as the **tela chorioidea inferior quarti.** It carries the **choroid plexus of the fourth ventricle** (*plexus chorioideus ventriculi quarti.*)

II. The Inter-brain (Thalamencephalon).

The inter-brain is the region of the third ventricle, and comprises the parts developed from the second cerebral vesicle, together with parts from that portion of the first vesicle which is not concerned in the formation of the cerebral hemispheres.

The inter-brain is connected above and in front with the cerebral hemispheres; behind, with the mid-brain or mesencephalon. On its upper surface it is entirely concealed from view, as it is covered by those portions of the internal surfaces of the cerebral hemispheres which have fused together to form the corpus callosum and the fornix, and is separated from the latter by the two layers of pia mater which form the velum interpositum. Inferiorly it reaches the base of the brain, forming the structures contained in the interpeduncular space.

The Third Ventricle (*ventriculus tertius*) (Fig. 584).—The third ventricle is the cavity of the inter-brain; it is in the mid-line, is at a lower level than the lateral ventricles; and the epithelial layer of the ependyma from the lateral ventricles is prolonged into the third ventricle through the foramen of Monro. The third ven-

tricle contains cerebro-spinal fluid. It is a narrow median crevice between the two optic thalami, which constitute the side walls of the inter-brain. It is "about an inch in length from before backward and one-quarter of an inch broad at its widest part."[1] Its *roof* is formed by the velum interpositum, from which is suspended the choroid plexus of the third ventricle. Its *floor*, somewhat oblique in its direction, is formed, from before backward, by the tuber cinereum, with its infundibulum and pituitary body; the corpora albicantia; the posterior perforated space; and the tegmenta of the crura cerebri. Its *sides* are formed by the optic thalami, and are limited above by a delicate band of white fibres, the **pineal stria** (*stria medullaris thalami*), which runs along the junction of the mesial and upper

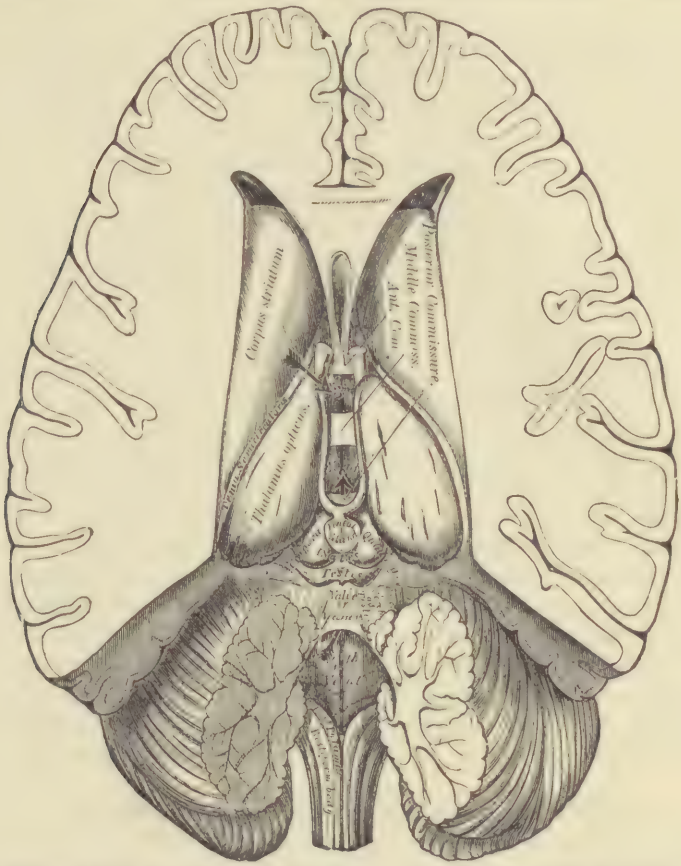

Fig. 584.—The third and fourth ventricles. An arrow has been placed in the position of the foramen of Monro.

surfaces of the optic thalamus to join the anterior pillars of the fornix. Its sides are somewhat convex, so that in the middle of the ventricle the two lateral walls are almost in contact, and are here united across the middle line by a band of gray nervous matter, the **middle, gray,** or **soft commissure** (Fig. 584). The ventricle is bounded in front by the anterior pillars of the fornix and the lamina cinerea; behind by the pineal gland, the posterior commissure, and the upper end of the aqueduct of Sylvius, the iter a tertio ad quartum ventriculum. The cavity is much deeper in front than behind, and presents a recess at its anterior part, which lies over the optic commissure and is, therefore, termed the **optic recess** (*recessus opticus*). Behind and below this is the conical depression of the infundibulum (Fig. 587), passing

[1] Anatomy of the Brain and Spinal Cord. By Harris E. Santee.

downward and forward to the pituitary body. At its posterior extremity the cavity forms another and smaller recess, which extends into the stalk of the pineal gland, and is termed the **pineal recess** (*recessus pinealis*). The anterior part of the third ventricle is called the **aula**. At the upper and anterior part of the third ventricle, immediately behind the anterior pillars of the fornix and in front of the optic thalamus, is an opening, the **foramen of Monro** (*foramen interventriculare* [*Monroi*]), by which this ventricle communicates with the lateral ventricle on either side (Figs. 548, 574, 575, and 587). The foramen of Monro opens into each lateral ventricle at the point of junction of the anterior horn and the body of the ventricle. It lies between the anterior pillar of the fornix and the anterior margin of the optic thalamus and ends by opening into the anterior and superior extremity of the third ventricle. Running back from the foramen of Monro toward the aqueduct of Sylvius is a furrow called the **sulcus of Monro** (*sulcus hypothalamicus* [*Monroi*]). At the posterior part of the floor of the third ventricle, beneath the **posterior commissure**, is the opening of the **aqueduct of Sylvius** or **iter a tertio ad quartum ventriculum** (Fig. 587), the channel which joins the third and fourth ventricles (p. 912). The *roof* of the cavity of the third ventricle is limited in front and behind by transverse bands of white matter, known respectively as the **anterior** and **posterior commissures**. The former has already been described in connection with the corpus striatum (p. 896).

The Middle, Gray, or Soft Commissure (*massa intermedia* or *commissura mollis*) (Fig. 584).—The middle, gray, or soft commissure consists almost entirely of gray matter. It connects the two optic thalami, and is continuous with the gray matter lining the anterior part of the third ventricle. It is frequently broken in examining the brain, and might then be supposed to be wanting; it is sometimes double.

The Posterior Commissure (*commissura posterior*) (Figs. 584 and 587.—The posterior commissure is a rounded band of white fibres, which stretches across from one optic thalamus to the other, overlying the upper end of the aqueduct of Sylvius. It is usually described as belonging to the inter-brain, but would appear to belong in part to the mid-brain, since some of its fibres are commissural and connect the anterior corpora quadrigemina to the fillet of the opposite side (see below). In addition there are other decussating fibres, which come from the tegmentum of the crus cerebri on one side and decussate with those of the opposite side in the posterior commissure, and passing through the optic thalamus reach the cerebral hemispheres. Fibres have also been described as taking their origin in the pineal body and ganglion habenulae, and passing across to the posterior longitudinal bundle and oculomotor nucleus of the opposite side; these fibres occupy the ventral part of the commissure, and receive their myelin sheath before those in its dorsal part. But to a certain extent the posterior commissure belongs to the inter-brain, since it contains fibres which serve as commissural fibres between the two optic thalami.

The Optic Thalamus (*thalamus*) (Figs. 576, 577, 578, 579, 580, 582, and 584).—The optic thalami are two large oblong masses, situated on either side of the third ventricle, and lying between the diverging portions of the corpora striata. They are composed mainly of gray matter, but the free surface of each is coated with a thin layer of white nervous tissue, the **stratum zonale**. They present outer and under surfaces, which are not free, but are blended with contiguous parts of the brain, and upper, inner, and posterior surfaces, which are free. The anterior extremity is narrow, and forms the posterior boundary of the foramen of Monro. The *outer surface* is in contact with the posterior limb of the internal capsule, which separates it from the lenticular nucleus. The *inferior surface* rests upon and is continuous with the tegmentum of the crus cerebri. Its *upper surface* is free, and is separated from the caudate nucleus by a furrow which lodges the vein of the

corpus striatum, and the taenia semicircularis. It is divided into an outer and an inner part by a groove which runs from behind, forward, and inward. The *outer part* forms a portion of the floor of the lateral ventricle, and is covered by the ependyma of that cavity; it terminates in front in a tubercle, the **anterior tubercle of the optic thalamus** (*tuberculum anterius thalami*). The *inner part* is covered by the velum interpositum, which separates it from the fornix, and is excluded from both the lateral and third ventricles by the reflection of the lining of these cavities, and is therefore destitute of an ependymal covering.

The *internal surface* forms the lateral wall of the third ventricle, and running along its upper border is the peduncle of the pineal gland, from which the ependyma of the third ventricle is reflected on to the under surface of the velum interpositum. The shelf-like edge of the ependyma separates the superior from the internal surface of the thalamus. The edge is called the **taenia thalami**, and close to it is a narrow band of longitudinal fibres called the **pineal striae** (*striae medullaris thalami*). The taenia thalami and the pineal striae pass backward and then inward into the stalk of the pineal gland. The portion of the taenia which turns inward has posterior to it a small triangular depression called the **trigone of the habenula** (*trigonum habenulae*). This depression is just in front of the superior quadrigeminal body. Passing in a medial direction from the trigonum habenulae is a collection of white fibres, the **habenula**. The fibres of the anterior portion of this band are continuous with those of the opposite side, and constitute the **commissure of the habenula** (*commissura habenularum*). The fibres of the posterior portion constitute the peduncle of the pineal gland (p. 906). The *posterior surface* projects beyond the level of the corpora quadrigemina, and forms a well-marked rounded prominence, the **posterior tubercle** or **pulvinar**. The pulvinar is continued externally into a second eminence, the **external geniculate body** (*corpus geniculatum laterale*), which is placed above and to the outer side of the **internal geniculate body** (*corpus geniculatum mediale*), and from which it is separated by the **superior brachium**, one of the roots of the optic tract.

The *optic* or *free upper surface* of the thalamus is covered by white fibres derived, in part, at least, from the optic tract and radiation. The thalamus is formed chiefly of gray matter, which is arranged in three masses partially separated from each other by white matter called the **internal medullary lamina** (*lamina medullaris interna*), which is named internal in contradistinction to a second or **external medullary lamina** (*lamina medullaris externa*), which coats the outer surface of the thalamus and lies between it and the internal capsule. These masses of gray matter are the **nuclei of the optic thalamus**. Twenty nuclei have been described (Nissl). The chief nuclei are the following:

1. **The External** or **Lateral Nucleus** (*nucleus lateralis thalami*).—The external or lateral nucleus, the largest of the nuclei, between the external and internal medullary laminæ and extending the entire length of the thalamus, including, as Prof. Cunningham points out, the entire pulvinar, most of the tegmental fibres, and one-fifth of the optic fibres, terminate in this nucleus, and from it originate the fibres of the **thalamic radiation.**

2. **The Middle** or **Internal Nucleus** (*nucleus medialis thalami*).—The middle or internal nucleus is separated by the internal medullary lamina from the other gray nuclei of the same side. It joins the middle nucleus of the opposite thalamus by means of the middle commissure.

3. **The Anterior Nucleus** (*nucleus anterior thalami*).—The anterior nucleus is in the anterior tubercle, and in it terminate the fibres of the bundle of Vicq d'Azyr which come from the corpus mamillare (Fig. 586).

In the substance of the thalamus are two other distinct nuclei, (4) the **central nucleus of Luys** and (5) the **nucleus arcuatus**. The **nucleus** or **ganglion of the habenula** lies in the trigonum habenulae.

Connections of the Optic Thalamus (Figs. 586, 589, and 590).—The optic thalamus is a ganglion interposed between the sensory tracts in the tegmentum and the cerebral cortex, being connected also with the optic tract. In this ganglion or in the adjacent ganglia of the subthalamic region, "almost every impulse of general sensation, on its journey to the cerebral cortex, is transferred to a higher neurone."[1] The crusta of the crus cerebri is external to the optic thalamus and passes into the internal capsule. The tegmental fibres of the crus (Fig. 586) pass to the under surface of the thalamus, and the forward prolongation of the tegmentum which becomes continuous with the under surface of the thalamus is called the **subthalamic region,** and most of the longitudinal fibres enter this ganglion, some of them terminating in it, some of them traversing it and entering the internal capsule. The internal capsule (Figs. 578, 589, and 590) is composed of fibres going to and coming from the cerebral cortex. Most of these fibres are descending and form the crus cerebri. From all over the external surface of the optic thalamus fibres emerge, pass into the internal capsule, and from there go to the cerebral cortex. These fibres constitute the **thalamic radiation.**

The nuclei of the thalamus have been described (p. 904). The white matter receives the fibres of the tegmentum and fillet, the majority of which enter the lateral nucleus; it receives fibres (axones) from the entire cerebral cortex and sends fibres to the cortical special sense areas of sight, hearing, and smell and to the area of general sensation) the *somaesthetic area*).

The following groups of fibres of white matter are found in the thalamus: 1. The anterior pillar of the fornix, which passes through the inner part of the optic thalamus on its way to the corpus mamillare, and the bundle of Vicq d'Azyr, (*fasciculus thalamomamillaris*) (Fig. 586), which arises in the corpus mamillare and ascends to the anterior gray nucleus. 2. Two bundles of fibres emerging from the external surface of the thalamus. The **superior bundle** (*ansa lenticularis*) *arises* largely in the lateral nucleus, passes through the internal capsule and the lenticular nucleus; it then enters the external capsule, and passes to the insula, the paracentral lobule, the superior frontal convolution, and "the entire limbic lobe"[2] (Fig. 589). The **inferior bundle** (*ansa peduncularis*) *arises* in the lateral nucleus, passes through the internal capsule below the lenticular nucleus, "enters into both the medullary laminae of that nucleus and the external capsule. It ends chiefly in the cortex of the ascending frontal and ascending parietal convolutions"[3] (Fig. 589). These fibres constitute the **ventral** or **inferior stalk of the thalamic radiation.** 3. The **anterior stalk of the thalamic radiation** (Figs. 588 and 590) arises in the lateral nucleus, passes to the frontal portion of the internal capsule, and reaches the inferior and middle frontal convolutions, the anterior portion of the superior frontal convolution, and the middle of the gyrus fornicatus (Santee), and is called the **optic radiation** (*radiatio occipitothalamica*). The anterior stalk of the thalamic radiation, plus the ansa lenticularis and the ansa peduncularis, constitutes the **cortical fillet** or the **three systems of Flechsig** (p. 915). 4. The **posterior stalk** of the thalamic radiation (Fig. 590). The afferent part arises in the pulvinar and the external geniculate body, passes through the internal capsule, and terminates in the occipital cortex. The efferent portion terminates in the superior quadrigeminal body. 5. The **acoustic radiation** (Fig. 590) *arises* about the internal geniculate body, passes through the internal capsule, and reaches the auditory region in the temporal cortex.

The Pineal Body, Epiphysis Cerebri, Conarium, or Pineal Gland (*corpus pineale*) (Figs. 584 and 587).—The pineal body or gland, so named from its peculiar shape (pinus, a *fir-cone*), is a small reddish-gray body, conical in shape (hence its synonym, *conarium*), placed immediately above and behind the

[1] Anatomy of the Brain and Spinal Cord. By Harris E. Santee. [2] Ibid. [3] Ibid.

posterior commissure and between the anterior corpora quadrigemina, on which it rests. It is covered by the velum interpositum, which intervenes between it and the splenium of the corpus callosum. It is an upgrowth from the second cerebral vesicle (hence the name epiphysis), and is at first hollow, but soon becomes solid and loses its connection with the ventricular cavity. It is retained in its position by a duplicature of pia mater, derived from the under surface of the velum interpositum, which almost completely invests it. The pineal gland is about four lines in length and from two to three in width at its base, and is said to be larger in the child than in the adult, and in the female than in the male. It is attached on either side by a flattened stalk or peduncle of white matter, the **pedunculus conarii** (*habenula*). This stalk consists of two laminae, upper and lower, separated by a little recess, the **pineal recess** (*recessus pinealis*). The lower lamina is prolonged into the posterior commissure. The upper divides into two strands, the **peduncles of the pineal gland** (*striae pinealis*); these extend on either side along the optic thalamus at the junction of its mesial and upper surfaces to the anterior pillars of the fornix, with which they blend. The two stalks join together at their posterior extremity, in front of the pineal gland, forming a sort of festoon, and the base of the gland is connected to their posterior margin at the point of junction.

Structure.—The pineal gland consists of a number of follicles, lined by epithelium, and connected together by ingrowths of connective tissue. The follicles contain a transparent viscid fluid and a quantity of sabulous matter named **brain sand** (*acervulus cerebri*), composed of phosphate and carbonate of lime, phosphate of magnesia and ammonia, with a little animal matter. These concretions are almost constant in their existence, and are present at all periods of life. They are found upon the surface of the pineal body and occasionally upon its peduncles.

Morphologically the pineal gland is regarded as the homologue of the structure termed the *pineal eye* of the lizards. In these reptiles the epiphysis cerebri is attached by an elongated stalk and projects through the parietal foramen. Its extremity lies immediately under the epidermis, and on microscopic examination presents, in a rudimentary fashion, structures similar to those found in the eyeball.

III. The Mid-brain (Mesencephalon) (Figs. 557, 584, 585, 587).

The mid-brain is the short and constricted portion of the brain which lies in the opening of the tentorium cerebelli (*incisura tentorii*) and which connects the pons Varolii with the inter-brain and hemispheres, and hence it is frequently called the **isthmus cerebri** (*isthmus rhombencephali*). It is developed from the third cerebral vesicle, the cavity of which becomes the aqueduct of Sylvius. It comprises the crura cerebri, the corpora quadrigemina, the geniculate bodies, and the Sylvian aqueduct. Its direction is from before backward and downward. In front and above it is continuous with the inter-brain; below with the pons. Its two surfaces are ventral and dorsal. They are free, but concealed: the ventral surface by the apices of the temporal lobes which overlap it; the dorsal, by the overhanging cerebral hemispheres. The *ventral surface*, when exposed by drawing aside the temporal lobes, is seen to consist of two cylindrical bundles of white matter which emerge from the pons and diverge as they pass forward and outward to enter the inner and under part of either hemisphere. They are the **cerebral peduncles** (*crura cerebri*), and between them is a triangular area, already described as part of the **interpeduncular space** (*fossa interpeduncularis*) (see pp. 884 and 885); near the point of divergence of the crura the roots of the third nerve are seen to emerge in several bundles from a groove, the **sulcus oculomotorius** (*sulcus nervi oculomotorii*) (Fig. 570). The *dorsal surface* (Fig. 584) is not visible until a considerable portion of the cerebral hemispheres and other overlying structures have

been removed. It then presents four rounded eminences placed in pairs, two in front and two behind, and separated from one another by crucial depression. These are termed the **corpora quadrigemina** (*tubercula quadrigemina*) (Figs. 584 and 585). The ventral and dorsal surfaces meet on the side of the mid-brain, and are separated from each other by a furrow, the **lateral groove** (*sulcus lateralis mesencephali*), which runs from below upward and forward (Fig. 585).

If a cross-section be made through the mesencephalon (Fig. 585), it will be seen that each lateral half is divided into two unequal portions by a lamina of deeply pigmented gray matter, named the **substantia nigra**. The postero-superior portion of the crus is named the **tegmentum**, and the antero-inferior the **crusta** or **pes**. The substantia nigra is curved on section with its concavity upward, and extends from the lateral groove externally to the oculomotor sulcus internally. The two crustae are in contact in front of the pons, from which point they diverge from one another, but the two halves of the tegmentum are joined to each other in the mesial plane by a prolongation forward of the raphé or median septum of the pons. Laterally the tegmenta are free, but dorsally they blend with the corpora quadrigemina.

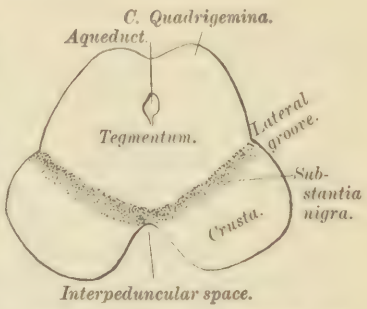

FIG. 585. Transverse section of the mid-brain.

Crusta or Pes (*basis pedunculi*) (Fig. 585).—The crusta is known as the pes of the crus cerebri. The crustae are two in number, are semilunar on section, and are separated by the interpeduncular space (Fig. 570). From the front of the pons each crusta passes upward, forward, and outward, enters the cerebrum to the outer side of the thalamus, and its fibres enter and spread out in the **internal capsule** (Figs. 589 and 590). The great bulk of the fibres are limited to the superior lamina of the capsule. The *deep portion* of the crusta contains the **intermediate bundle** or **tract** (Fig. 590), the fibres of which rise in the corpus striatum and terminate in motor cranial nuclei and the nucleus pontis, and from this nucleus fibres pass by way of the middle peduncle of the cerebellum to the cortex of the opposite cerebellar hemisphere.

The *superficial portion* of the crusta contains three sets of fibres (Figs. 589 and 590): 1. The outer one-fifth is composed, according to Dejerine, of fibres which take origin in the cortex of the superior, middle, and inferior temporal convolutions, the **cerebro-cortico-pontal tract** (*tractus cerebrocorticopontalis temporalis*). They pass through the inferior lamina of the internal capsule and through a portion of the superior lamina, and mostly terminate in the nucleus pontis. Some few of these fibres terminate in the motor nuclei of the cranial nerves.[1] 2. The middle three-fifths, which is largely composed of motor fibres, is known as the **pyramidal tract** (*fasciculus longitudinalis pyramidalis*). These fibres take origin in the cells of the Rolandic area of the cortex, converge to the internal capsule, and pass down through its genu and through the anterior two-thirds of its posterior limb to the crusta, from which they are prolonged as longitudinal fibres through the ventral portion of the pons and as the pyramid through the medulla. Below the medulla they pass into the direct and crossed pyramidal tracts of the spinal cord. The median portion of the pyramidal tract occupies the genu of the internal capsule and passes to the muscles of the face and the muscles of speech. The fibres which pass to the arm muscles, in the crusta, are posterior and external to the fibres which go to the face. Behind and external to the arm fibres are the fibres to the muscles of the trunk

[1] Spitzka; Santee.

and leg. A few fibres from the cerebellum are placed among the pyramidal fibres. These fibres reached the pons by way of the middle cerebellar peduncle, ascend from the pons with the longitudinal fibres, and reach the crusta. 3. The inner one-fifth of the crusta is formed by the fibres of the **median fillet** (*lemniscus medialis*) and motor fibres coming from the cortex in front of the Rolandic fissure (from the prefrontal lobe). This tract from the prefrontal lobe descends through the anterior limb of the internal capsule and through the crusta and reaches the nucleus pontis, from which point it is connected by fibres with the cerebellar hemisphere of the opposite side. It is called the **frontal cerebro-cortico-pontal tract** (*tractus cerebrocorticopontalis frontalis*). The **median fillet** is composed of central sensory fibres from the spinal nerves and all the cranial nerves, except the cochlear branch of the auditory (Santee). It arises from the fillet, and at the lower part of the crusta is situated at the mesial border. As it ascends it courses obliquely outward to meet the lateral border of the pyramidal tract. It enters the sub-thalamic region, and ends in the lateral nucleus of the optic thalamus. Some of the fibres of this tract reach the cortex by joining the ansa peduncularis and the ansa lenticularis.

The Tegmentum (Fig. 585).—The tegmentum (the *cover*) is that portion of the mid-brain which is superior to the substantia nigra and covers the two crustae and the substantia nigra. Its ventral surface is placed within the concave surface of the substantia nigra. The internal geniculate bodies and the corpora quadrigemina are upon its dorsal surface. The anterior extremity of the tegmentum enters the optic thalami, and the posterior extremity is continued into the pons. The tegmentum contains the aqueduct of Sylvius (p. 912 and Figs. 585 and 587).

Fibres of the Tegmentum (Fig. 590).—The pontine formatio reticularis, the gray matter of the floor of the fourth ventricle, and the longitudinal fibres of the dorsal portion of the pons are continued and compose the tegmentum, which structure has upon its dorsal aspect the geniculate and quadrigeminal ganglia. Each half of the tegmentum consists of strands of longitudinal white fibres separated from each other by transversely arched fibres. There is also a considerable quantity of gray matter. The peculiarly reticulated structure formed by the gray and white matter is named the **formatio reticularis**, and is similar to the structure met with in the pons and medulla, with which it is continuous.

The Red Nucleus of the Tegmentum (*nucleus tegmenti*) (Fig. 589).—The red nucleus of the tegmentum is a tract of gray matter situated partly in the tegmentum and partly in the subthalamic tegmental region on either side of the middle line. It is composed of numerous large cells which are deeply pigmented. It is pierced by the fibres of the third nerve. The red nucleus sends fibres to the corpus dentatum by means of the opposite superior peduncles of the cerebellum, and also gives off the crossed descending tract. The **nucleus of Luys** (*nucleus hypothalamicus*) is above and external to the red nucleus and between it and the crusta. It receives fibres from the median fillet and from the corpus striatum, and is connected by fibres to the lamina cinerea and tuber cinereum, which are known as the **commissure of Meynert** (Santee).

The longitudinal fibres in some parts of the tegmentum are arranged in six fairly well-defined tracts, which are described as follows by Harris E. Santee in the *Anatomy of the Brain and Spinal Cord:*

1. The **Posterior Longitudinal Bundle** (*fasciculus longitudinalis medialis*) (Fig. 586) is in large part an associated tract. It lies by the side of the raphé just below the aqueduct. These fibres ascend from the gray substance of the anterior cornu of the spinal cord. In the anterior column of the cord they probably form short longitudinal commissures between different segments of the cord. They ascend through the pyramid of the medulla, form the posterior longitudinal bundle of the

pons, and enter the tegmentum. The posterior longitudinal bundle, while traversing the pons, receives fibres from the cerebellum, and in the pons and medulla receives fibres from the sensory nuclei of cranial nerves. "It carries motor fibres from the sixth to the third nerve; also descending motor fibres from the nucleus of the motor oculi to the genu of the seventh or facial nerve." Soon after entering the tegmentum the posterior longitudinal bundle decussates across the raphé with the bundle of the opposite side. This constitutes the **lower decussation**, and the decussated fibres pass to the nuclei of the third, fourth, and other cranial nerves. The undecussated fibres ascend, and in the posterior commissure decussate. This is known as the **upper decussation**, and the fibres enter "the pineal body and stratum dorsale of the hypothalamic region."

FIG. 586.—The short tracts in the brain-stem and inter-brain. Sagittal section through the middle of the brain-stem: *inf*, infundibulum; *c. mam*, corpus mamillare; *fasc. Vic*, bundles of Vicq d'Azyr; *f. teg*, tegmental bundle; *ped. m*, peduncle of corpus mamillare; *fasc. rt*, fasciculus retroflexus; *fasc. l. inf*, posterior longitudinal bundle; II, III, VI, XII, corresponding cranial nerves; *c*, pineal gland. (Jakob.)

2. The **Anterior Longitudinal Bundle** is composed of fibres which pass from the superior quadrigeminal body to the ciliary centre (dilator fibres of the pupil) and other centres in the spinal cord.

3. The **Fillet** or **Lemniscus** is "a segment in the direct sensory tract. It carries spinal and cranial impulses to the corpora quadrigemina and optic thalamus." It takes its chief origin from the medulla, and passes through the formatio reticularis of the pons to the ventral portion of the tegmentum, where it divides into two portions, the **interolivary fillet** and the **lateral fillet**.

The **interolivary fillet** (*lemniscus interolivaris*) arises from the opposite side of the medulla oblongata (from the nucleus gracilis and nucleus cuneatus), decussates with the sensory fibres, and terminates in the lateral nucleus of the thalamus. A bundle of fibres come off from the interolivary fillet soon after its origin and

passes to the superior quadrigeminal bodies. This bundle is the **upper** or **superior fillet** (*lemniscus superior*). The interolivary bundle after giving off the superior fillet is known as the **median** or **mesial fillet** (*lemniscus medialis* or *mesialis*). It ascends, turns toward the ventral surface of the tegmentum, passes through the substantia nigra, and along the inner one-fifth of the crusta to the thalamus, and from the thalamus connection with the cortex is established by the ansa lenticularis and the ansa peduncularis.

The **lower** or **lateral fillet** (*lemniscus lateralis*) arises almost entirely from the cochlear nuclei, and mostly from the opposite nucleus. It is situated in the ventral part of the tegmentum, through which it passes obliquely and emerges at its side, and after crossing the superior peduncle of the cerebellum, passes to the inferior quadrigeminal bodies. It is reinforced by some fibres from the superior medullary velum. It is a path in the conduction of auditory impressions. These impressions pass from the auditory nerve to the lateral fillet, from this to the inferior brachium, and then to the cortex by the acoustic radiation (Fig. 590).

4. The **Superior Peduncle of the Cerebellum** (*brachium conjunctivum*) (Figs. 590 and 599) ascends from the dorsal surface of the pons. It is connected to its fellow peduncle by a band of white matter called the **valve of Vieussens** (*velum medullare anterius*) (Fig. 584). The fibres of the superior peduncles of the cerebellum pass beneath the quadrigeminal bodies, and to a large extent decussate across the raphé and below the Sylvian aqueduct. It is thus evident that the fibres from one-half of the cerebellum pass largely to the opposite half of the cerebrum. The numerous crossed and the few uncrossed fibres pass forward, enclosing the red nucleus (in which structure many of the fibres terminate and from which structure it obtains some fibres), and passes to the "stratum dorsale of the hypothalamic region."

5. The **Olivary Fasciculus** (*fasciculus tegmenti centralis*) (Fig. 589) arises from the inferior olivary nucleus of the medulla, ascends through the medulla and pons to the tegmentum, passes through the decussation of the superior peduncles of the cerebellum, and ascends to the outer side of the posterior longitudinal bundle of tegmental fibres, to end in the lenticular nucleus.

6. The **Crossed Descending Tract** arises in the red nucleus (Fig. 589), decussates with the opposite tract, enters the lateral fillet, reaches the medulla, where it "mingles with the antero-lateral ascending cerebellar tract," and passes into the pyramidal tract of the cord, to end in "the lateral horn and centre of the gray crescent." The nucleus of Luys (Fig. 589) is the anterior termination of the substantia nigra.

The Substantia Nigra (Figs. 585 and 589).—This, as already stated, constitutes the central portion of the mid-brain. It is a layer of deeply pigmented gray matter, which separates the crusta below from the tegmentum above. It can be seen at the base of the brain between the crustae. In this region it is known as the **posterior perforated lamina** (*substantia perforata posterior*) (Fig. 570). In each **lateral sulcus** the edge of the substantia nigra reaches the surface (Fig. 585). The substantia nigra extends from the pons behind to the corpora albicantia and nucleus of Luys in front. It is thicker internally than externally, where it is partially divided up by the mesial fillet passing from the tegmentum to the crusta. It is traversed at its inner part by some of the fibres of origin of the third cranial nerve, which emerge from the motor oculi groove. The cells are small and multipolar, and are characterized by containing a large amount of dark pigment granules.

The **Interpeduncular Ganglion** (*ganglion interpedunculare*) is just in front of the pons in the median line. Some fibres (the *fasciculus retroflexus*) (Fig. 586) join this ganglion to the nucleus habenulae of the thalamus (Forel, Santee). In each half of the substantia nigra, laterally and anteriorly, is a nucleus known as the **nucleus of Luys** (*nucleus hypothalamicus*) (Fig. 589). The **zona incerta** separates the nucleus of Luys from the red nucleus of the tegmentum.

The Corpora or Tubercula Quadrigemina (Figs. 574, 584, 585, 586, and 587).—The corpora or tubercula quadrigemina are four rounded eminences placed in pairs, two in front and two behind, and separated from one another by the **crucial groove** or **depression**. They are situated on the dorsal surface of the mid-brain, immediately behind the third ventricle and posterior commissure, and beneath the splenium of the corpus callosum. The **anterior** or **upper pair** (*colliculi superiores*), called the **nates**, are the larger. They are oval, their long diameter being directed forward and outward, and are of a gray color. The **posterior** or **lower pair** (*colliculi inferiores*), called the **testes**, are hemispherical in form, and lighter in color than the preceding. From the outer side of each of these eminences a prominent white band, termed the **brachium**, is continued forward and outward. The band from the nates (*brachium quadrigeminum superius*) passes obliquely outward between the pulvinar and the inner geniculate bodies into the *external geniculate body*. The band from the testes (*brachium quadrigeminum inferius*) loses itself beneath an oval prominence on the side of the quadrigeminal body. This prominence is called the **internal geniculate body**. The corpora quadrigemina are larger in the lower animals than in man. In fishes, reptiles, and birds they are hollow, and only two in number (*corpora bigemina*); they represent the anterior quadrigeminals of mammals. In these lower animals the corpora bigemina are frequently termed the **optic lobes**, because of their connection with the optic tracts. In the mammalia the corpora are four in number, and solid. In the human fœtus all four bodies are differentiated by the fifth month, and form at this time a considerable proportion of the brain. In man the anterior quadrigeminal bodies are sometimes called the **optic lobes** and the posterior bodies the **auditory lobes**.

Structure.—The corpora quadrigemina are composed of white matter externally, and gray matter within. The *posterior pair* consist almost entirely of gray matter, covered over by a very thin stratum of white substance. Beneath the gray matter is a thin layer of white fibres, forming a part of the lower fillet. This separates the gray matter of the posterior corpora quadrigemina from the central gray matter of the aqueduct. The *anterior pair* are covered superficially by a thin stratum of white matter. The **stratum zonale**, the fibres of which are fine and arranged transversely. Beneath this is the **stratum cinereum**, a layer of gray matter which resembles a cup, semilunar in shape, thicker in the centre, and thinning off toward the margins, and consisting of numerous multipolar cells, for the most part of small size, embedded in a fine network of nerve-fibres. Below this again is the **stratum opticum** or **upper gray-white layer**, characterized by the large amount of fine nerve-fibres which intersect the gray matter. These fibres vary in size in different parts of the layer, but have for the most part a longitudinal direction. The nerve-cells between the fibres are larger, and send their axis-cylinder processes into the next stratum. Finally there is the **stratum lemnisci**, or **deep gray-white layer**, which separates the rest of the quadrigeminal body from the gray matter around the aqueduct. It consists of fibres partly derived from the upper fillet and partly from the cells of the preceding layer. Interspersed among these fibres are nerve-cells of large size.

The anterior quadrigeminal body contains an anterior layer of longitudinal fibres, which takes origin in close relation to the optic fibres and ends in the ciliary centre of the spinal cord. In the posterior quadrigeminal body the white fibres are continuous posteriorly with the lateral fillet, and are continuous laterally with the brachium. The anterior quadrigeminal bodies "associate optic fibres with the nuclei of the third, fourth, and sixth cranial nerves and with the cilio-spinal centre in the cervical cord" (Santee). The posterior bodies constitute "a way-station in the auditory conduction path" (Santee) (Fig. 590).

The Corpora Geniculata.—The corpora geniculata are two small, oblong masses on each side, situated behind and beneath the posterior end of the optic

thalamus, and named, from their position, **external** and **internal geniculate bodies.** These two bodies are separated from each other by the **brachium anterius of the anterior quadrigeminal body.** It is convenient and customary to describe these two bodies together, but the student should bear in mind that the corpus geniculatum externum belongs in reality to the optic thalamus; the corpus geniculatum internum, which is part of the tegmentum, alone belonging to the mid-brain.

The External Geniculate Body (*corpus geniculatum laterale*) (Fig. 613).—The external geniculate body is of a dark color, and presents a laminated arrangement, consisting of alternate layers of gray and white matter. Its cells are large, multipolar, and pigmented; their processes are intimately related with the visual area in the cerebral cortex of the occipital region (Fig. 590). It is believed that the intercellular gray matter of these bodies is composed, to a considerable extent, of the terminations of the optic nerve, which form synapses around the cells. About 80 per cent. of the optic fibres enter the external geniculate body (von Monokow, Santee). It is, in fact, the termination of the outer root of the optic tract.

The Internal Geniculate Body (*corpus geniculatum mediale*) (Fig. 613).—The internal geniculate body is the termination of the inner root of the optic tract. It seems

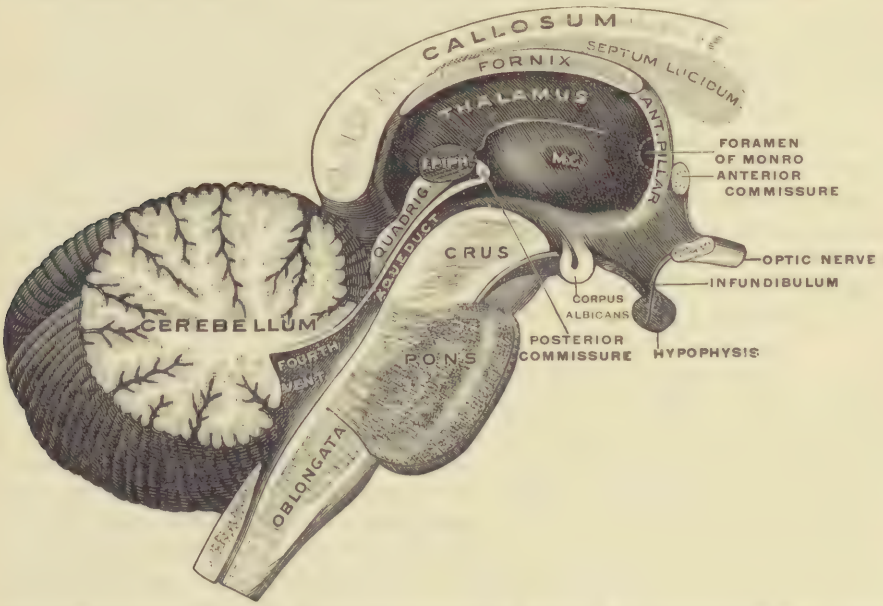

FIG. 587.—Median section through the third and fourth ventricles, left half. *M.C.*, middle commissure. (Testut.)

to receive some of the fibres of the optic tract and is "a way-station in the auditory tract" (Santee). It is smaller in size and lighter in color than the external geniculate body, and does not present a laminated arrangement. It receives the **posterior brachium** from the inferior quadrigeminal body. The internal geniculate bodies are connected with each other through the optic commissure by a band of intercerebral fibres of the optic tract named **Gudden's commissure.** The anterior quadrigeminal body, the pulvinar, and the external geniculate body are intimately concerned with vision. They constitute the lower cerebral centre for the optic nerve-fibres which end in them. Extirpation of the eyes in newly born animals entails an arrest of their development, but has no effect on the posterior quadrigeminal body or the internal geniculate body. These latter also are well developed in the mole, in which animal the superior quadrigeminal body is rudimentary.

The Aqueduct of Sylvius or Iter a Tertio ad Quartum Ventriculum (*aquaeductus cerebri*) (Figs. 574, 584, 585, and 587).—This is a narrow canal, about

half an inch in length and from one-sixteenth to one-eighth of an inch in height, situated between the corpora quadrigemina and the tegmentum, and connecting the third with the fourth ventricle. Its shape on transverse section varies, being T-shaped below, triangular above, and oval about the middle of its course. It is lined by columnar ciliated epithelium, and is surrounded by a layer of gray matter, called the **central gray matter of the aqueduct,** which is continuous with the gray matter of the third and fourth ventricles. This gray matter is separated above from that of the corpora quadrigemina by the **stratum lemnisci;** below the central gray matter lie the posterior longitudinal bundle and the formatio reticularis of the tegmentum. The central gray matter is more abundant below the canal than above it. In the gray matter are certain defined groups of cells, which are the nuclei of the **third** and **fourth cranial nerves.**

Subthalamic Region.—One other structure, to which allusion has already been made, requires mention in this connection; it is the **subthalamic region.** It is a prolongation forward of the tegmentum of the crus cerebri, which becomes continuous with the lower surface of the optic thalamus. Toward the anterior part of the crus cerebri the tegmentum becomes thinned out, and is blended with the superjacent portion of the optic thalamus. To this region, the name **subthalamic tegmental region** has been given. In front it is lost at the base of the brain in the gray matter of the anterior perforated space, and is continuous with the gray matter of the floor of the third ventricle. The subthalamic tegmental region contains a forward prolongation of the **red nucleus,** and consists from above downward of three layers: (1) **stratum dorsale,** which is directly applied to the under surface of the optic thalamus, and consists of fine longitudinal fibres; (2) the **zona incerta,** a continuation forward of the formatio reticularis of the tegmentum; and (3) the **corpus subthalamicum** or **the nucleus of Luys** (*nucleus of Luys* or *nucleus hypothalamicus*), a mass of gray matter which on section presents a lenticular shape, and is the termination of the substantia nigra.

Structure of the Cerebrum.—The cerebrum, like the other parts of the great nerve centre, is composed of **gray** and **white matter.** In order to give some general idea of its construction, at all events in part, it may be compared, for the sake of illustration, to a tree, the trunk of which divides into two main divisions, and these break up into smaller branches, which finally end in twigs, to which are attached the leaves, forming an investment to the branches and covering the whole tree. The trunk is represented by the medulla oblongata as it passes through the foramen magnum; the two main divisions by the crura cerebri, which break up into smaller branches; these diverge from each other, divide and subdivide, until they reach the surface of the hemispheres, where they terminate in single nerve-fibres, which are continuous with the basal axial cylinder processes of the nerve-cells, the representatives of the leaves. These cells are arranged on the surface, covering the hemispheres like a cap, and constitute the **cerebral cortex.** But here the analogy ends, for in the cerebrum there are, in addition to this cortex, other masses of gray matter situated in the middle of the brain; and other white fibres besides the diverging ones that have been mentioned, and which serve either to connect the two cerebral hemispheres, or to unite different structures in the same hemisphere.

The White Matter of the Cerebrum.—The white matter of the cerebrum consists of medullated fibres, varying in size and arranged in bundles, separated by neuroglia. They may be divided into three distinct systems, according to the course they take. 1. **Projection** or **peduncular fibres** (Figs. 588, 589, and 590), which connect the hemisphere with the medulla oblongata and cord. 2. **Transverse** or **commissural fibres** (*C.C.* in Fig. 588), which unite together the two hemispheres. 3. **Association fibres** (Figs. 591 and 592), which connect different structures in the same hemisphere. Many of the association fibres are collateral

branches of the projection fibres, but others are the axones of independent cells.

1. The **Projection** or **Peduncular Fibres** (Figs. 588, 589, and 590) are either **centrifugal** (motor) or **centripetal** (sensory), and they connect the cerebral cortex with every portion of the body, and either project impulses from the cortex to every portion of the body or bring impressions from all parts to the cortex. The **basal ganglia** intercept many projection fibres, especially centripetal fibres. The projection fibres are composed first of the "medullated axis-cylinders of the large and medium-sized pyramids and a few of the polymorphous neurones in the cerebral cortex; and second, of medullated axones of neurones whose centres are situated in masses of gray matter below the cerebral cortex."[1] These fibres form in the hemisphere the corona radiata and the internal capsule, and in the mid-brain the crus. The fibres of the crus are arranged in two strata, the **ventral** or **superficial stratum** or **crusta** and the **dorsal** or **deep stratum** or **tegmentum**. Between the two strata is the **substantia nigra.**

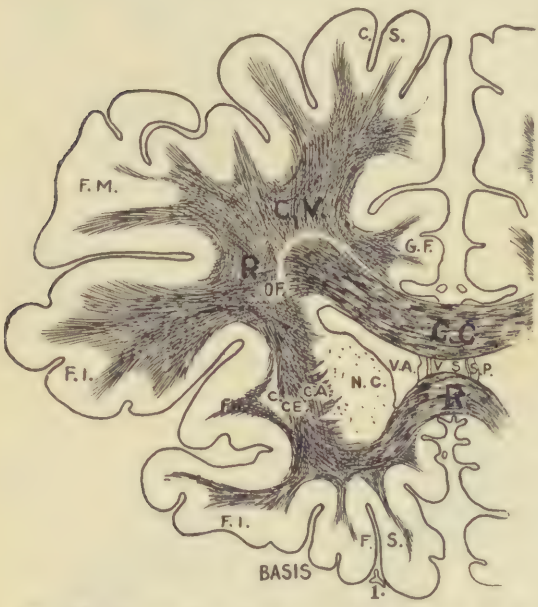

FIG. 588. Section through the frontal lobe, showing the beginning of the most anterior bundles of the corona radiata, which contain the first fibres of the pyramidal tract (*R*). *C. C.*, corpus callosum; *C. V.*, centrum semiovale Vieussenii; *C. A.*, anterior limb of the internal capsule; *F. I.*, inferior frontal convolution (base of the third frontal convolution = motor speech centre). (Jakob.)

THE CENTRIFUGAL OR MOTOR PROJECTION FIBRES.—Most of the motor fibres are included in the crusta. The deep portion of the *crus* is composed of the **intermediate bundle or tract** (p. 907), and the superficial portion of the *crus* is composed of three sets of fibres (p. 907): 1. The **temporal cerebro-cortico-pontal tract** (*tractus cerebrocorticopontalis temporalis*), occupying the outer one-fifth of the crus. 2. The **pyramidal tract** (*fasciculus longitudinalis pyramidalis*), occupying the middle three-fifths of the crus. These fibres pass to the pyramid of the medulla and to the direct and crossed pyramidal tracts of the spinal cord. A few fibres from the cerebellum are placed among the pyramidal fibres. They reach the pons by way of the middle cerebellar peduncle, ascend from the pons with the longitudinal fibres, and reach the crusta. 3. The inner one-fifth of the crusta is formed by the **median fillet** and **motor fibres** coming from the cortex in front of the Rolandic fissure. The tegmentum contains some few motor fibres arranged in several bundles – viz., the **anterior longitudinal bundle**, a portion of the superior peduncle of the cerebellum: the descending or motor root of the fifth nerve, the crossed descending tract from the red nucleus. To these previously mentioned motor fibres in the tegmentum, Santee adds "certain fibres in the formatio reticularis."[2]

THE CENTRIPETAL OR SENSORY PROJECTION FIBRES.—In the tegmentum are the sensory fibres, some of the fibres of the formatio reticularis, some of the fibres of the posterior longitudinal bundle, the fillets, most of the fibres of the superior cerebellar peduncle, the outer root of the optic tract, and the olivary fasciculus. Nearly all of the bundles terminate in the basal ganglia, "but the paths of con-

[1] Anatomy of the Brain and Spinal Cord. By Harris E. Santee. [2] Ibid.

duction are continued through the internal capsule" (Santee). In the internal capsule the sensory projection fibres comprise the **three systems of Flechsig** (the cortical fillet), the **optic radiation,** and the **acoustic radiation.**

THE THREE SYSTEMS OF FLECHSIG.—The chief origin of the three systems of Flechsig is in the lateral nucleus of the thalamus. The **first system of Flechsig** is composed of fibres of common sensation and is called the **ansa peduncularis.** It passes from the thalamus to the cortex of the ascending frontal and parietal convolutions. The fibres of this first system are in the inferior lamina of the internal capsule, and are posterior to the pyramidal tract. Some fibres of the ansa peduncularis pass through the lenticular nucleus, others pass through the external capsule, but all of them terminate as do those in the internal capsule, in the cortex. The **second system of Flechsig** is called the **ansa lenticularis.** Its fibres convey impressions of common sensation. It arises from the thalamus at a higher level than the ansa peduncularis, and in the internal capsule its fibres are among the pyramidal fibres. It terminates in the cortex about the central convolution, the superior frontal convolution, the paracentral lobule, and the limbic lobe. Some fibres pass through the internal capsule to the lenticular nucleus and aid in forming the external capsule. The **third system of Flechsig** is the **anterior stalk of the thalamic radiation.** It arises in the thalamus, passes to the frontal portion of the internal capsule, and reaches the inferior, middle, and superior frontal convolutions and the gyrus fornicatus. The third system also conveys common sensory impressions.

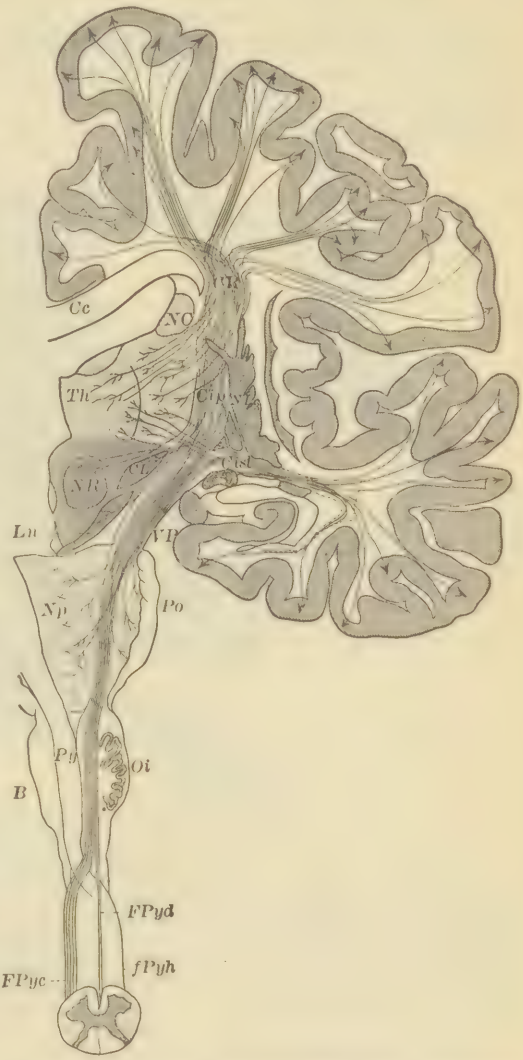

FIG. 589.—Scheme of the projection fibres of the cerebral cortex. *Cc.* Corpus callosum. *Cr.* Internal capsule, into which fibres pass from the cortex above the Sylvian fissure. *NC.* Caudate nucleus. *NL.* Lenticular nucleus. *Th.* Optic thalamus, in which many fibres from all parts of the cortex end. *Cip.* Posterior division of the internal capsule (the sensory tract). *Cisl.* Sublenticular part of the internal capsule, containing fibres of auditory tract and fibres to the thalamus from the cortex below the Sylvian fissure. *CL.* Luys's body. *NR.* Red nucleus of tegmentum. *Ln.* Locus niger. *VP.* Tract from capsule to pons. *Po.* Pons. *NP.* Gray matter of pons. *Oi.* Olive. *Py.* Pyramidal tract in medulla, passing to *FPyd*, anterior median column of cord, and to *FPyc*, lateral column of cord of opposite side, and to *fPyh*, lateral column of cord of same side. *B.* Medulla. (Dejerine, Anatomie des Centres Nerveux, vol. ii. p. 2.)

The **optic radiation** (*D* in Fig. 590) takes origin in the pulvinar of the thalamus and in the internal corpus geniculatum. The fibres pass back of the lenticular nucleus and reach the cortex of the cuneate lobe, in which region the corresponding half of each retina is represented.

The **acoustic radiation** (*D* in Fig. 590) with the inferior brachium from the inferior quadrigeminal body, according to Barker, constitute the continuation of

the auditory path "from the end of the lateral fillet, in the inferior quadrigeminal body, to the internal geniculate body, and then, through the retro-lenticular part of the internal capsule, to the transverse temporal gyri and the third and fourth fifths of the superior temporal convolution."[1]

2. The **Transverse** or **Commissural Fibres** (Figs. 572, 573, and *C.C.* in Fig. 588) connect the two hemispheres. They include: (*a*) the transverse fibres of the corpus callosum (p. 886); (*b*) the anterior commissure (p. 896); (*c*) the posterior commissure (p. 903), and have already been described.

FIG. 590.—The projection tracts joining the cortex with lower nerve centres. Sagittal section, showing the arrangements of tracts in the internal capsule. *A*, tract from the frontal lobe to the anterior half of the capsule, thence in part to the optic thalamus, A^2, and in part to the pons, and thus to the cerebellar hemisphere of the opposite side; *B*, motor tract from the central convolutions to the facial nucleus in the pons and to the spinal cord; *C*, sensory tract from posterior columns of the cord, through the posterior part of the medulla, pons, crus, and capsule to the parietal lobe; *D*, visual tract from the optic thalamus (*OT*) to the occipital lobe; *E*, auditory tract from the int. geniculate body (to which a tract passes from the *VIII. N.* nucleus) to the temporal lobe; *F*, superior cerebellar peduncle; *G*, middle cerebellar peduncle; *H*, inferior cerebellar peduncle; *CN*, caudate nucleus; *CQ*, corpora quadrigemina. The numerals refer to the cranial nerves. (Starr.)

3. The **Association Fibres** (Figs. 591 and 592) connect different structures in the same hemispheres, and are in or near to the cortex. They take origin from the small pyramidal and polymorphous cells of the deep layer of the cortex. Their direction is parallel to the surface of the hemisphere, and in their course they cross the projection and commissural fibres. They are of two kinds: (1) those which unite adjacent convolutions, **short association fibres**; (2) those which pass between more distant parts in the same hemisphere, **long association fibres**.

The **short association fibres** are situated immediately beneath the gray substance of the cortex of the hemispheres, and connect together adjacent convolutions. They constitute subcortical tracts and are divided into **arcuate fibres** and **tangential fibres**. Some of these fibres connect the "visual sensory area with the visual memory area, and the auditory sensory with the auditory memory area."[2]

The **long association fibres** associate cerebral centres which are far apart. They are gathered into bundles and dip down deep into the centrum ovale. They

[1] Anatomy of the Brain and Spinal Cord, by Harris E. Santee

[2] Ibid.

include the following: (*a*) the **uncinate fasciculus**; (*b*) the **cingulum**; (*c*) the **superior longitudinal fasciculus**; (*d*) the **inferior longitudinal fasciculus**; (*e*) the **perpendicular fasciculus**; (*f*) the **fornix**; (*g*) the **occipito-frontal fasciculus.**

FIG. 591.—Diagram showing association-fibres of the hemisphere. (Testut.)

(*a*) THE UNCINATE FASCICULUS (*fasciculus uncinatus*) (Fig. 592).—The uncinate fasciculus passes across the bottom of the Sylvian fissure and connects the

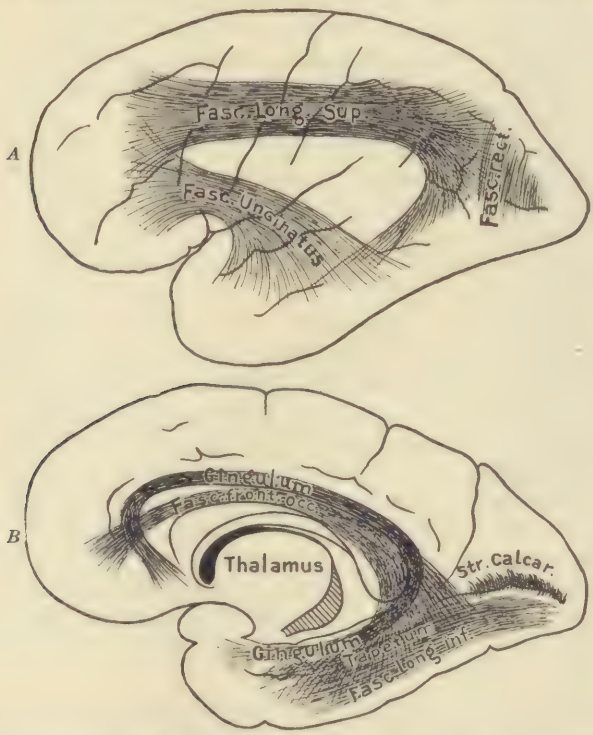

FIG. 592.—The long association fibres. *A* shows the bundles contained in the lateral white substance of the hemispheres; *B*, those in the mesial white matter. At the upper border a few short association bundles are shown diagrammatically. (Jakob.)

uncinate convolution with the orbital portion of the frontal lobe. Barker points out that this fasciculus joins the third frontal, internal orbital, and posterior orbital convolutions with the limbic lobe.

(*b*) The Cingulum or the Fillet of the Gyrus Fornicatus (Fig. 592) is a band of white matter which encircles the hemisphere in an antero-posterior direction, lying in the substance of the convolution of the corpus callosum. Commencing in front at the anterior perforated space, it passes forward and upward parallel with the rostrum, wind around the genu, runs in the convolution from before backward, immediately above the corpus callosum, turns around its posterior extremity, and passes into the Hippocampus major, through which it courses to its anterior extremity. According to Beem there are three sets of fibres in the cingulum. The anterior fibres join the internal olfactory root and the anterior perforated lamina with the front of the frontal lobe. The horizontal fibres join the gyrus fornicatus with the frontal lobe. The posterior fibres join the fusiform convolution (the fourth temporal) with the hippocampal convolution and the temporal lobe.[1]

(*c*) The Superior Longitudinal Fasciculus (*fasciculus longitudinalis superior*) (Fig. 592).—The superior longitudinal fasciculus is beneath the convex surface of the hemisphere. It joins the frontal cortex with the parietal and temporal cortex and brings into relation the motor speech centres and the centres of auditory and visual memories.

(*d*) The Inferior Longitudinal Fasciculus (*fasciculus longitudinalis inferior*) (Fig. 592).—The inferior longitudinal fasciculus associates the centres of auditory and visual memory. It is a collection of fibres which connects the temporal and occipital lobes, running along the outer wall of the descending and posterior cornua of the lateral ventricle.

(*e*) The Perpendicular Fasciculus or Fasciculus Rectus (Fig. 592).—The perpendicular fasciculus runs vertically in front of the occipital lobe, and connects the inferior parietal lobule with the second and third temporal convolutions, and also connects the superior occipital convolution with the inferior occipital and the fourth temporal convolutions.

(*f*) The Fornix (*corpus fornicis*) (Fig. 586).—The fornix by its anterior pillar is connected with the corpus albicans and by means of the bundle of Vicq d'Azyr with the optic thalamus. Most of the posterior pillar ends in the hippocampus major, but some of the fibres (the corpus fimbriatum) go to the uncinate convolution. Through the fibres of the lyra it probably also unites the opposite hippocampal convolutions.

(*g*) The Occipito-frontal Fasciculus of Forel (*fasciculus occipitofrontalis*) (Fig. 592).—The occipito-frontal fasciculus is placed between the cingulum and the superior longitudinal fasciculus. It connects the frontal cortex with the occipital cortex. Some regard it as a part of the corpus callosum.

The Gray Matter of the Cerebrum.—The gray matter of the cerebrum, in accordance with its situation, is disposed in three great groups: (1) The **gray matter of the cerebral cortex** or **cortical gray matter.** (2) The **gray matter of the ganglia** or **ganglionar gray matter.** (3) The **central** or **ventricular gray matter.**

The Gray Matter of the Cortex.—The cortex, bark or envelope of the cerebrum, is a thin layer of gray matter on the surface, which encompasses the white matter of the hemispheres (*centrum ovale*). The cortex has been mapped out into definite areas and centres, each of which is connected with a well-defined function (p. 952).

On examining a section through one of the convolutions of the Rolandic area with a lens, it is seen to consist of alternating white and gray layers thus disposed from the surface inward: (1) a thin layer of white substance; (2) a layer of gray substance; (3) a second layer of white substance (outer band of Baillarger or band of Gennari); (4) a second gray layer; (5) a third white layer (inner band of

[1] Anatomy of the Brain and Nervous System. By Harris E. Santee.

Baillarger); (6) a third gray layer, which rests on the medullary substance of the convolution.

The cortex is made up of nerve-cells which vary in size and shape, and of nerve-fibres, some of which are medullated, but most of which are non-medullated, embedded in a matrix of neuroglia.

The nerve-cells in a typical section of the cortex are arranged in five layers (Fig. 593) named from the surface inward as follows: (1) the **molecular layer**; (2) the **layer of small pyramidal cells**; (3) the **layer of large pyramidal cells**; (4) the **layer of polymorphous cells**; (5) the **layer of fusiform cell-bodies** (Santee) (not shown in Fig. 593).

The Molecular, the Superficial or the Neuroglia Layer.—This layer is immediately adjacent to the pia mater. Neuroglia constitutes the greatest amount of the superficial layer; hence its other name of neuroglia layer. In this layer the cells are irregular and are known as the **neurones of Cajal**. The cells are polygonal, triangular, and fusiform in shape, and are associative in function. Each polygonal cell gives off some four or five dendrites, while its axones may arise directly from the cell or from one of its dendrites. The axones and dendrites of these cells ramify in the molecular layer. Each triangular cell gives off two or three dendrites, from one of which the axone arises, the dendrites and the axone ramifying in the molecular layer. The fusiform cells are placed with their long axes parallel to the surface and are mostly bipolar, each pole being prolonged into a dendrite, which runs horizontally for some distance and furnishes ascending branches. Their axones, two or three in number, arise from the dendrites, and, like them, take a horizontal course, giving off numerous ascending collaterals. The distribution of the axones and dendrites of all three sets of cells is limited to the molecular layer.

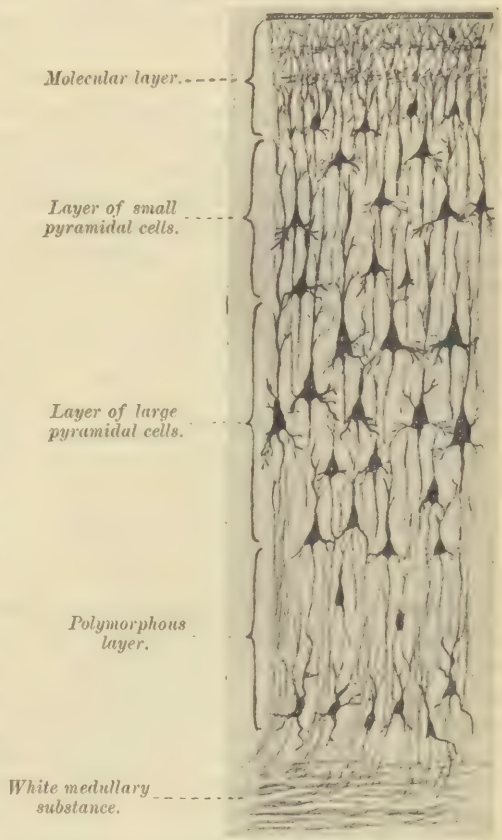

Fig. 593.—The four layers of cells in the cerebral cortex. Modified from Testut. (After Cajal.)

Besides the neuroglia, the cells, and the gray fibres, this layer contains medullated nerve-fibres arranged in a network and constituting the superficial white layer.

The Layer of Small and the Layer of Large Pyramidal Cells.—The cells in the second and third layers may be studied together, since, with the exception of the difference in size and the more superficial position of the smaller cells, they resemble each other. The body of each cell is pyramidal in shape, its base being directed to the deeper parts and its apex toward the surface. It contains granular pigment, and stains deeply with ordinary reagents. The nucleus is nucleolated, of large size, and round or oval in shape. The base of the cell gives off the axone, and this passes into the central white substance, giving off collaterals in its course, and is distributed as a projection, commissural, or association fibre.

Both the apical and basal parts of the cell give off dendrites. The apical dendrite is directed toward the surface, and ends in the molecular layer by dividing into numerous branches, all of which may be seen, when prepared by the silver or methylene-blue method, to be studded with projecting bristle-like processes. The larger pyramidal cells, especially in the Rolandic area, may exceed 50μ in length and 40μ in breadth, and are termed **giant cells**. The chief function of the small pyramids is commissural and associative. The chief function of the large pyramids is motor, but they have also commissural and associative functions.

Layer of Polymorphous Cells.—The cells in this layer, as their name implies, are very irregular in contour, the commonest varieties being of a spindle, star, oval, or triangular shape. Their dendrites are directed outward, toward, but do not reach, the molecular layer; their axones pass into the subjacent white matter. From this layer come commissural fibres, long association fibres, and some projection fibres.

There are two other kinds of cells in the cerebral cortex, but their axones pass in a direction opposite to that of the pyramidal and polymorphous cells, among which they lie. They are: (*a*) the cells of Golgi, the axones of which do not become medullated, but divide immediately after their origin into a large number of branches, which are directed toward the surface of the cortex; (*b*) the cells of Martinotti, which are chiefly found in the polymorphous layer. Their dendrites are short, and may have an ascending or descending course, while their axones pass out into the molecular layer and form an extensive horizontal arborization.

Layer of Fusiform Cell-bodies.—It receives the name of the **claustral formation**, because it is formed like the claustrum. This layer is not sharply defined from the white matter beneath; the change from one to the other is gradual. The long axes of most of the cells are perpendicular to the surface of the hemisphere, but beneath the fissures they are parallel to the surface (Santee). "The commissural and long association fibres belong, for the most part, to the fusiform and polymorphous neurones."[1]

Nerve-fibres.—These fill up a large part of the intervals between the cells. Some of these fibres form fascicului; some are isolated, and others are arranged in plexuses. They may be medullated or non-medullated—the latter comprising the axones of the smallest pyramidal cells and the cells of Golgi. In their direction the fibres may be either transverse, the **transverse tangential** or **horizontal fibres**, or vertical, the **vertical** or **radial fibres**. The **transverse fibres** run parallel to the surface of the hemisphere, intersecting the vertical fibres at a right angle. They consist of several strata, of which the following are the most important: (1) a **stratum of white fibres** covering the superficial aspect of the molecular layer; (2) the **band of Bechterew**, found in certain parts of the superficial portion of the layer of the smaller pyramidal cells; (3) the **external** or **outer band of Baillarger** or the **band of Gennari**, which runs through the layer of large pyramidal cells; (4) the **internal band of Baillarger**, which intervenes between the layer of large pyramidal cells and the polymorphous layer. According to Cajal, the transverse fibres consist of (*a*) the collaterals of the pyramidal and polymorphous cells and of the cells of Martinotti; (*b*) the arborizations of the axones of Golgi's cells; (*c*) the collaterals and terminal arborizations of the projection, commissural, or association fibres. The **vertical fibres.**—Some of these—viz., the axones of the pyramidal and polymorphous cells—are directed toward the central white matter, while others, the terminations of the commissural, projection, or association fibres, pass outward to end in the cortex. The axones of the cells of Martinotti are also ascending fibres.

In certain parts of the cortex this typical structure is departed from. The chief

[1] Anatomy of the Brain and Spinal Cord. By Harris E. Santee.

of these regions are: (1) the **occipital lobe**, (2) the **hippocampus major**, (3) the **dentate convolution**, and (4) the **olfactory bulb**.

Special Types of Gray Matter. 1. **The Occipital Lobe.**—In the cuneus and the calcarine fissure of the occipital lobe, Cajal has recently described as many as nine layers. Here the inner band of Baillarger is absent; the outer band of Baillarger or band of Gennari is, on the other hand, of considerable thickness. If a section be examined microscopically, an additional layer is seen to be interpolated between the molecular layer and the layer of small pyramidal cells. This extra layer consists of two or three strata of fusiform cells, the long axes of which are at right angles to the surface. Each cell gives off two dendrites, external and internal, from the latter of which the axone arises and passes into the white central substance. In the layer of small pyramidal cells, fusiform cells, identical with the above, are seen, as well as ovoid or star-like cells with ascending axones, the **cells of Martinotti**. This area of the cortex forms the visual centre, and it has been shown by Dr. J. S. Bolton[1] that in old-standing cases of optic atrophy the thickness of Gennari's band is reduced by nearly 50 per cent.

2. **The Hippocampus Major.**—In the hippocampus major the molecular layer is very thick and contains a large number of Golgi cells. It has been divided into three strata: (*a*) **S. convolutum** or **S. granulosum**, containing many tangential fibres; (*b*) **S. lacunosum**, presenting numerous lymphatic or vascular spaces; (*c*) **S. radiatum**, exhibiting a rich plexus of fibrils. The two layers of pyramidal cells are condensed into one, and the cells are mostly of large size. The axones of the cells in the polymorphous layer may run in an ascending, descending, or horizontal direction. Between the polymorphous layer and the ventricular ependyma is the white substance of the alveus.

3. **The Dentate Convolution.**—In the rudimentary dentate convolution the molecular layer contains some pyramidal cells, while the layer of pyramidal cells is almost entirely represented by small ovoid cells.

4. **The Olfactory Bulb.**—In many of the lower animals this contains a cavity which communicates through the hollow olfactory stalk with the cavity of the lateral ventricle. In man the original cavity is filled up by neuroglia and its wall becomes thickened, but much more so on its ventral than on its dorsal aspect. Its dorsal part contains a small amount of gray and white matter, but it is scanty and ill defined. A section through the ventral part shows it to consist of the following layers from without inward. (1) A layer of *olfactory nerve-fibres*, which are the non-medullated axones prolonged from the olfactory cells of the nose, and which reach the bulb by passing through the cribriform plate of the ethmoid bone. At first they cover the bulb, and then penetrate it to end by forming synapses with the dendrites of the mitral cells, presently to be described. (2) *Glomerular layer (stratum glomerulosum)*.—This contains numerous spheroidal reticulated enlargements, termed **glomeruli**, which are produced by the branching and arborization of the processes of the olfactory nerve-fibres with the descending dendrites of the mitral cells. (3) *Molecular layer.*—This layer is formed of a matrix of neuroglia, embedded in which are the *mitral cells*. These cells are pyramidal in shape, and the basal part of each gives off a thick dendrite which descends into the glomerular layer, where it arborizes as indicated above, and others which interlace with similar dendrites of neighboring mitral cells. The axones pass through the next layer into the white matter of the bulb, from which, after becoming bent on themselves at a right angle, they are continued into the olfactory tract. (4) *Nerve-fibre layer.*—This lies next the central core of neuroglia, and its fibres consist of the axones or afferent processes of the mitral cells which are passing to the brain; some efferent fibres are, however, also present, and terminate in the

[1] Phil. Trans. of Royal Society, Series B, vol. cxciii. p. 165.

molecular layer, but nothing is known as to their exact origin. It is to be remembered that the olfactory path is uncrossed or almost completely uncrossed.

The Gray Matter of the Ganglia or the Ganglionar Gray Matter.—These ganglia have been previously described. They are as follows: The corpus striatum, the optic thalamus, the external geniculate body, the internal geniculate body, the nucleus of Luys, the red nucleus of the tegmentum, the anterior quadrigeminal body, the posterior quadrigeminal body, the substantia nigra, and the interpeduncular ganglion.

The Central or Ventricular Gray Matter.—This includes the lamina cinerea, the tuber cinereum, the middle commissure, the nuclei of the third and fourth cranial nerves, and the gray matter about the aqueduct of Sylvius.

IV. The Hind-brain (Rhombencephalon).

From the hind-brain or rhombencephalon, as previously stated, come two vesicles, the **metencephalon,** or upper portion of the hind-brain or the **hind-brain proper,** and the **myelencephalon,** or lower portion of the hind-brain. From the metencephalon come the **pons** and the **cerebellum.** From the myelencephalon comes the **medulla oblongata.** The original hind-brain remains in the brain of the adult as the fourth ventricle.

Pons Varolii (Figs. 557, 599, and 603).—The pons Varolii is the bond of union between the various segments of the encephalon, connecting the cerebrum above, the medulla oblongata below, and the cerebellum behind. It lies upon a portion of the **clivus,** the groove of bone between the foramen magnum and the dorsum sellae, and is situated above the medulla oblongata, below the crura cerebri, and between the hemispheres of the cerebellum. It is about an inch in length, an inch in thickness, and an inch and a half in width. It presents four surfaces: the **superior surface,** which is attached, by direct continuation of fibres, to the mid-brain; the **inferior surface,** which is continuous with the medulla oblongata; the **anterior** or **ventral** and the **posterior** or **dorsal surfaces** are free.

The **Anterior** or **Ventral Surface,** the **Tuber Annulare** or **Base** (*pars basilaris pontis*), is very prominent, markedly convex from side to side, but less so from before backward. It consists of transverse white fibres (Fig. 594), which arch like a bridge across the middle line, and on either side are gathered together into a compact mass, forming the **middle peduncle of the cerebellum** (Fig. 599). Above and below it presents a well-defined border; below, its transverse fibres slightly overlap the pyramidal bodies of the medulla, which disappear into its substance; above, the transverse fibres slightly overlap the crura cerebri which emerge from it. This surface rests upon the clivus of the sphenoid bone, and presents in the middle line a **longitudinal groove** (*sulcus basilaris*) (Fig. 603), wider in front than behind, in which rests the **basilar artery.** Slightly in advance of the middle of the ventral surface of the pons and at the margin the two roots of the fifth nerve emerge.

The Posterior or Dorsal Surface (*pars dorsalis pontis*).—The posterior or dorsal surface of the pons is free, but is concealed from view by the cerebellum. It forms the upper part of the floor of the fourth ventricle, and will be described with this cavity (Fig. 604 and p. 942).

Structure.—Transverse sections of the pons Varolii show that it consists of two parts, which differ in appearance and structure from each other: the *anterior* or *ventral portion* (Fig. 594) consists for the most part of fibres arranged in transverse and longitudinal bundles with a small amount of gray matter; the *posterior* or *dorsal portion* is chiefly constituted by a continuation upward of the reticular formation of the gray matter of the medulla, and is called the **tegmental portion,** as most of its constituents are continued into the tegmentum of the crus cerebri. It is subdivided into lateral halves by a median raphé continuous with that of the

medulla, but the raphé does not extend into the ventral half of the pons, being here obliterated by the transverse fibres.

Transverse Fibres of the Pons.—The transverse fibres are placed in the ventral portion of the pons. These are disposed in three sets:

1. The **Superficial** or **Ventral Transverse Fibres** (*fibrae pontis superficiales*) (Fig. 594) constitute a rather thin layer on the ventral surface of the pons. This thin white layer is called the **tuber annulare.**

2. The **Middle** or **Deep Transverse Fibres** are placed dorsally or above the superficial transverse fibres, and form a thick layer, with much gray matter between them. These collections of gray matter are named the **nuclei pontis.** In this layer of transverse fibres are longitudinal fibres coming from the middle three-fifths of the crustae and passing to the pyramids of the medulla and also

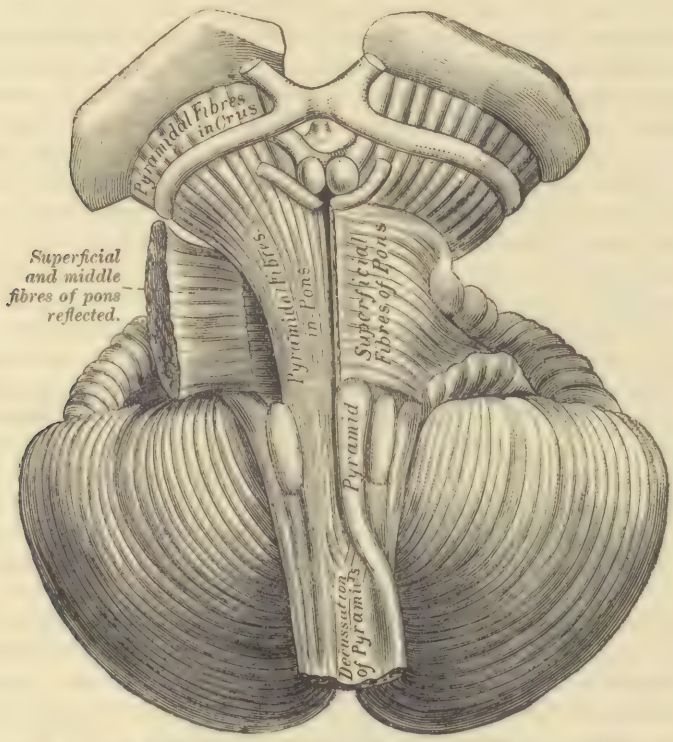

FIG. 594.—Superficial dissection of the medulla oblongata and pons. (Ellis.)

fibres of the fronto-pontal, intermediate, and temporo-frontal tracts (Santee). The **middle cerebellar peduncles** (*brachia pontis*) (Fig. 599) are formed by the superficial and middle transverse fibres.

3. The **Dorsal Transverse** or **Dorsal Deep Transverse Fibres** lie dorsally to the middle transverse fibres and the pyramidal fibres between them and the formatio reticularis. These fibres are collected into a distinct bundle which is most definite in the posterior portion of the pons and in which region it is named the **trapezium** (*corpus trapezoideum*), because of its shape. The trapezium is the mark of the boundary between the dorsal and ventral surfaces. The chief origin of the trapezium is from the cochlear nerve nuclei; they decussate and pass by the lateral fillet to the inferior quadrigeminal body. Santee points out that the trapezium and lateral fillet are part of the auditory conduction path.

Longitudinal Fibres of the Pons.—These are found in both the ventral and dorsal portions. There are three sets:

The **Ventral Longitudinal** or **Ventral Deep Longitudinal Fibres** (Fig. 594) are chiefly the continuation of the pyramidal fibres of the crustae which reach the pyramids of the medulla. They form a thick bundle. Among these fibres are some from the opposite cerebellar peduncles and the nuclei pontis. During the descent of the pyramidal tract it grows constantly smaller, because it loses here and there fibres which pass to motor cranial-nerve nuclei. The pressure of the thick bundle of pyramidal fibres causes a bulging of the superficial transverse fibres on the ventral surface of the pons and the formation of the mesial groove between them.

The **Middle Longitudinal** or **Dorsal Deep Longitudinal Fibres** are placed in the floor of the fourth ventricle in the *pontine formatio reticularis*, which is continuous with the formatio reticularis of the medulla oblongata. The pontine formatio reticularis is a network of these longitudinal fibres with some oblique fibres, the network containing gray matter. Some of the gray matter of the formatio reticularis forms the nuclei of certain cranial nerves; the rest of it forms the nuclei of the formatio reticularis. Santee describes six bundles of longitudinal fibres in the formatio reticularis: 1. The **fillet** (*lemniscus*), consisting of the **lateral**, the **median**, and the **superior fillet** (*lemniscus lateralis, lemniscus medialis, lemniscus superior*), passing to and through the tegmentum to the thalamus and the two quadrigeminal bodies. 2. The **posterior longitudinal bundle** (*fasciculus longitudinalis medialis*) contains both ascending and descending fibres; most of the fibres do not decussate but reach the anterior column of the same side of the cord. Some of its fibres decussate through the pons, medulla, and mid-brain. According to Santee, it receives ascending fibres from the gray matter of the anterior cornu of the spinal cord, from the sensory nuclei of cranial nerves, and through the middle peduncle from the cerebellum. It terminates in the subthalamic region. The fibres decussate across the posterior commissure. In this bundle are motor fibres passing from the sixth to the third nerves and from the third to the seventh. 3. The **anterior longitudinal bundle** (*fasciculus ventralis*) passes from the superior quadrigeminal body to the gray matter of the anterior cornu of the cervical cord. "It is the pupillo-dilator tract."[1] 4. The **olivary bundle** or the **central tegmental tract** (*fasciculus tegmenti centralis*) arises from the inferior olivary nucleus of the medulla, ascends to the lenticular nucleus, from which situation some of the fibres pass to the cortex. 5. The **crossed descending tract** from the red nucleus. It arises in the red nucleus of the tegmentum, soon crosses the raphé, and, as Barker points out, reaches the lumbar region of the cord. In the pons the fibres are in the lateral fillet. 6. The **ascending** or **inferior sensory root of the fifth nerve** (*tractus spinalis nervi trigemini*) arises near the Rolandic tubercle in the medulla and effects a junction with the superior root ventrally to the superior peduncles of the cerebellum.

The **Dorsal Longitudinal** or **Superficial Longitudinal Fibres** constitute the roof of the superior portion of the fourth ventricle, and form the superior peduncles of the cerebellum (p. 932) and the valve of Vieussens (p. 933).

Gray Matter of the Pons.—The nuclei pontis constitute a portion of it, the gray matter of the formatio recticularis the balance.

The **Nuclei Pontis,** which have been previously referred to, are collections of gray matter on each side of the pons, between the fibres of the middle transverse bundle and of the ventral longitudinal bundle of the pons. The nucleus pontis of each side receives fibres from the **crusta**—viz., the intermediate bundle, the frontal cerebro-cortico-pontal tract (p. 893), and the temporal cerebro-cortico-pontal tract (p. 894), and also receives fibres from the middle peduncle of the cerebellum (p. 934). It sends fibres by the middle peduncle to the opposite cerebellar hemisphere. The nuclei pontis contain numerous multipolar ganglion cells.

[1] Anatomy of the Brain and Spinal Cord. By Harris E. Santee.

The **Gray Matter of the Pontine** or **Formatio Reticularis** forms the **superior olivary nucleus**, the **nuclei of the trapezium**, numerous **nuclei of the formatio reticularis**, and **nuclei of certain cranial nerves.** The portion of the formatio reticularis between the roots of the sixth pair of cranial nerves is called the **formatio reticularis alba**; the portion between the roots of the sixth and seventh nerves is called the **formatio reticularis grisea.**

The **Superior Olivary Nucleus** (*nucleus olivaris superior*) is upon the dorsal surface of the outer part of that collection of fibres known as the trapezium. It is not large enough to be visible to the naked eye and contains very small nerve-cells. It is a part of the auditory pathway, and its fibres enter the accessory auditory nucleus of the opposite side. The nuclei of the trapezium are in the auditory pathway. There are numerous other nuclei in the formatio reticularis (nuclei of the formatio reticularis, or the **nucleus magnocellularis diffusus of Koelliker**). The cells of these nuclei are large and multipolar, and their axones cross to the opposite side of the pons. They receive fibres from cranial-nerve nuclei and axones from the cells of the folium of the cerebellum which are called **cells of Purkinje.** These nuclei are probably connected with various pontine tracts.

The **Nuclei of the Fifth Nerve** (Fig. 613) in the pons are two in number, one for the motor root and the other for the sensory. The **motor nucleus** is situated in the higher portion of the pons, close under the dorsal surface and along the line of the lateral margin of the fourth ventricle. The **sensory nucleus** lies external to the motor one, beneath the superior peduncle of the cerebellum, which forms the lateral boundary of the upper half of the fourth ventricle. Some of the fibres from these nuclei pass to the raphé of the pons, and thence probably to the higher parts of the brain; the rest form the nerve-roots of the motor and sensory parts of the fifth nerve respectively. They pass through the pons to emerge on its ventral surface at its lateral and constricted portion, nearer its superior than its inferior margin. It must be mentioned that the whole of the roots of the fifth nerve are not formed from these nuclei. The sensory root is partly formed by a long tract of fibres, known as the **ascending root,** which can be traced through the pons to the nucleus of Rolando in the medulla. The motor root, in like manner, is partly formed by a long tract of fibres, which passes downward from the gray matter in the floor of the fourth ventricle and the floor of the Sylvian aqueduct and which is termed the **descending root.**

The **Nucleus of the Sixth Nerve** (Fig. 613) is situated beneath the floor of the fourth ventricle, on either side of the middle line. It lies close to the root of the facial nerve, immediately to be described, being a little external to and beneath it, and corresponds to the upper half of the fasciculus teres of the floor of the fourth ventricle (Fig. 606). The fibres pass through the substance of the pons, and emerge at the lower margin of this structure, between it and the upper end of the medulla.

The **Nucleus of the Facial Nerve** (*nucleus n. facialis*) (Fig. 613) is of elongated form, and is situated deeply in the reticular formation below the superior fovea of the floor of the fourth ventricle. The roots of the nerve derived from it pursue a remarkably tortuous course in the substance of the pons. At first they pass backward and inward till they reach the floor of the fourth ventricle, close to the median groove, where they are collected into a rounded bundle. This passes upward and forward, producing an elevation (*fasciculus teres*) in the floor of the ventricle, and then takes a sharp bend and arches outward through the substance of the pons to emerge at its lower border in the interval between the olivary and restiform bodies of the medulla. The **pars intermedia of Wrisberg** takes origin from the floor of the fourth ventricle beneath the inferior fovea.

The **Nuclei of the Auditory Nerve** (*nuclei n. acustici*) (Fig. 613) are two in number, **dorsal** and **ventral.** The origin of the **dorsal** or **vestibular root** is from a nucleus situated in the medulla, but prolonged upward into the pons, where it lies beneath the

upper half of the floor of the fourth ventricle (*nuclei n. vestibularis*). The dorsal root also takes origin from the cerebellum (from the **nucleus fastigii** and the **nucleus globosus**). According to Golgi, the vestibular root is also in connection with the **nucleus of Deiters** and the **nucleus of Bechterew**. The **ventral** or **cochlear root** arises from the ventral or accessory nucleus (*nuclei n. cochlearis*) which is also partly contained in the medulla and partly in the pons. In the medulla it is situated on the antero-external surface of the restiform body, lying between the vestibular and cochlear divisions of the auditory nerve, the latter being to its outer side. In the pons it is seen to lie beyond the boundary of the fourth ventricle on the outer and ventral aspect of the restiform body. A third nucleus, **nucleus of Deiters,** is sometimes termed the outer nucleus of the auditory nerve. It is situated below the outer angle of the fourth ventricle, and contains multipolar nerve-cells of large size. The outer portion of the nucleus of Deiters is called **Bechterew's nucleus.** The root of the auditory nerve consists of two portions, lateral and mesial, which pass, one to the outer and the other to the inner side of the restiform body, those from the lateral part arising mainly from the ventral nucleus, those from the mesial part arising from the dorsal auditory nucleus. They emerge at the lower border of the pons, in the groove between the olivary and restiform bodies.

The Cerebellum or Little Brain (Figs. 557, 595, 596, 597, 598, and 599).—The cerebellum is contained in the inferior occipital fossæ, and is situated beneath the occipital lobes of the cerebrum, from which it is separated by the tentorium cerebelli. In form it is oblong and flattened from above downward, its great diameter being from side to side. It measures from three and a half to four inches transversely, two to two and a half inches from before backward, and is about two inches thick in the centre, and about six lines thick at the circumference. It consists of **gray** and **white matter:** the former, darker than that of the cerebrum, occupies the surface (*substantia corticalis*), and masses of it are also found in the interior. The white matter is in the interior (*corpus medullare*). The surface of the cerebellum is not convoluted like that of the cerebrum, but is traversed by numerous curved furrows or sulci, which vary in depth at different parts, and separate the laminæ of which it is composed.

Lobes of the Cerebellum.—The cerebellum consists of three parts or lobes, a median and two lateral. They are all continuous with each other, and are substantially the same in structure. The median portion is called the **worm** or **vermiform process** (*vermis*), from the annulated appearance which it presents, owing to transverse ridges and furrows upon it. On the upper surface of the cerebellum, the worm is only slightly elevated above the level of the lateral portions, but on the under surface it is sunk almost out of sight in a deep depression, which is called the **valley** or **vallecula** (*vallecula cerebelli*). The lateral parts of the cerebellum are called **hemispheres** (*hemisphaeria cerebelli*); they attain a considerable size, overlapping and obscuring the inferior part of the worm. Below and behind they are separated by a deep notch, the **posterior cerebellar notch** or the **incisura marsupialis** (*incisura cerebelli posterior*), and in front by a broader, shallower notch, the **anterior cerebellar notch** or the **incisura semilunaris** (*incisura cerebelli anterior*). The anterior notch lies close to the pons and upper part of the medulla, and its upper edge encircles the posterior corpora quadrigemina. The posterior notch is free, and contains, in the recent state, the upper part of the falx cerebelli. The sides of the notches are formed by the margins of the hemispheres, while the bottom of the notches is formed by the anterior and posterior extremities of the worm respectively. The cerebellum is characterized by its laminated or foliated appearance; it is everywhere marked by deep, transverse, somewhat curved fissures, which lie close together, and extend for a considerable depth into the substance of the cerebellum, dividing it into a series of layers or leaves. Upon making sections across the laminæ

it will be seen that the folia, though differing in appearance from the convolutions of the cerebrum, are homologous with them, inasmuch as they consist of a central white substance, with a covering or cortex of gray matter.

The largest and deepest fissure is the **great horizontal fissure** (*sulcus horizontalis cerebelli*) (Figs. 595 and 596). It commences in front at the pons, and passes horizontally around the free margin of the hemisphere to the middle line behind, and divides the cerebellum into an upper and lower portion. Several secondary but deep fissures separate the cerebellum into lobes, and these are further subdivided by shallower sulci, which separate the individual folia or laminae from each other.

When the cerebellum is removed from the pons and medulla, the **transverse fissure** (*fissura transversa cerebelli*) is seen upon its anterior margin. This fissure is between the superior and inferior medullary laminae.

The white matter in the interior of the cerebellum is known as the **medullary body** (*corpus medullare*). About the middle it divides into a **superior** and an **inferior lamina** (*laminae medullares*). These laminae help to form the fourth ventricle. The superior lamina is composed of the superior medullary velum and the peduncles of the cerebellum. The inferior lamina constitutes the inferior medullary velum.

The cerebellum is connected to the cerebrum, pons, and medulla by three pairs of peduncles, which will be described in the sequel; a *superior* pair connect it with the cerebrum; a *middle* pair, with the pons; and an *inferior* pair, with the medulla.

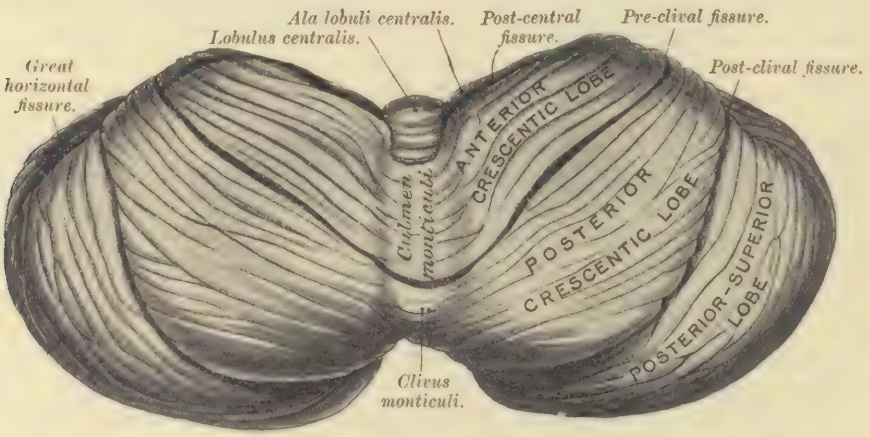

FIG 595.—Upper surface of the cerebellum. (Schäfer.)

The Upper Surface of the Cerebellum (*facies cerebelli superior*) (Fig. 595).—The superior surface of the cerebellum is somewhat elevated in the middle line and sloped toward its circumference, its hemispheres being connected together by an elevated median portion or lobe, the **superior vermis** or **superior vermiform process** (*vermis superior cerebelli*). The front of the superior vermis is elevated, and the highest point is called the **monticulus cerebelli.** The surface is traversed by four curved fissures, which are named from their situation, in front or behind two prominent lobes of the worm, the **central lobe** and the **clivus**: (1) the **pre-central fissure** (*sulcus praecentralis cerebelli*); (2) the **post-central fissure** (*sulcus postcentralis*); (3) the **pre-clival fissure,** and (4) the **post-clival fissure.** These four fissures divide the entire upper surface of the cerebellum into five lobes, but the portion of the lobe in the worm has received a different name from that in the hemisphere, though the two are continuous with each other. The five lobes in the worm are named from before backward: (1) the **lingula,** (2) the **central lobule,** (3) the **culmen monticuli**, (4) the **clivus monticuli**, and (5) the **folium cacuminis** (*folium vermis*).

The five lobes in the hemispheres are named from before backward: (1) the **fraenulum,** (2) the **ala lobuli centralis,** (3) **anterior crescentic,** (4) **posterior crescentic,** and (5) **posterior superior.** The arrangement of these fissures and lobules will be understood by reference to the accompanying schematic arrangement, in which the lobules are named in order from before backward with the fissures which separate them:

Worm.	*Hemisphere.*
Lingula.	Fraenulum.
Pre-central Fissure.	
Lobulus centralis.	Ala lobuli centralis.
Post-central Fissure.	
Culmen monticuli.	Anterior crescentic lobe.
Pre-clival Fissure.	
Clivus monticuli.	Posterior crescentic lobe.
Post-clival Fissure.	
Folium cacuminis.	Posterior superior lobe.

The **Lingula** (*lingula cerebelli*) (Fig. 598)is a tongue-shaped process of the vermis, which lies in the anterior cerebellar notch in front of the lobulus centralis, and is partially or completely concealed by it. It is in relation, in front, with the valve of Vieussens, on the dorsal surface of which it rests and with which it is connected; its white matter being continuous with that of the valve. At either side the lingula gradually shades off, and is prolonged only for a short distance into the hemispheres, where it forms the **fraenulum** (*vinculum lingulae cerebelli*). This does not stretch beyond the superior peduncle of the cerebellum over which it lies.

The Central Lobe and Alae (*lobulus centralis*).—The lobus or lobulus centralis is a small square lobe, situated in the anterior notch. It overlaps the lingula and is in turn partially concealed by the culmen monticuli. Laterally the lobulus centralis extends along the upper and anterior part of each hemisphere, where it forms a wing-like prolongation, the **ala lobuli centralis.**

The **Culmen Monticuli Cerebelli** is much larger than the two lobes just described, and constitutes, with the succeeding lobe, the **clivus,** the bulk of the upper worm. In front it partially overlaps and obscures the lobulus centralis, and behind it is separated from the clivus by the **pre-clival fissure.** It forms the most prominent part of the upper worm, and is marked on its surface by three or four secondary fissures, dividing it up into smaller lobules. Laterally it is continuous with the **anterior crescentic lobe of the hemisphere** (*pars anterior lobuli quadrangularis*), which is distinctly differentiated from the posterior crescentic lobe by the pre-clival fissure, though the two were formerly classed together as the quadrate lobe of the lateral hemisphere.

The **Clivus Monticuli** (*declive monticuli cerebelli*) is of considerable size, and, as stated above, forms with the culmen the major part of the superior worm. It consists of a group of laminae, which in front are separated from the culmen by the pre-clival fissure and behind appear to be almost continuous with the folium cacuminis, especially in the median line; but it will be found, on careful examination, to be separated from it by a well-defined fissure, the **post-clival fissure.** Laterally this lobe is continued into the hemispheres as the **posterior crescentic lobe** (*pars posterior lobuli quadrangularis*), which is somewhat semilunar in shape, and, with the anterior crescentic lobe, constitutes the greater part of the upper surface of the hemispheres.

The **Folium Cacuminis** (*folium vermis*) is a short and narrow, concealed band at the posterior extremity of the worm, consisting apparently of a single folium, but in reality marked on its upper and under surfaces by secondary fissures. Laterally it expands in either hemisphere into a considerable lobe, which is semilunar in shape, and is situated at the postero-superior part of the hemisphere and

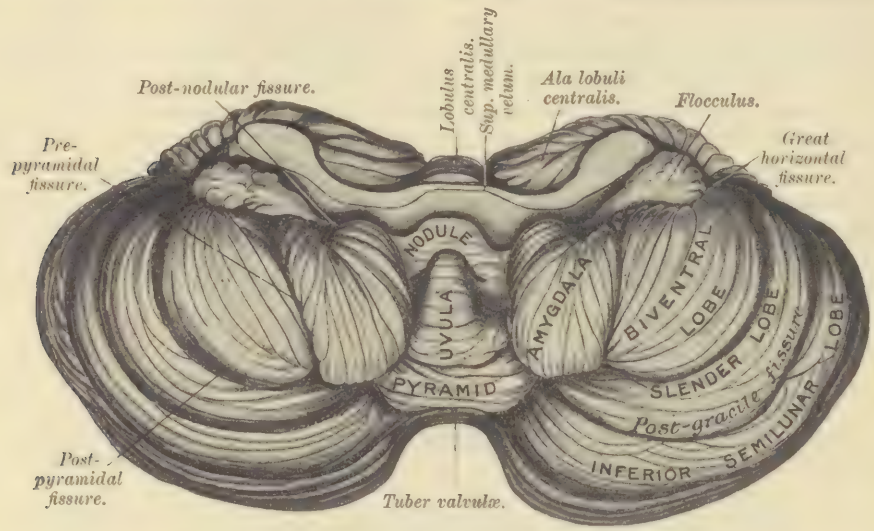

Fig. 596.—Under surface of the cerebellum. (Schäfer.)

is bounded below by the **great horizontal fissure.** It is named the **posterior superior lobe** (*lobulus semilunaris superior*), and occupies the posterior third of the upper surface of the hemisphere, forming its rounded postero-lateral border.

The Under Surface of the Cerebellum (*facies cerebelli inferior*) (Figs. 596 and 597). —The under surface of the cerebellum presents in the middle line the **inferior vermis**

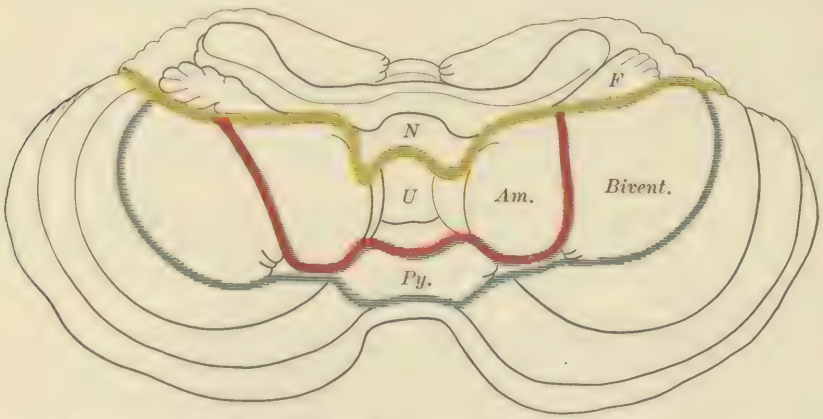

Fig. 597.—Diagram showing fissures on under surface of the cerebellum. *F.* Flocculus. *N.* Nodule. *U.* Uvula. *Py.* Pyramid. *Am.* Amygdala. *Bivent.* Biventral lobe.

or **inferior vermiform process** (*vermis inferior cerebelli*), buried in the vallecula, and separated from the hemispheres by lateral grooves. Here, as on the upper surface, there are deep fissures, dividing it into separate segments or lobes, but the arrangement is more complicated, and the relation of the segments of the worm to those of the hemisphere is less clearly marked. The fissures are three

in number, but are not so regularly disposed as those on the upper surface (Fig. 597). They are named, from their relation to the pyramid and nodule, two of the lobes on the under surface of the worm: (1) **post-nodular,** (2) **pre-pyramidal,** and (3) **post-pyramidal fissures.** The part of the worm in front of the post-nodular fissure is termed the **nodule** (*nodulus vermis*), and the lobule in the hemisphere corresponding with this is the **flocculus.** The next lobe is situated between the post-nodular and pre-pyramidal fissures. In the vermiform process it is known as the **uvula,** and its lateral expansion in the hemisphere is named the **amygdala** or **tonsil.** The lobule of the worm between the pre- and post-pyramidal fissures is the **pyramid,** and its corresponding part in the hemisphere is the **biventral** or **digastric lobe.** Finally, behind the post-pyramidal fissure in the worm is a small lobe, the **tuber valvulae** or **tuber posticum**; this, in the hemispheres, expands into a large lobe, which occupies at least two-thirds of the inferior surface of the cerebellum, and is subdivided into two by a secondary fissure, named the **post-gracile fissure.** The anterior of the two subdivisions is named the **slender lobe**; and the posterior, the **inferior semilunar** or **posterior inferior lobe.** These fissures and lobes are here arranged, from before backward, in a schematic form:

Worm.	*Hemisphere.*
Nodule.	Flocculus.
Post-nodular Fissure.	
Uvula.	Amygdala.
Pre-pyramidal Fissure.	
Pyramid.	Biventral lobe.
Post-pyramidal Fissure.	
Tuber valvulae	Slender lobe. *Post-gracile Fissure.* Inferior semilunar lobe.

The Fissures of the Under Surfaces of the Cerebellum.—The chief fissures of the under surface, as stated above, are three in number, and are not so regularly disposed as on the upper surface.

(1) The **Post-nodular Fissure** in the worm courses transversely across it, separating the nodule in front from the uvula behind. When it reaches the hemispheres it passes in front of the amygdala, and then crosses between the flocculus in front and the biventral lobe behind, and joins the anterior end of the great horizontal fissure.

(2) The **Pre-pyramidal Fissure** crosses the worm between the uvula in front and the pyramid behind, then curves laterally behind the amygdala, and passes forward along the outer border of this lobe, between it and the biventral lobe, to join the post-nodular sulcus.

(3) The **Post-pyramidal Fissure** passes across the worm behind the pyramid and in front of the tuber valvulae, and in the hemispheres courses behind the amygdala and biventral lobes, and then along the outer border of the biventral lobe to the post-nodular sulcus. It cuts off at least two-thirds of the inferior surface of the hemisphere. From it a secondary sulcus springs, and, coursing forward and outward, divides this surface into two parts and falls into the great horizontal fissure. This sulcus is termed the **post-gracile fissure.**

The Lobes of the Inferior Surface of the Cerebellum.—The **Nodule** (*nodulus vermis*) is a distinct prominence, forming the anterior extremity of the inferior worm. It projects into the roof of the fourth ventricle, and can only be distinctly seen after the cerebellum has been separated from the medulla and pons. On each side of

the nodule is a thin layer of white substance, named the **inferior medullary velum**. It is semilunar in form, its convex border being continuous with the middle peduncle of the cerebellum; it extends on either side as far as the flocculus, which it connects with the nodule.

The **flocculus** (*flocculi secondarii*) is a prominent, irregular lobule, situated just in front of the biventral lobe, between it and the middle peduncle of the cerebellum. It takes origin from a fold of gray matter in the inferior medullary velum, which is anterior to the tonsil. This fold is called the **peduncle of the flocculus** (*pedunculus flocculi*). Externally the gray fold enlarges and the enlargement is the flocculus. It is subdivided into a few small laminae.

The **Uvula** (*uvula vermis*) occupies a considerable portion of the inferior worm; it is separated on either side from the amygdala by a deep groove, the **sulcus valleculae**, at the bottom of which it is connected to the amygdala by a commissure of gray matter, indented on its surface, and called the **furrowed band**. The uvula is marked on its surface by three or four transverse fissures.

The **Tonsil** or **Amygdala** (*tonsilla cerebelli*) is a rounded mass in the lateral hemisphere. There are two tonsils, one in each lateral hemisphere. Each lies in a deep fossa between the uvula and the biventral lobe; this fossa is known by the name of the **bird's nest** (*nidus avis*).

The **Pyramid Lobe** (*pyramis vermis*) is a conical projection, forming the largest prominence of the lower worm. It is separated from the hemispheres by the sulcus valleculae, across which it is connected to the biventral lobe by an indistinct band of gray matter, analogous to the furrowed band already described.

The **Biventral Lobe** or **Digastric Lobule** (*lobulus biventer*) is triangular in shape, with the apex pointing inward and backward to become joined by the connecting band to the pyramid. The external border is separated from the slender lobe by the post-pyramidal fissure. The base is directed forward, and is on a line with the anterior border of the amygdala, and is separated from the flocculus by the post-nodular fissure.

The **Tuber Valvulae** or **Tuber Posticum** (*tuber vermis*) is the posterior division of the inferior worm. It is of small size, and laterally spreads out into the large posterior inferior lobes of the hemispheres. These lobes, which, as stated above, comprise at least two-thirds of the inferior surface of the hemisphere, are divided into two by the *post-gracile fissure*. The anterior lobe is named the **slender lobe**, and the posterior, the **inferior semilunar lobe** (*lobulus semilunaris inferior*). Both these lobes show a tendency to subdivision into two; that of the slender lobe is well marked, and its subdivisions are sometimes described as distinct lobes and named the **anterior** and **posterior slender lobes**, the fissure between them being termed the **intra-gracile fissure**.

The Internal Structure of the Cerebellum.—The cerebellum consists of **white** and **gray matter.**

The White Matter.—If a sagittal section (Fig. 598) is made through either hemisphere of the cerebellum, the interior will be found to consist of a central stem of white matter, the **medullary body** (*corpus medullare*), which contains in its interior a gray mass, the **corpus dentatum** (*nucleus dentatus*). It is a fold of gray matter thrown into corrugations and surrounding a centre of white matter. From the surface of this central stem a series of plates of medullary matter are detached, which, covered with gray matter, form the laminae. In consequence of the main branches from the central stem dividing and subdividing, the section presents a characteristic appearance, which is named the **arbor vitae cerebelli**. If a vertical section is made in the median plane of the cerebellum it will be found that the central stem divides into two main branches, which, from their direction, may be named respectively the **vertical** and the **horizontal branch**. The **vertical branch** passes upward to the culmen, where it subdivides freely, some of its ramifi-

cations passing forward and upward to the central lobe. The **horizontal branch** passes backward to the folium cacuminis, considerably diminished in size in consequence of having given off large secondary branches: one, from its upper surface, ascends to the clivus; the others descend, and enter the lobes in the inferior vermiform process, the tuber valvulae, the pyramid, the uvula, and the nodule. In the interior of the worm is white matter called the **corpus trapezoides**. It is not necessary to describe in detail the various divisions of the white matter, as they correspond to the lobes on the surface.

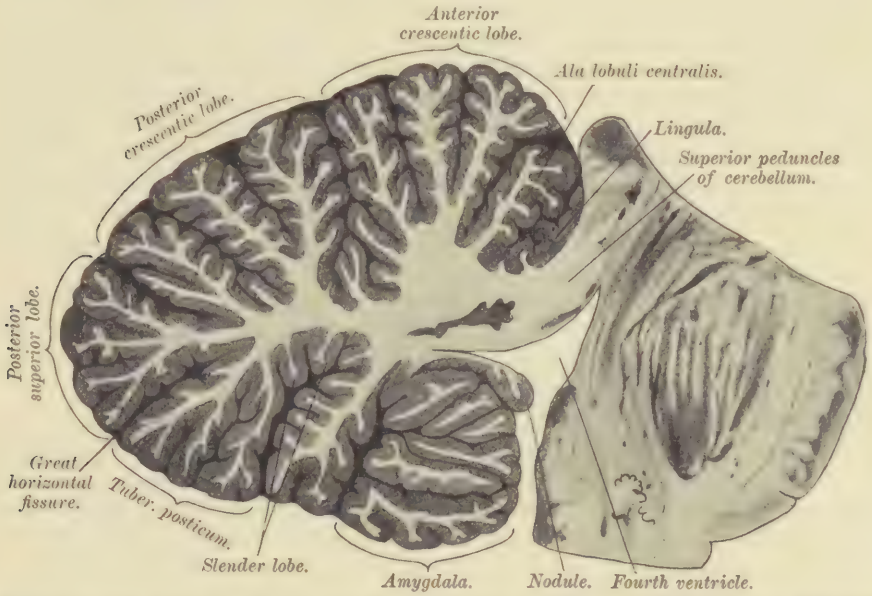

FIG. 598.—Sagittal section of the cerebellum, near the point of junction of the worm with the hemisphere. (Schäfer.)

The white matter of the cerebellum includes three systems of fibres: (1) **projection** or **peduncular fibres**, which are directly continuous with those of the peduncles of the cerebellum; (2) the **fibres proper** (*fibrae propriae*) of the cerebellum itself.

Projection or Peduncular Fibres.—The medullary body, as it emerges from the anterior cerebellar notch, is composed of projection fibres. These fibres are continuous with the branches of the medullary body and constitute the **arbor vitae**. The medullary body divides into a **superior lamina** and an **inferior lamina**, and it also forms a portion of the fourth ventricle. The inferior lamina is the inferior medullary velum, and its fibres reach the nodule and each flocculus. The superior lamina forms the superior medullary velum and the cerebellar peduncles.

The Peduncles of the Cerebellum (Figs. 599 and 600).—From the anterior part of each hemisphere arise three large processes or peduncles—**superior, middle**, and **inferior peduncles**—by which the cerebellum is connected with the rest of the encephalon.

The **Superior Cerebellar Peduncles** or **Crura ad Cerebrum** (*brachia conjunctiva cerebelli*) form the upper lateral boundaries of the floor of the fourth ventricle. As they extend forward and upward they converge on the dorsal aspect of the ventricle, and thus assist in roofing it in. They may be traced as far as the corpora quadrigemina, under which they pass. They enter the upper and mesial part of

the medullary substance of the hemispheres, beneath the ala lobuli centralis and the fraenulum, and pass to a great extent into the interior of the corpus dentatum, though some of their fibres wind around it and reach the gray cortical matter, especially of the inferior surface.

There are both afferent and efferent fibres in the superior peduncle, and the fibres are in two bundles (Fig. 600). The fibres to the cerebrum are axones of cells, most of which are situated in the corpus dentatum, but some of the fibres to the cerebrum come from the Purkinje cells of the cerebellar cortex, and probably also a few come from the smaller nuclei in the central white substance. The majority of the fibres decussate below the corpora quadrigemina, and pass to the opposite red nucleus of the tegmentum, from which a relay is prolonged through the optic thalamus to the cerebral cortex. The fibres of the second group take origin in the opposite red nucleus and end in the corpus dentatum (Santee).

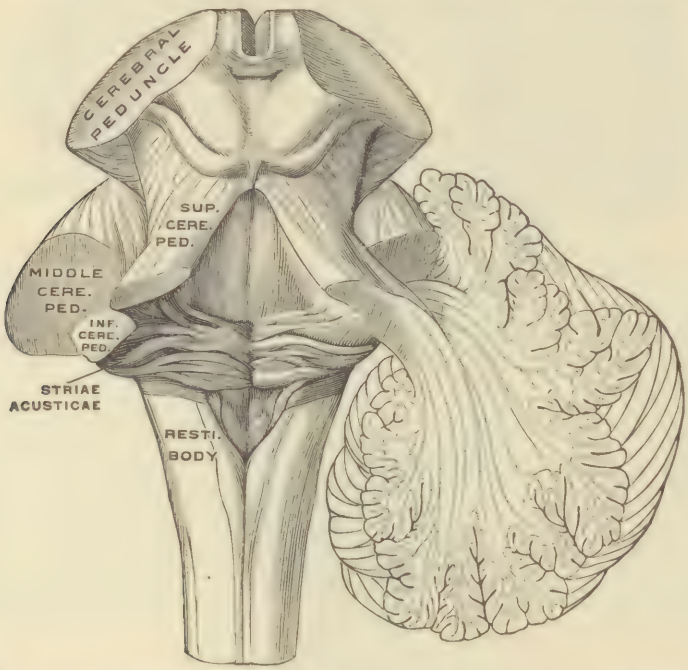

FIG. 599.—The peduncles of the cerebellum. On the left the three peduncles have been cut at their entrance into the cerebellum; on the right side they are shown penetrating the cerebellar hemisphere. (Poirier and Charpy.)

THE VALVE OF VIEUSSENS OR SUPERIOR MEDULLARY VELUM (*velum medullare anterius*) (Figs. 574, 584, 604, and 606).—Stretched across from one superior cerebellar peduncle to the other is a thin, transparent lamina of white matter, the **valve of Vieussens**; on to the dorsal surface of its lower half the folia of the lingula are prolonged. It helps to form with the superior peduncles the roof of the upper part of the fourth ventricle, and is continuous with the central white stem of the cerebellum. It is narrow above, where it passes beneath the corpora quadrigemina, and broader below, at its connection with the white substance of the superior worm of the cerebellum. A slightly elevated ridge descends upon the upper part of the valve from between the lower corpora quadrigemina, and on either side of this may be seen the fourth nerve. The majority of the fibres of the superior medullary velum are chiefly longitudinal fibres, passing between the cerebrum and the worm of the cerebellum. What is known as the antero-lateral ascending cerebellar tract of Gowers is said by Hoche to pass to the worm by way of

the superior velum. The velum also contains some commissural fibres and decussating fibres of the roots of the fourth nerves.

The **Middle Peduncles** or **Crura ad Posterior** (*brachia pontis*) are the largest of the three pairs. They consist of a mass of curved fibres, which, as already described, pass to the pons and fovea, comprises most of the transverse fibres of the pons. These tracts are both afferent and efferent, and the middle peduncle emerges from the cerebellum at the anterior notch, between the margins of the great horizontal fissure. The fibres of the middle peduncle (Fig. 600) rise from

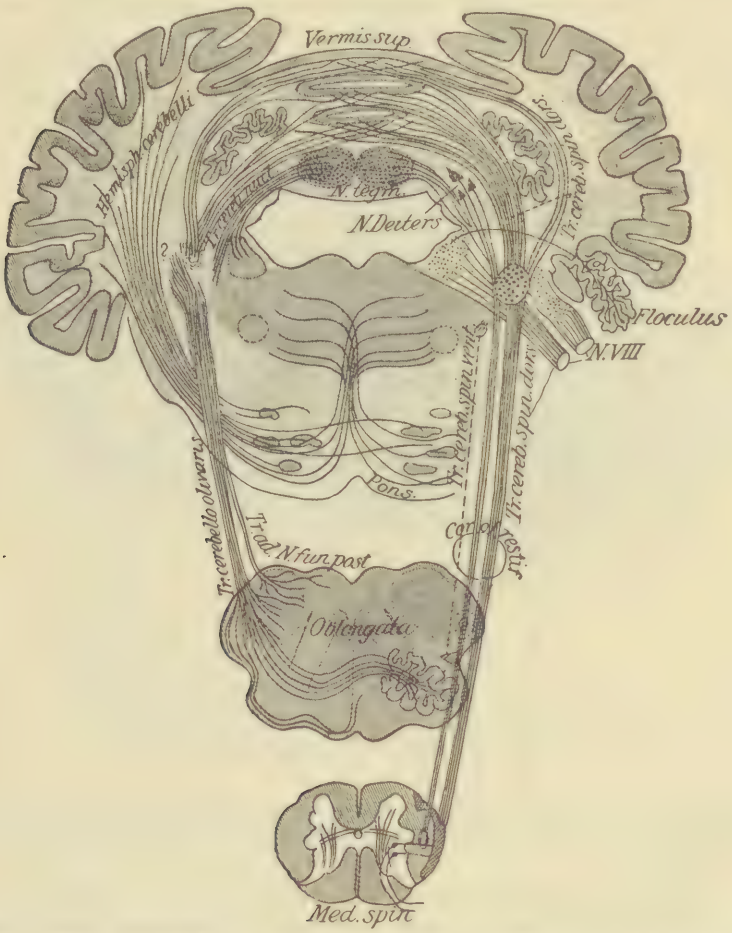

FIG. 600.—Diagram showing the origin and course of the fibres of the peduncles of the cerebellum. (Edinger.)

all portions of the cortex of the cerebellum. In the peduncle the fibres effect a crossing, so that fibres from the anterior part of the hemisphere pass to the posterior part of the pons, and fibres from the posterior portion of the hemisphere pass to the anterior portion of the pons. The fibres approach the median line and terminate on both sides of the raphé in the nuclei pontis and the nuclei of the formatio reticularis (Cajal). The balance of the fibres are "axones of cell-bodies, situated mainly in the opposite nucleus pontis."[1] These fibres "form a segment in the indirect motor paths contained above the pons, in the medial

[1] Anatomy of the Brain and Spinal Cord. By Harris E. Santee.

and lateral fifths, and the intermediate bundle of the crusta. Collaterals from both groups of fibres ascend and descend in the pons. They run upward with both crustae, but chiefly with the opposite one; and they accompany the fillet and posterior longitudinal bundle of the same side to the nuclei of the third, fourth, and sixth cranial nerves."[1]

The **Inferior Peduncles** or **Crura ad Medullam** (*corpora restiformia*) connect the cerebellum with the medulla oblongata. The fibres (Fig. 600) are both afferent and efferent and begin in the gray cortex of the upper surface of the cerebellar hemispheres and the worm. They descend in a direction downward and inward, from part of the lateral walls of the fourth ventricle, reach the medulla, and become the **restiform bodies**, which will be subsequently described (p. 941). The following are the chief sets of fibres in the inferior peduncles: 1. The **direct cerebellar tract**, which takes origin in Clarke's column of the spinal cord and terminates in the superior worm of the cerebellum. 2. The **external arciform fibres**, which rise in the gracile and cuneate nuclei of the medulla and terminate in the vermis superior. The posterior or uncrossed fibres terminate on the same side, the anterior or crossed fibres on the opposite side. 3. The **acustico-cerebellar tract.** These fibres originate from the nucleus of the auditory nerve in the floor of the fourth ventricle, and terminate in the opposite nucleus fastigii and nucleus globosus of the cerebellum. 4. Fibres which pass between the **lateral nucleus of the medulla oblongata** and the corresponding side of the cerebellar cortex. 5. The

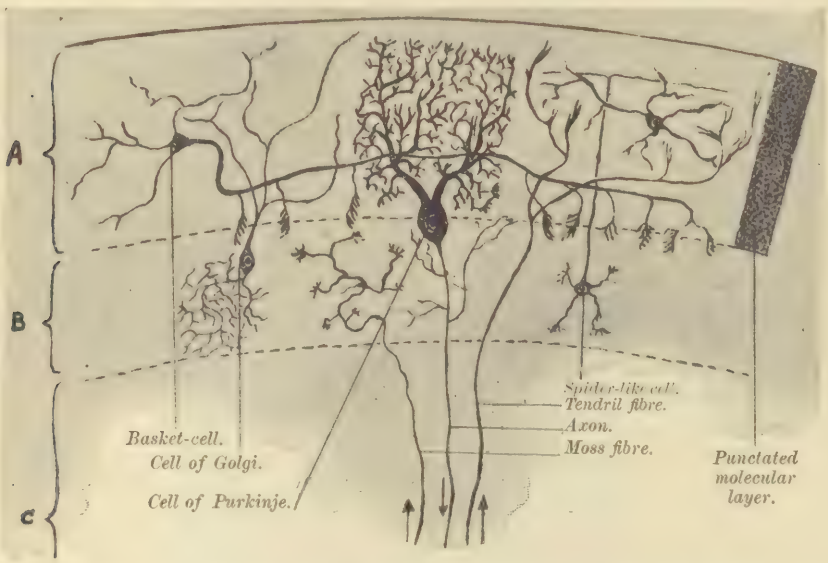

FIG. 601.—Diagrammatic representation of the cells of the cerebellum. *A*. Molecular layer. *B*. Nuclear layer. *C*. White matter. (Modified from Foster's Physiology.)

descending cerebellar tract, which originates in the cerebellar cortex and which passes down by way of the restiform body of the medulla and the antero-lateral column of the spinal cord and reaches the anterior gray horn of the cord. 6. The **internal arciform fibres,** which pass between the cerebellar cortex and the opposite olivary body of the medulla (the **cerebello-olivary tract**). Santee emphasizes the fact that most of the fibres which emerge from the cerebellum in the middle and inferior peduncles are "axones of Purkinje's cells; they connect the cerebellum with the motor nuclei of cranial and spinal nerves."[2]

[1] Anatomy of the Brain and Spinal Cord. By Harris E. Santee. [2] Ibid.

The Fibres Proper of the Cerebellum.—The **fibrae propriae** of the cerebellum are of two kinds: (1) **commissural fibres,** which cross the middle line to connect the opposite halves of the cerebellum, some at the anterior part and others at the posterior part of the vermiform process; (2) **association fibres,** which are antero-posterior fibres connecting adjacent laminae with each other.

The Gray Matter of the Cerebellum.—The gray matter of the cerebellum is found in two situations: (1) on the surface, forming the cortex; (2) as independent masses in the interior.

1. The **Cortex of the Cerebellum** (*substantia corticalis*) presents a characteristic foliated appearance, due to the series of laminae which are given off from the central white matter; these in their turn give off secondary laminae, which are covered with gray matter. This arrangement gives to the cut surface of the organ a foliated appearance (Fig. 598). Externally, the cortex is covered by pia matter; internally, is the medullary centre, consisting mainly of nerve-fibres.

Microscopic Appearance of the Cortex (Figs. 601 and 602).—The cortex presents a remarkable structure, consisting of two distinct layers—viz., an **external** or **superficial molecular layer,** and an **internal, deep, nuclear, rust-colored,** or **granular layer.** Between the two layers is an incomplete stratum of the characteristic cells of the cerebellum, the **corpuscles of Purkinje.**

The *external, superficial gray* or *molecular layer* (Figs. 601 and 602) consists of fibres and cells. The nerve-fibres are delicate fibrillae, and are derived from the following sources: (*a*) the dendrites and axone collaterals of Purkinje's cells; (*b*) fibres from cells in the granular layer; (*c*) fibres from the central white substance of the cerebellum; (*d*) fibres derived from cells in the molecular layer itself. In addition to these are other fibres, which have a vertical direction. These are the processes of large glia-cells, situated in the granular layer. They pass outward to the periphery of the gray matter, where they expand into little conical enlargements, which form a sort of limiting membrane beneath the pia mater, analogous to the membrana limitans interna in the retina, formed by the fibres of Müller.

The *cells* of the molecular layer are small, and are arranged in two strata, an outer and an inner. They all possess branching axis-cylinder processes; those of the inner layer run for some distance horizontally, *i. e.*, parallel with the surface of the folia, giving off at intervals collaterals, which pass in a vertical direction toward the cell-bodies of Purkinje's corpuscles, around which they become enlarged and ramify like a basket. Hence these cells of the inner portion of the external layer are named **basket-cells** (Fig. 601).

The *cells* or *corpuscles of Purkinje* (Fig. 602) are flask-shaped cells, situated at the junction of the molecular and granular layers, their bases resting against the latter. From the bottom of each flask one axis-cylinder process arises; this passes through the granular layer, and, becoming medullated, is continued as a nerve-fibre in the medullary substance beneath. This axone gives off fine collaterals as it passes through the granular layer, some of which run back into the molecular layer. From the neck of the flask numerous dendrites are given off, which branch in an antler-like manner in the molecular layer and terminate in free extremities.

The *internal, rust-colored, nuclear* or *granular layer* (Figs. 601 and 602) is characterized by containing numerous small nerve-cells or granules of a reddish-brown color, together with many nerve-fibrils. Most of the cells are nearly spherical and provided with short dendrites, which spread out in a spider-like manner in the granular layer. Their axones pass outward into the molecular layer, and, bifurcating at right angles, run horizontally for some distance. In the outer part of the granular layer are also to be observed some larger cells, of the type termed **Golgi cells** (Fig. 601). Their axones undergo frequent division as soon as they leave the nerve-cells, and pass into the granular layer, while their dendrites ramify chiefly in the molecular layer.

Finally, in the gray matter of the cerebellar cortex fibres are to be seen which come from the white centre and penetrate the cortex. The cell origin of these fibres is unknown, though it is believed that it is probably in the gray matter of the spinal cord. Some of these fibres end in the granular layer, by dividing into numerous branches, on which are to be seen peculiar moss-like appendages; hence they have been termed by Ramón y Cajal the **moss fibres** (Fig. 601); they form an arborescence around the cells of the granular layer. Other fibres derived from the medullary centre can be traced into the molecular layer, where their branches cling around the dendrites of Purkinje's cells, and hence they have been named the **clinging** or **tendril fibres** (Fig. 601).

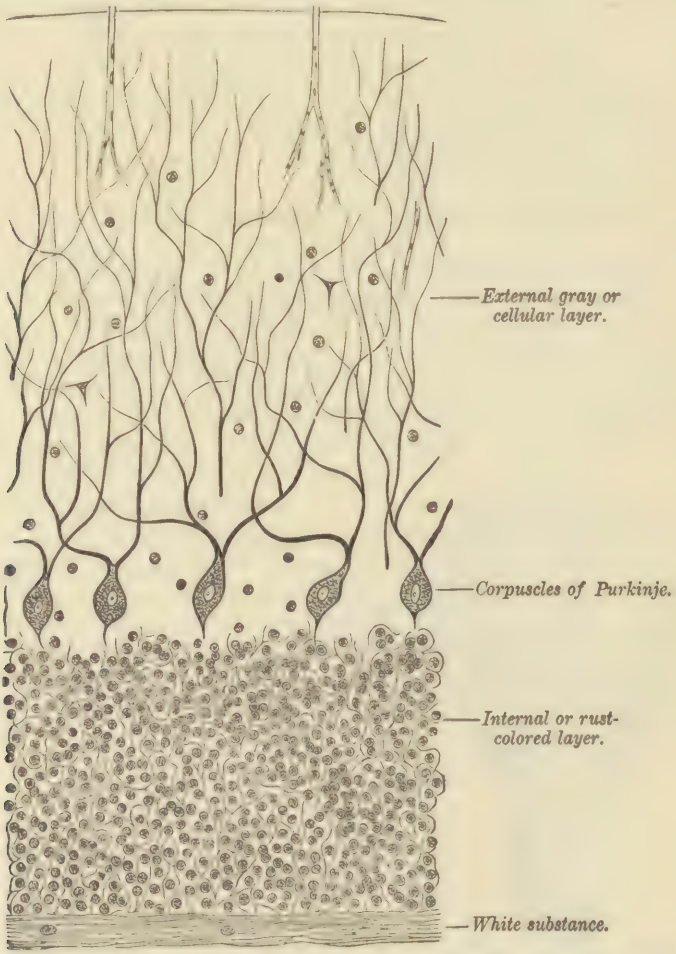

FIG. 602.—Vertical section through the gray matter of the human cerebellum. Magnified about 100 diameters. (Klein and Noble Smith.)

2. The **Independent Centres of Gray Matter in the Cerebellum** are four in number on each side: one is of large size, and is known as the **corpus dentatum**; the other three, much smaller, are situated near the middle of the cerebellum, and are known as the **nucleus emboliformis, nucleus globosus,** and **nucleus fastigii.**

The **corpus dentatum** or **ganglion of the cerebellum** (*nucleus dentatus*) is a gray nucleus situated a little to the inner side of the centre of the stem of the white matter of the hemisphere. It consists of an irregularly folded lamina of a grayish-yellow color, containing white fibres, and presenting on its antero-internal aspect an opening, the **hilum** (*hilus nuclei dentati*), from which most of the fibres of the

superior cerebellar peduncle emerge. The **nucleus emboliformis** is a mass of gray matter placed immediately to the inner side of the corpus dentatum, and partly covering its hilum. The **nucleus globosus** is an elongated mass of gray matter, directed antero-posteriorly, and placed to the inner side of the preceding. The **nucleus fastigii** is somewhat larger than the other two, and is situated close to the middle line at the anterior end of the superior vermiform process, and immediately over the roof of the fourth ventricle, from which it is separated by a thin layer of white matter. It is known as the **roof nucleus of Stilling.**

Weight of the Cerebellum.—Its average weight in the male is about 5 oz., 4 drs. It attains its maximum weight between the twenty-fifth and fortieth years, its increase in weight after the fourteenth year being relatively greater in the female than in the male. The proportion between the cerebellum and cerebrum is, in the male, as 1 to $8\frac{1}{5}$, and in the female as 1 to 8. In the infant the cerebellum is proportionately much smaller than in the adult, the relation between it and the cerebrum being, according to Chaussier, between 1 to 13, and 1 to 26; by Cruveilhier, the proportion was found to be 1 to 20.

V. The Medulla Oblongata (Myelencephalon) (Figs. 557, 594, 603, 604).

The medulla oblongata, known also as the **spinal bulb,** is the lowest division of the encephalon, and is continuous with the spinal cord. It is, in fact, the intracranial portion of the spinal cord. It is developed from the fifth cerebral vesicle, the cavity of which forms the lower half of the fourth ventricle. It extends from the lower margin of the pons Varolii to a plane passing transversely just below the decussation of the pyramids, at which level the spinal cord commences. This plane corresponds to the lower margin of the foramen magnum. The upper limit of the medulla is marked off from the pons Varolii on its ventral aspect by the abrupt lower margin of the latter.

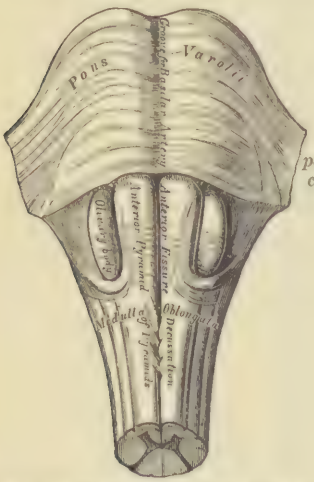

FIG. 603.—Medulla oblongata and pons Varolii. Anterior surface.

The medulla oblongata is directed from above obliquely downward and backward; its ventral surface rests on the basilar groove of the occipital bone, while its dorsal surface is received into the fossa between the hemispheres of the cerebellum, and forms the lower part of the floor of the fourth ventricle. It is pyramidal in shape, its broad extremity directed upward, its lower end being narrow at its point of connection with the cord. It measures an inch in length, three-quarters of an inch in breadth at its widest part, and half an inch in thickness. Its surface is marked, in the median line, in front and behind, by an **anterior** and a **posterior median fissure** (*fissura mediana anterior* and *fissura mediana posterior*), which are continuous with similar fissures on the anterior and posterior surfaces of the cord, but neither one of them extends the entire length of the bulb. The anterior fissure contains a fold of pia mater, and terminates just below the pons in a *cul-de-sac*, the **foramen caecum of Vicq d'Azyr.** It is interrupted at its lower part by some bundles of fibres, which cross obliquely from one side to the other, forming the **decussation of the pyramids** (*decussatio pyramidum*) (Figs. 594 and 605). The posterior fissure is a deep but narrow fissure, continued upward to about the middle of the medulla. As it ascends its depth diminishes, and about the middle of the posterior surface of the medulla the central canal of the cord

opens, and the lips of the shallow posterior fissure diverge and bound the triangular opening, which is the lower portion of the floor of the fourth ventricle (Figs. 604 and 606). As the lower half of the medulla contains the central canal of the cord, it is called the **closed portion**; the upper half of the medulla is above the opening of the central canal and is called the **open portion.**

These two fissures divide the medulla into two symmetrical halves, each half presenting elongated eminences, which are continuous with the columns of the cord. By taking the lines along which some of the cranial nerves emerge from the medulla as landmarks, the surface of this portion of the nervous system may be divided into three columns, in the same way as the spinal cord is divided into three columns by the lines corresponding to the points of exit of the anterior and posterior roots of the spinal nerves. The **hypoglossal nerve-roots** arise from a furrow on the antero-lateral surface of the medulla, which is known as the **antero-lateral furrow**, or the **ventro-lateral groove** (*sulcus lateralis anterior*). There is no furrow on the cord corresponding with this medullary furrow. The roots of the **glossopharyngeal** and **pneumogastric nerves** and the **accessory root of the spinal accessory nerve** lie in a furrow upon the postero-lateral surface of the medulla. This furrow is called the **postero-lateral furrow** or **dorso-lateral groove** (*sulcus lateralis posterior*). This groove is the continuation of the postero-lateral fissure of the cord. It is not straight, but turns forward as it ascends. At the termination of this groove anteriorly the **seventh** and **eighth cranial nerves emerge.** At the lower portion of the medulla the groove ceases for a short distance as the direct cerebellar tract passes from the lateral to the posterior surface of the bulb. The *anterior column* comprises that portion which is situated between the anterior median fissure and the antero-lateral furrow; this column is called the **anterior pyramid** or simply the **pyramid** (Fig. 603). The *lateral column* comprises that portion which is situated between the antero-lateral and the postero-lateral furrows. In the lower part of the medulla this column is single, and is called the **lateral tract**; but in the upper part an oval-shaped body comes forward between it and the pyramid, and pushes aside the lateral tract. This is called the **olivary body** (Fig. 603) The *posterior column* (Fig. 604) comprises that portion which is situated between the postero-lateral furrow and the posterior median fissure. It is marked by slight furrows dividing it into smaller columns, and these in the lower part of the medulla are named, from without inward, the **fasciculus of Rolando**, the **fasciculus cuneatus** and the **fasciculus gracilis**; in the upper part of the medulla, the fasciculus of Rolando and the fasciculus cuneatus appear to become fused together and seem to form the single body, called the **restiform body** (Fig. 604). As a matter of fact the restiform body is not so formed (p. 941).

The Pyramid (*pyramis medullae oblongatae*) (Figs. 594 and 603).—The pyramid is a pyramidal bundle of white matter. A pyramid is placed one on either side of the anterior median fissure, and separated from the olivary body by a slight depression, from which the roots of the hypoglossal nerve emerge (antero-lateral furrow). At the lower border of the pons these bodies are somewhat constricted and are here crossed by a band of arched fibres, the **ponticulus of Arnold**; below this they become enlarged, and then taper as they descend to their lower extremity. The fibres of which compose these pyramids may be arranged in two bundles: an *outer*, continuous below with the **direct** or **uncrossed pyramidal tract** of the anterior column of the same side of the spinal cord, and an *inner*, continuous with the **crossed pyramidal tract** of the lateral column of the opposite side of the cord (Fig. 605). As will be subsequently mentioned, the direct pyramidal tract in the cord lies next to the anterior median fissure, but as the crossed pyramidal tract of the cord ascends to the medulla it decussates with its fellow of the opposite side across the anterior median fissure, and so displaces laterally the direct pyramidal tract, and ascends,

after decussation, through the medulla to its inner or mesial side. This decussation is usually spoken of as the **decussation of the pyramids** (Figs. 594 and 605), but it must be borne in mind that it is only a portion of the fibres of the pyramid (90 per cent. of them) which decussate; namely, those derived from the crossed pyramidal tract of the cord; the outermost fibres, derived from the anterior column of the cord, do not decussate. Each pyramid enters the substance of the pons in one bundle, and may be traced through it, after breaking up into several smaller fasciculi, into the corresponding crus cerebri.

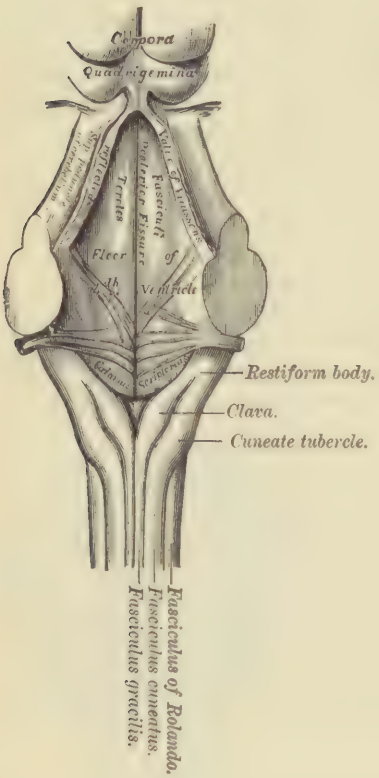

FIG. 604.—Posterior surface of the medulla oblongata.

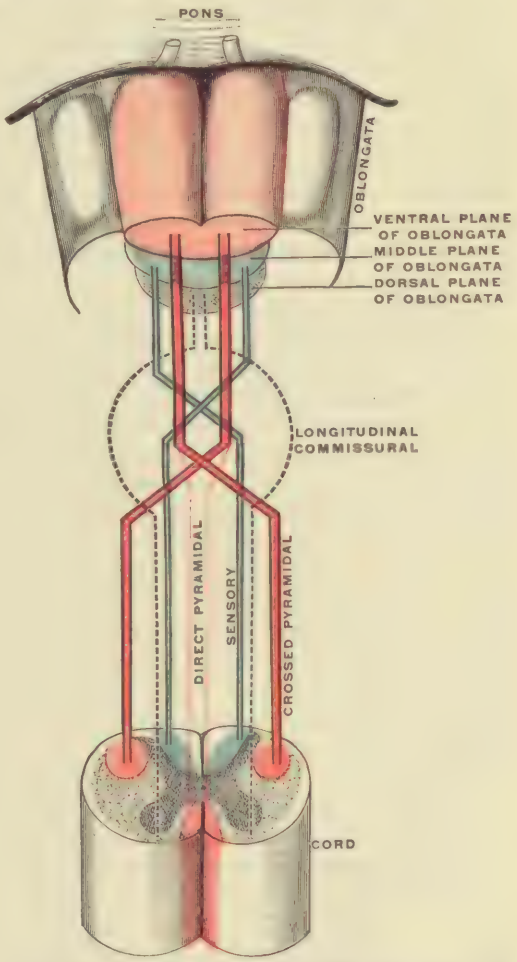

FIG. 605.—Diagram to show the crossing of the pyramids (red) and of the lemniscus (blue). (Testut.)

The Lateral Column or Lateral Area.—The lateral column or area is between the antero-lateral and postero-lateral furrows. In the lower part of the medulla it is of the same width as the lateral column of the cord, and appears on the surface to be a direct continuation of it. As a matter of fact it is only a part of the lateral column of the spinal cord which is continued upward into this column; for the crossed pyramidal tract passes into the pyramid of the opposite side, and the direct cerebellar tract of the lateral column of the cord passes into the restiform body. The rest of the lateral column of the cord, that is to say, the **antero-lateral ground bundle** (*fasciculus proprius anterolateralis*) and the **antero-lateral cerebellar tract** (*fasciculus anterolateralis superficialis*), can be traced

upward into this area. In the upper part of the medulla, the lateral tract, on account of the interpolation of the olivary body, becomes almost concealed by this body.

The Olive, Olivary Body or Olivary Eminence (*oliva*) (Figs. 586, 589, and 603).—The olivary body or eminence is a prominent oval mass, bulging from the upper part of the lateral column of the medulla. It is situated on the outer side of the pyramid, from which it is separated by the slight groove, along which the fibres of the hypoglossal nerve emerge. It is separated externally from the restiform body by a longitudinal, narrow band of fibres, prolonged upward from the lateral tract, and by the groove, from which the glosso-pharyngeal, pneumogastric, and spinal accessory nerves arise. It is equal in breadth to the pyramid; it is broader above than below, and is about half an inch in length, being separated above from the pons Varolii by a slight depression, in which a band of arched fibres is sometimes to be seen. Numerous white fibres, **superficial or external arciform** or **arcuate fibres** (Fig. 607), are seen winding across the lower half of the pyramid and the olivary body to enter the restiform body. The olivary body is formed by the olivary nucleus of the medulla (Fig. 607), a lamina of gray matter, the surface of which is covered by a very thin layer of white matter.

The Funiculus or Fasciculus of Rolando (*fasciculus lateralis*) (Fig. 604).—The fasciculus of Rolando is a longitudinal prominence on the outer side of the lateral tract. It begins at the lower end of the medulla by a tapering extremity, and has, apparently, no corresponding column in the cord. It gradually enlarges as it ascends, and forms, at a level with the lower border of the olivary body, a considerable prominence, known as the **tubercle of Rolando** (*tuberculum Rolandi*) (Fig. 607). This is caused by the substantia gelatinosa of Rolando of the cord gradually finding its way to the surface, so as to form a prominence there. About half an inch below the pons the fasciculus of Rolando appears to blend with the fasciculus cuneatus. In front, it is separated from the lateral tract by a distinct groove, the continuation upward of the postero-lateral groove of the cord; behind, the separation from the fasciculus cuneatus is much less distinct.

The **Wedge-shaped** or **Cuneate Funiculus** or the **Fasciculus Cuneatus** (Fig. 604) is the direct continuation upward of the postero-lateral column (tract of Burdach) of the cord. It is situated between the fasciculus of Rolando and the fasciculus gracilis. It enlarges as it ascends, and forms, opposite the lower extremity of the fourth ventricle, a slight eminence or enlargement, the **cuneate tubercle** (*tuberculum cuneatum*) (Fig. 604), which is marked only in children. Above this point it disappears from the surface.

The **Slender Funiculus** or the **Fasciculus Gracilis** (Fig. 604) is the direct continuation upward of the postero-median column of the cord (tract of Goll). It is a narrow white band, placed parallel to and along the side of the posterior median fissure. It is separated from the fasciculus cuneatus by a slight groove, continuous with that on the surface of the cord, which marks off the postero-median column. At first the fasciculi of the two sides lie in close contact on either side of the posterior median fissure. Opposite the apex of the fourth ventricle each presents an enlargement, the **clava** (Fig. 604); they then diverge and form the lateral boundaries of the lower part of the fourth ventricle, and gradually tapering off become no longer traceable. The surface prominence of the fasciculus gracilis is formed by the gray nucleus beneath. This nucleus is known as the **nucleus fasciculi gracilis.**

The Restiform Body (*corpus restiforme*) (Fig. 604).—The upper part of the posterior area of the medulla is occupied by the restiform body. It appears, at first sight, as if this body were the direct continuation upward of the fasciculus cuneatus and the fasciculus of Rolando, and it was formerly

described as such. This, however, is not so, for the restiform body is largely formed by a set of fibres, the **superficial** or **external arciform** or **arcuate fibres** (Fig. 607), which issue from the anterior median fissure and will presently be described. They pass laterally over the pyramid and olive, and assist in forming the restiform body. There is also a narrow strand of fibres, derived from the lateral column of the cord, the **direct cerebellar tract** (*fasciculus cerebello-spinalis*), which joins the above-mentioned arcuate fibres. These two sets of fibres, reinforced by the **internal arcuate fibres** from the opposite side of the medulla, form the restiform body.

The restiform bodies are the largest prominences of the medulla, and are placed between the lateral tracts in front and the fasciculus cuneatus behind, from both of which they are separated by slight grooves. As they ascend they diverge from each other, assist in forming the lower part of the lateral boundaries of the fourth ventricle, and then enter the corresponding hemisphere of the cerebellum, forming its inferior peduncles.

The Posterior Surface of the Medulla Oblongata (*facies posterius*) (Fig. 604).—The posterior surface of the medulla oblongata forms part of the floor of the fourth ventricle (Fig. 606). This portion is of a triangular form, bounded on each side by the diverging fasciculi graciles and cuneati and restiform bodies. The divergence of these two fasciculi and of the restiform bodies, together with the opening out of the posterior fissure and central canal of the spinal cord, displays in the floor of the ventricle the gray matter of the medulla, which is continuous below with the gray matter of the cord. In the middle line is seen a longitudinal furrow, which divides this part of the ventricle into right and left halves, and is continuous below with the central canal of the cord.

The Arciform or Arcuate Fibres (Fig. 607).—The arciform or arcuate fibres, which have been mentioned as forming part of the restiform body, are found in the upper half of the medulla, crossing its surface and also traversing its substance. They are divided for purposes of description into two sets—**external** and **internal.** The **external** or **superficial arciform** or **arcuate fibres** (*fibrae arcuatae externae*) have already been alluded to as crossing the pyramid and olivary body on each side. They emerge from the anterior median fissure, and if traced into it are found to enter the raphé and cross to the opposite side, after which their further course is a matter of some doubt. After emerging from the anterior median fissure they cross the pyramid and olivary body, often concealing from view the upper part of the cuneate and Rolandic fasciculi, and enter the restiform body. As they cross the olivary body they are reinforced by some of the internal arciform fibres, which come to the surface on the inner side of, or through, this structure. The **internal arciform** or **arcuate fibres** (*fibrae arcuatae internae*) are described with the microscopic anatomy of the medulla.

It is advisable, at this stage, to take up the consideration of the cavity of the fourth ventricle, an acquaintance with which will render the description of the internal structure of the medulla oblongata more intelligible.

The Fourth Ventricle (Ventriculus Quartus) (Fig. 606).

The fourth ventricle is the cavity common to the metencephalon, and the myelencephalon is in the pons and medulla oblongata and is anterior or ventral to the cerebellum. It is lozenge- or diamond-shaped; that is to say, it is composed of two triangles, with their bases in contact. The sides of the lower triangle are formed by the divergence of the fasciculi graciles, fasciculi cuneati, and restiform bodies of the medulla on either side. As these columns pass upward in the medulla they turn outward from the median line, and, diverging from each other, form the lateral boundaries of the lower half of the fourth ventricle. In like manner the

sides of the upper triangle are formed by the convergence of the superior peduncles of the cerebellum. These peduncles are separated below by a somewhat wide interval, but as they pass upward and forward toward the corpora quadrigemina they gradually converge and ultimately come into contact with each other. This cavity is therefore bounded laterally on each side by the superior peduncle of the cerebellum in its upper half, and by the fasciculus gracilis, the fasciculus cuneatus, and the restiform body in its lower half. It presents four angles. The upper angle reaches as high as the upper border of the pons, and corresponds with the lower opening of the **aqueduct of Sylvius**, by which this ventricle communicates with the third ventricle (Fig. 587). The lower angle is on a level with the lower border of the olivary body, and is continuous with the central canal of the spinal cord. From the resemblance that it bears to the point of a writing pen it has been named the **calamus scriptorius**. Its lateral angles extend for some distance between the medulla and the cerebellum, each forming a pointed lateral recess.

The Roof or Posterior Wall of the Fourth Ventricle.—The roof of the fourth ventricle is formed from above downward by the following structures: a part of the **superior peduncles of the cerebellum**, the **anterior** or **superior medullary velum**, the **posterior** or **inferior medullary velum**, the **tela chorioidea inferior**, the **obex**, and the **lingula**. The superior half of the roof meets the inferior half at an acute angle to form the **tent of the fourth ventricle** (*fastigium*).

The Superior Peduncles of the Cerebellum (*brachia conjunctiva cerebelli*) (Figs. 557, 598, 599, 604, and 606).—The superior peduncles of the cerebellum, when they emerge from the medullary substance of its hemispheres, pass upward and forward, forming the lateral boundaries of the upper half of the fourth ventricle, but, converging as they approach the corpora quadrigemina, the mesial portions of the peduncles form a part of the roof of the cavity, in consequence of the ventricle extending to a slight extent underneath the peduncles.

The Anterior or Superior Medullary Velum (**Valve of Vieussens**) (*velum medullare anterius*) (Figs. 584, 596, 605, and 606).—In the angular interval left between the two superior peduncles is a thin lamina of white matter, continuous with the white centre of the cerebellum, which bridges across from one peduncle to the other, and so completes the roof of the superior part of the ventricle. This is the **superior medullary velum** or **valve of Vieussens**. Its dorsal surface is covered by the folia of the lingula, already described (p. 928).

The Posterior or Inferior Medullary Velum (*velum medullare posterius*).—The posterior or inferior medullary velum is a thin layer of white substance, prolonged from the white centre of the medulla on either side of the nodule, which assists in forming a part of the roof of the fourth ventricle, stretching over it toward its lateral angles. It is continuous with the white substance of the cerebellum by its convex edge, while its thin concave margin is apparently free. In reality, however, it is continuous with the epithelium of the ventricle, which is prolonged downward from the velum to the edge of the lingula.

The Tela Chorioidea Inferior (*tela chorioidea ventriculi quarti*).—The tela chorioidea inferior is a layer of pia mater which covers in the lower part of the fourth ventricle below the inferior medullary velum. Superiorly it is reflected on to the under surface of the cerebellum, while inferiorly it is continued on to the restiform bodies and lower part of the medulla. This part of the roof of the ventricle contains no nervous matter, but consists merely of the ventricular epithelium covered by pia mater. The tela chorioidea inferior, like the velum interpositum or tela chorioidea superior (p. 855), really consists of two layers, which become more or less adherent, viz., that covering the under surface of the cerebellum and that covering the epithelium. It also possesses on each side a **choroid plexus** (*plexus chorioideus ventriculi quarti*), which projects into the ventricular cavity invaginating before it the epithelial lining. Each plexus consists of a *vertical portion* which extends forward, near the

middle line, from the foramen of Majendie, and of a *transverse part*, which passes outward into the lateral recess of the ventricle as far as the foramina of Key and Retzius. The two plexuses present the form of a T, the vertical limb of which is, however, double, || . The tela does not form a complete membrane, for in it there are three openings: one in the middle line at the inferior angle of the ventricle, just above the position of the opening of the central canal of the cord; this is the **foramen of Majendie** (*apertura medialis ventriculi quarti*); the other two are at the right and left extremities of the lateral recesses of the ventricle, and each is named the **foramen of Key and Retzius** (*apertura lateralis ventriculi quarti*) (see pp. 852 and 853). Through these foramina the ventricles of the brain communicate with the subarachnoid space.

The Obex.—The obex is a thin, triangular lamina of gray matter, continuous below with the anterior gray commissure of the cord, which fills in the angle between the two diverging fasciculi graciles for a short distance.

The Ligula.—The ligula (*taenia ventriculi quarti*) are narrow bands of white matter, which project from the internal border of the funiculi graciles. They at first run upward and forward, and then turn outward over the restiform bodies, as far as the lateral recesses of the ventricle. Their inner borders are continuous with the epithelial roof of the ventricle.

The Floor or Anterior Wall of the Fourth Ventricle (*fossa rhomboidea*) (Figs. 599, 604, and 606).—The floor of the fourth ventricle is rhomboidal in shape,

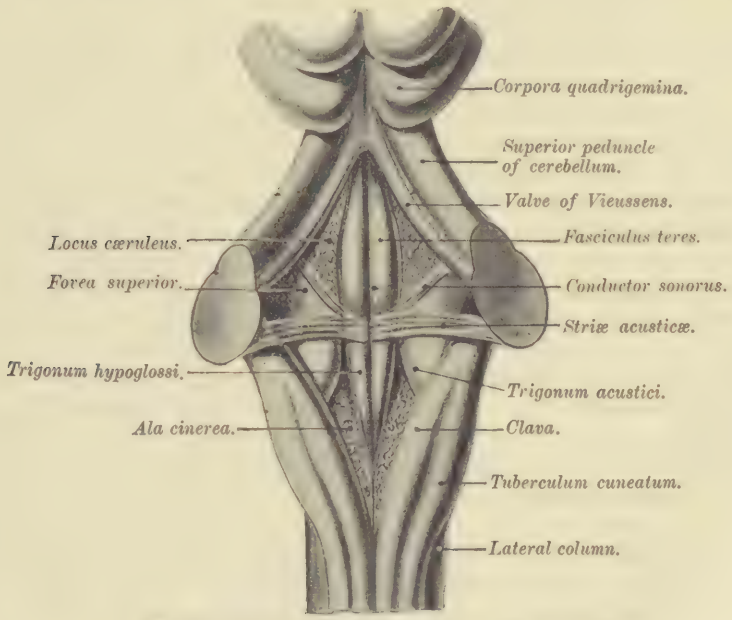

Fig. 606.—Floor of the fourth ventricle. Diagrammatic.

and is traversed by a **vertical median fissure** (*sulcus longitudinalis fossae rhomboideae*), which below is continuous with the central canal of the spinal cord. At the junction of the fourth ventricle with the central canal of the cord is a dilatation or ampulla called the **ventricle of Arantius**. At the widest part of the fourth ventricle, opposite the level of the lateral recesses, it is marked by some transverse white lines, the **striae medullares** or **striae acusticae**. These consist of white fibres, which emerge from the longitudinal sulcus, and pass outward across the floor of the ventricle. Most of the striae acusticae take origin from cochlear nucleus, but some arise from the cochlear root. Most of them pass to the trape-

zium and lateral fillet of the opposite side, but some become external arciform fibres (Koelliker). These striae divide the floor of the ventricle into two triangles, **inferior** and **superior.**

The Inferior Triangle (Fig. 606).—The inferior triangle, or lower or posterior half of the floor, presents above an angular groove, the **fovea inferior,** the apex of which is at the striae, while the two limbs diverge below, and form the sides of a triangular dark area, termed the **ala cinerea,** which becomes elevated into a prominence below (*eminentia cinerea*). This area corresponds with the nuclei of the vagus and glosso-pharyngeal nerves, and is therefore termed the **trigonum vagi.** A second triangular area lies between the inner limb of the fovea and the median sulcus; its base is directed upward, and limited by the striæ medullaris. It is termed the **trigonum n. hypoglossi,** because it corresponds in position to the tract of nerve-cells from which the hypoglossal nerve takes origin. A third triangular area to the outer side of the fovea inferior is named the **trigonum acustici** (*area acustica*). It lies between the groove forming the outer boundary of the fovea inferior and the lateral wall of the ventricle, and, like the trigonum hypoglossi, has its base directed upward. Here it is continuous with a prominence, the **tuberculum acusticum,** which extends into the anterior part of the floor of the ventricle.

The Superior Triangle (Fig. 606).—The superior triangle or upper or anterior half of the floor of the fourth ventricle, *i. e.*, the part above the striae medullaris, presents in the middle line the continuation of the median longitudinal sulcus. On either side of this is a spindle-shaped longitudinal eminence, prominent in its centre, but less so above and below. This is the **eminentia teres** or **fasciculus teres** (*colliculus facialis*), and is produced by an underlying bundle of white fibres, the **fasciculus teres** (*eminentia medialis*), formed, in part at all events, by the fibres of the facial nerve. Immediately above and to the outer side of the eminentia teres is an angular depression, the **fovea superior**; this is sometimes crossed by a whitish band of fibres, the **conductor sonorus,** which is connected below with the striae medullares of the same side. Above the fovea is a bluish depressed area, the **locus caeruleus.** Its color is due to some pigmented nerve-cells, showing through the white covering of the floor. These pigmented cells are named the **substantia ferruginea,** and in them one of the roots of the fifth nerve terminates.

The Lining Membrane.—The lining membrane of the fourth ventricle is continuous above with that of the third ventricle, through the aqueduct of Sylvius (p. 912), and below with that of the central canal of the spinal cord. The cavity of the ventricle communicates below with the subarachnoidean space by means of the foramen of Majendie and the foramina of Key and Retzius, already described.

The Internal Structure of the Medulla Oblongata (Figs. 607, 608, 609, 610, 611, 612).

If the cranial nerves emerging from the medulla are traced into its substance, it will be seen that they divide each half of the bulb into three wedge-shaped areas, which are named the **anterior, lateral,** and **posterior areas of the medulla,** and each of which corresponds to one of the subdivisions already described on the surface of this portion of the encephalon.

The Anterior Area.—The anterior area comprises that portion which is situated between the anterior median fissure and the fibres of superficial origin of the hypoglossal nerve. On the surface of the medulla this area corresponds to the pyramid (Fig. 607).

The Lateral Area.—The lateral area is situated between the fibres of superficial origin of the hypoglossal nerve on the one hand, and the fibres of superficial origin of the glosso-pharyngeal pneumogastric and spinal accessory nerves on the other. On the surface of the medulla, in its lower part, this area is single, and is

called the **lateral tract**; but in the upper part an oval-shaped body, the **olivary body**, comes forward between it and the pyramid, pushing aside the lateral tract (Fig. 607).

The Posterior Area.—The posterior area comprises that portion which is situated between the fibres of superficial origin of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves, and the posterior median fissure. On the surface of the medulla this area is marked by slight furrows, splitting it up into smaller columns; those in the lower part of the medulla are named, from without inward, the fasciculus of Rolando, the fasciculus cuneatus, and the fasciculus gracilis; in the upper part of the medulla they are replaced by the restiform body. Finally, the halves of the medulla are separated from each other by a median septum or raphé (Fig. 607).

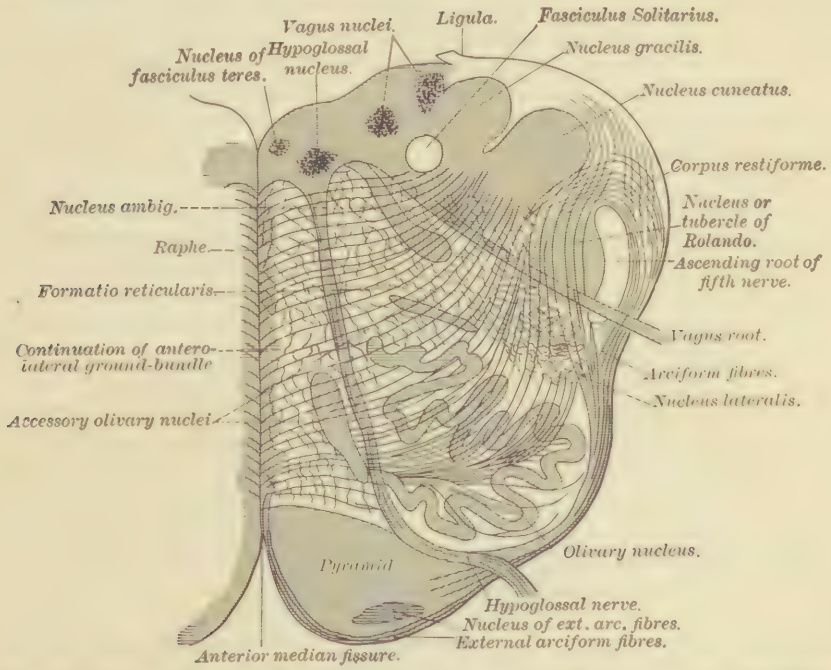

FIG. 607.—Section of the medulla oblongata at about the middle of the olivary body. (Schwalbe.)

Each of these three areas is made up of gray and white matter. The gray matter is derived for the most part from that of the cord. In like manner the white matter is partly made up of longitudinal fibres continuous with those of the cord, and partly of transverse fibres which intersect them.

In order to understand the internal structure of the medulla, it is necessary to describe the appearances as they are seen in the upper and lower portions of the medulla, since they differ considerably in these two parts.

The Lower Part of the Medulla (Figs. 608 and 609).—The first change in the internal structure is caused by the passage of the fibres of the crossed pyramidal tract obliquely through the gray matter of the anterior horn. As stated above, the pyramid is composed of fibres derived from the direct pyramidal tract of the anterior column of the cord of the same side, and from the crossed pyramidal tract of the lateral column of the opposite half of the cord. Those fibres which are derived from the direct pyramidal tract and which in the cord lie close to the median fissure are in the medulla placed to the outer side of the pyramid, being pushed aside, as it were, by the interpolation of the fibres derived from the crossed pyramidal tract, which

are much more numerous. The crossed pyramidal fibres ascend from the lateral column of the spinal cord, and, passing through the anterior gray cornu and across the middle line, form the inner part of the pyramid. In consequence of this passage of white fibres through its substance the anterior gray cornu is broken up into a coarse network, while one portion of it, the **caput cornu,** is entirely separated from the rest; only the base of the cornu remains intact, close to the ventrolateral aspect of the central canal. The caput cornu, thus separated, is displaced laterally, and comes to lie close to the caput cornu posterioris, which

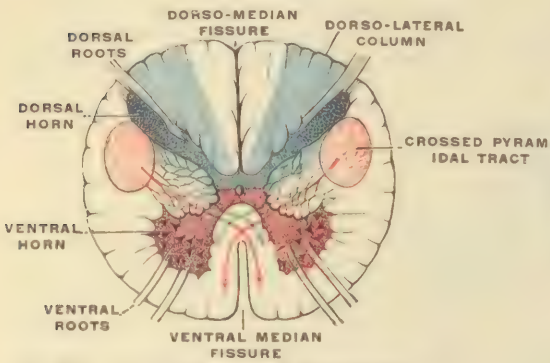

FIG. 608.—Transverse section of the oblongata at its lower end. (Testut.)

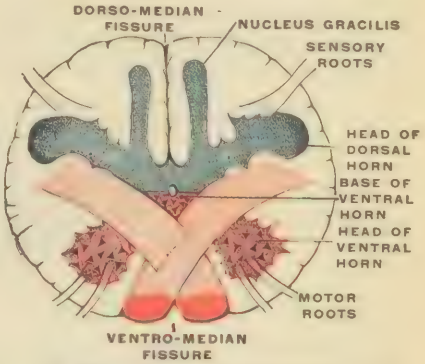

FIG. 609.—Transverse section of the oblongata at the decussation of the pyramids. (Testut, after Duval.)

has also shifted its position. In consequence of this breaking up of the greater part of the anterior gray cornu by white fibres a coarse network is formed in the anterior and lateral areas of the medulla, which is named the **formatio reticularis** (Fig. 607).

The posterior cornu also undergoes somewhat similar changes. It becomes subdivided by the passage through it of the sensory fibres of the columns of Goll and Burdach. These pass across to the opposite anterior area of the medulla, where they are seen to lie immediately on the dorsal aspect of the pyramids. In

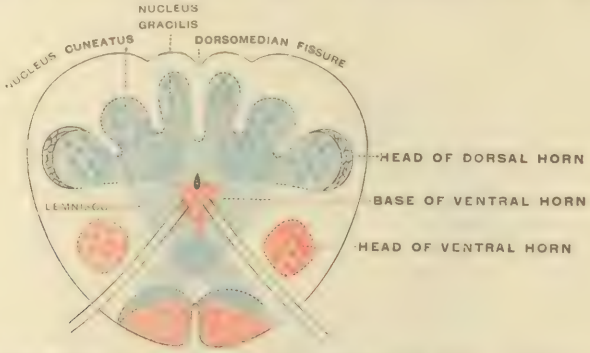

FIG. 610.—Transverse section of the oblongata at the crossing of the fillets. (Testut.)

their passage through the posterior horns of gray matter the latter become subdivided, in a manner somewhat similar to what has been seen to occur in the anterior horns. This crossing of the sensory fibres is termed the **superior pyramidal** or **sensory decussation** (Fig. 605). The caput cornu is displaced outward, so as almost to reach the surface, where it forms a projection, the **fasciculus of Rolando,** which enlarges above into a distinct prominence, the **tubercle of Rolando** (Fig. 607). Above the level of the tubercle of Rolando the caput cornu is separated from

the surface by a band of fibres termed the **ascending root of the fifth nerve** (*tractus spinalis n. trigemini*) and by the external arcuate fibres (Fig. 607). The neck of the cornu becomes broken up into a reticular formation by the decussation of the columns of Goll and Burdach, and by this means the caput is separated from the rest of the gray matter. The base of the cornu increases in size, and, as the central canal expands into the fourth ventricle, becomes pushed outward, and portions of it extend into the fasciculus graciles and cuneati, and produce externally the eminences of the clava and cuneate tubercle. A third portion of the base becomes separated from the rest, and is placed outside the nucleus of the fasciculus cuneatus. This is called the **accessory cuneate nucleus**, and is supposed to be a continuation upward of Clarke's vesicular column of the cord.

The Upper Part of the Medulla (Figs. 607, 611, and 612).—The upper part of the medulla comprises the portion which enters into the formation of the

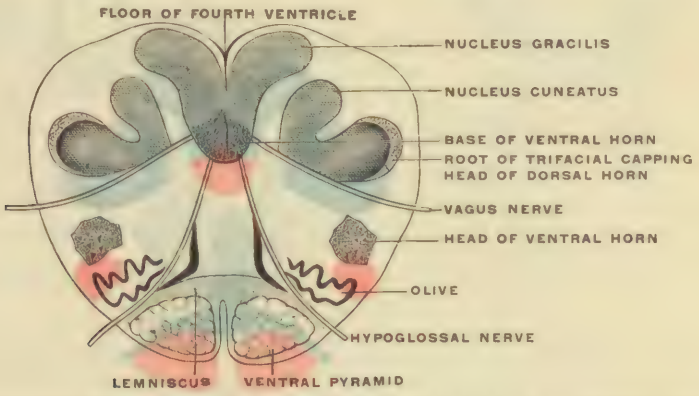

FIG. 611.—Transverse section of the oblongata at the lower end of the olives. The roof of the fourth ventricle is not represented. (Testut, after Duval.)

floor of the fourth ventricle, where, in fact, the upper end of the central canal has opened out into this cavity. In this region the formatio reticularis is confined chiefly to the anterior and lateral areas. In the ventral portion of the posterior area there is only a small amount of reticular formation, but in addition to this there are individual masses of cells scattered among the longitudinal fibres.

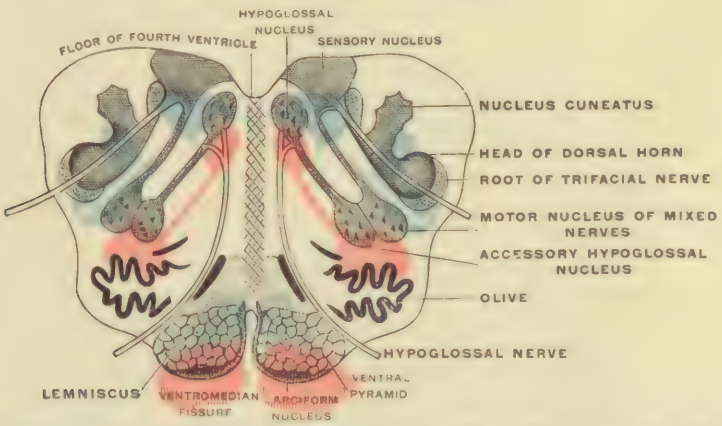

FIG. 612.—Transverse section of the oblongata at the middle of the olives. The roof of the fourth ventricle is not represented. (Testut, after Duval.)

The Formatio Reticularis (Fig. 607).—The formatio reticularis is a network of white matter in the deep portion of the medulla, the network containing

gray matter. It is situated behind the pyramid and olivary body, extending laterally as far as the restiform bodies, and dorsally to within a short distance of the floor of the fourth ventricle. It presents a peculiar reticulated appearance, from which it derives its name, and which is due to the intersection of bundles of fibres running at right angles to each other, some being longitudinal, others transverse. The formatio reticularis presents a different appearance in the anterior area from what it does in the lateral area. In the former there is almost an entire absence of nerve-cells in the reticulated network, and hence it is known as the **formatio reticularis alba**; whereas, in the lateral area, the nerve-cells are numerous, and, as a consequence, this part is known as the **formatio reticularis grisea.** In the substance of the formatio reticularis is a small nucleus of gray matter. It is situated near the dorsal aspect of the hilum of the olivary nucleus, and has been named the **inferior central nucleus.** The formatio reticularis contains both longitudinal and transverse fibres. In the anterior area the longitudinal fibres may be arranged in two well-defined sets: (1) One set lies immediately behind the pyramid, and is named the **interolivary fillet** or **lemniscus** (*lemniscus interolivaris*) (Fig. 610). The fibres of the fillet are chiefly derived from the cells of the gracile and cuneate nuclei (Fig. 607), and may therefore be regarded as relay fibres of the columns of Goll and Burdach of the spinal cord, which terminate in synapses around the cells of the gracile and cuneate nuclei. They are prolonged inward and forward across the middle line forming the **superior pyramidal** or **sensory decussation** or the **decussation of the fillet** (Fig. 605). (2) The other set is continuous from the antero-lateral ground bundle of the cord, and a portion of these fibres forms the **posterior longitudinal bundle** (*fasciculus longitudinalis medialis*), already referred to (p. 908). Both these sets of fibres are continued upward into the pons and mid-brain. The longitudinal fibres of the reticular formation in the lateral area are not arranged in distinct bundles. They are derived from the lateral column of the cord, after the crossed pyramidal tract has passed over to the opposite side. The longitudinal fibres of the posterior area are merely indeterminate fibres of the formatio reticularis, with the exception of two distinct bundles, which may be regarded as ascending roots of the fifth nerve (Fig. 607) and vago-glosso-pharyngeal nerves; the latter is termed the **fasciculus solitarius** (Fig. 607).

The **Transverse Fibres** of the reticular formation are the arched or arcuate fibres. The **external arciform** or **arcuate fibres** have already been described. The **internal arciform** or **arcuate fibres** (*fibrae arcuatae internae*) are more numerous than the superficial set; they traverse nearly the whole area of the upper half of the medulla, except the pyramid. They pass from the raphé; some become superficial and join the external arciform fibres, while others remain deep and pass to the olivary body, the restiform body, and to the nuclei of the fasciculus cuneatus and fasciculus gracilis.

Independent Nuclei (Fig. 613).—In the upper part of the medulla are several independent nuclei of gray matter, which may be divided into two sets: (1) those which are traceable from the gray matter of the spinal cord, and (2) those which are not represented in the cord. The former are the hypoglossal nucleus, the nucleus of the fasciculus teres, and those of the auditory, glosso-pharyngeal, vagus, and spinal accessory nerves. The latter are the nucleus of the olivary body and the accessory olivary nuclei. In addition to these, small collections of gray matter are to be found in the median septum or raphé.

The Hypoglossal Nucleus (Figs. 607, 612, and 613).—The base of the anterior horn, which in the lower part of the medulla was situated on the ventro-lateral aspect of the central canal, now approaches the floor of the ventricle, where it lies close to the median sulcus under the fasciculus teres. In it is a column of large nerve-cells, from which the roots of the hypoglossal nerve are derived. It is accordingly designated the **hypoglossal nucleus.**

The Auditory Nuclei (Fig. 613).—Toward the upper part of the medulla, a considerable tract of gray matter may be found lying immediately beneath that portion of the floor of the fourth ventricle which is known as the **trigonum acustici.** This is the **dorsal** or **inner auditory nucleus,** and it lies just external to the vago-glosso-pharyngeal nucleus. In addition to this there is a small collection of nerve-cells on the ventral surface of the restiform body, between the two roots of the auditory nerve, which is known as the **accessory** or **ventral auditory nucleus.** On the outer side of the restiform body is a mass of cells associated with the cochlear root of the auditory nerve. This mass is termed the **lateral acoustic tubercle** or **ganglion radicis cochlearis.**

Nuclei of the Glosso-pharyngeal and Vagus Nerves (Fig. 613).—These are two in number, **principal** and **accessory.** The **principal nucleus** of the two nerves lies beneath that portion of the floor of the fourth ventricle which is known as the ala cinerea

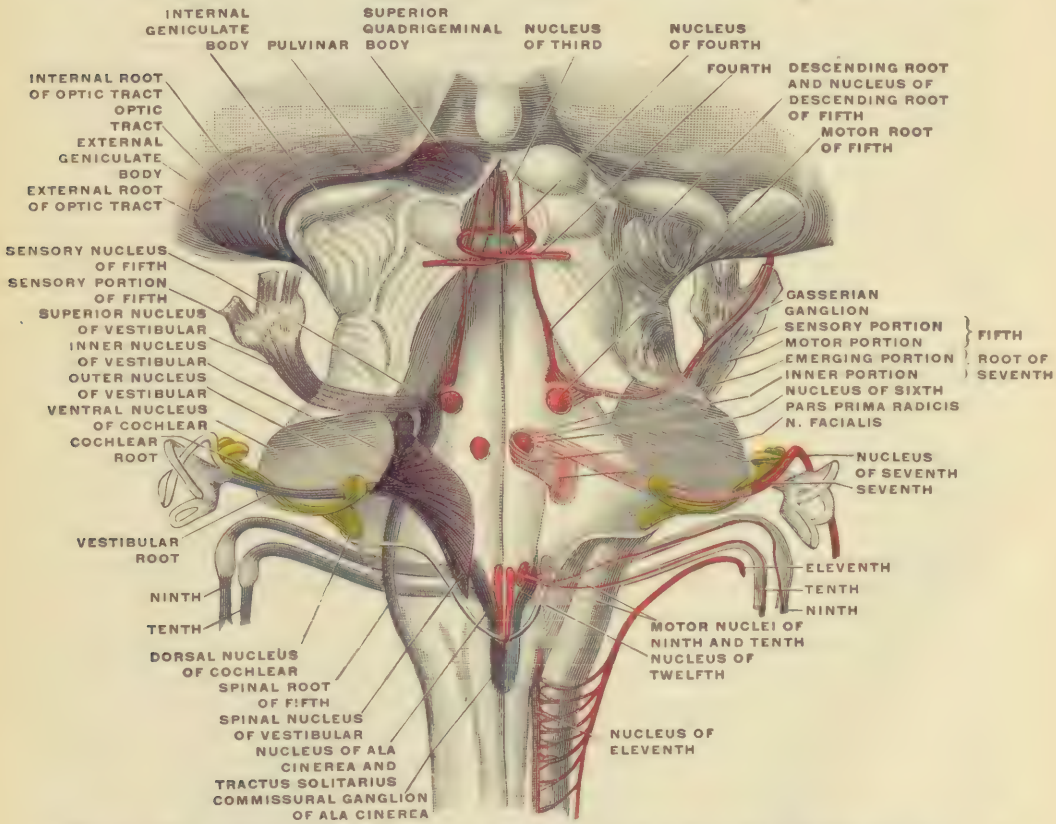

FIG. 613.—The nuclei of the origin of the motor and primary terminal nuclei of sensory cerebral nerves, schematically represented in a supposedly transparent brain stem, viewed from behind. Nuclei and roots of motor nerves, red; of sensory, reddish-violet; of the cochlear nerve, yellow; and of the optic nerve, bluish-violet. × 2. (Held.)

and fovea inferior. They form an oblong mass of gray matter, above the nucleus of the spinal accessory and lateral to the hypoglossal nucleus. The **accessory nuclei** are situated in the reticular formation of the posterior area, some distance from the floor of the fourth ventricle. They consist of a pear-shaped mass of cells, which is connected with the rest of the gray matter by a sort of stalk or peduncle, and was formerly known as the **nucleus ambiguus** (Fig. 607).

Nucleus of the Spinal Accessory Nerve (Fig. 613).—This nucleus consists of a group of cells, which is situated partly in the lower part of the medulla at the base of the posterior horn and close to the central canal. It extends upward,

lying beneath the lower part of the floor of the fourth ventricle and on the outer side of the hypoglossal nucleus.

The Nucleus of the Olivary Body (*nucleus olivaris inferior*) (Fig. 607).—When the olivary body is cut across, it is seen to be covered externally by white fibres, and internally to consist of a gray layer. The fibres which invest the nucleus are derived from the antero-lateral ground bundle. The gray layer is the **nucleus of the olivary body**, or, as it is sometimes called, the **corpus dentatum of the olive**. It is composed of a thin, wavy lamina, which is arranged in the form of a hollow capsule, open at its upper and inner part, and presenting a zigzag or dentated outline. Microscopically examined, the olivary nucleus is seen to consist of small, rounded, yellowish nerve-cells embedded in a matrix of neuroglia and fine nerve-fibres. White fibres, which can be traced from the raphé, and are probably derived from the opposite olive, enter the interior of the capsule by the aperture at its upper or inner part, these fibres constituting the **olivary peduncle**. The olivary peduncle is the lower portion of the **cerebello-olivary tract** (*fibræ cerebelloolivares*). This tract connects the cerebellar hemisphere with the opposite olivary nucleus.

The fibres of the olivary peduncle as they enter the olivary body diverge and some are lost in the gray matter of the olivary nucleus; others pass through it, and of these some turn backward to join the restiform body, and pass to the cerebellum as **internal arcuate fibres**; while others pierce the white matter of the olivary body and, reaching the surface, are continued to the restiform body as **external arcuate fibres**. The nucleus receives the **olivary bundle of the spinal cord**, the group of fibres called the **triangular tract of Helwig**. The **central tegmental tract** *arises* in the olivary nucleus and passes to the lenticular nucleus. The olivary nucleus receives another descending tract besides the cerebello-olivary, namely, the **vestibulo-olivary** (Santee). From the nucleus fibres pass by way of the lateral column to the anterior cornu of the same side of the spinal cord. Removal of one cerebellar hemisphere is followed by atrophy of the opposite olivary nucleus.

Accessory Olivary Nuclei (Fig. 607).—Two small isolated masses of gray matter are to be found, one on the mesial and the other on the dorsal aspect of the corpus dentatum. These are the **medial** or **internal accessory olivary nucleus** (*nucleus olivaris accessorius medialis*) and the **external** or **lateral accessory olivary nucleus** (*nucleus olivaris accessorius dorsalis*). They are connected with the restiform body by some of the internal arcuate fibres. The fibres of the hypoglossal nerve, as they traverse the bulb, pass between the medial accessory nucleus and the chief olivary nucleus.

The Raphé (Fig. 607).—The raphé is situated in the middle line of the medulla, above the decussation of the pyramids. It consists of nerve-fibres intermingled with nerve-cells. The fibres have different directions, which can only be seen in suitable microscopic sections, thus: 1. Some are antero-posterior; these in front are continuous with the superficial arciform fibres. 2. Some are longitudinal; these are derived from the arciform fibres, which on entering the raphé change their direction and become longitudinal. 3. Some are oblique; these are continuous with the deep arciform fibres which pass from the raphé.

The nerve-cells of the raphé are multipolar; some are connected with the antero-posterior fibres, others with the superficial arcuate fibres.

Weight of the Encephalon.—The average weight of the brain in the adult male is 49½ oz., or a little more than 3 lbs. avoirdupois; that of the female 44 oz.; the average difference between the two being from 5 to 6 oz. The prevailing weight of the brain in the male ranges between 46 oz. and 53 oz., and in the female between 41 oz. and 47 oz. In the male the maximum weight out of 278 cases was 65 oz., and the minimum weight 34 oz. The maximum weight of the adult female brain out of 191 cases was 56 oz., and the minimum weight 31 oz. According to Luschka, the average weight of a man's brain is 1424 grammes (about 45 oz.),

of a woman's 1272 grammes (about 41 oz.), and, according to Krause, 1570 grammes (about 48½ oz.) for the male and 1350 (about 43 oz.) for the female. It appears that the weight of the brain increases rapidly up to the seventh year, more slowly to between sixteen and twenty, and still more slowly to between thirty and forty, when it reaches its maximum. Beyond this period, as age advances and the mental faculties decline, the brain diminishes slowly in weight, about an ounce for each subsequent decennial period. These results apply alike to both sexes. Marshall concluded that if woman is judged by her height only, she has a smaller amount of cerebral matter than has man; if she is judged by her weight alone, she has more; but if both sexes are gauged by both standards, their "cerebral endowment is seen to be practically equal."[1]

The size of the brain was formerly said to bear a general relation to the intellectual capacity of the individual. Cuvier's brain weighed rather more than 64 oz., that of Daniel Webster 63¾ oz., that of Dr. Abercrombie 63 oz. On the other hand, the brain of an idiot seldom weighs more than 23 oz. But these facts are by no means conclusive, and it is well known that these weights have been equalled by the brains of persons who never displayed any remarkable intellect. Dr. Haldenman, of Cincinnati, has recorded the case of a mulatto, aged forty-five, whose brain weighed 68⅜ oz.; he had been a slave, and was never regarded as particularly intelligent; he was illiterate, but is said to have been reserved, meditative, and economical. Dr. James Morris recorded the case of a bricklayer, who could not read or write, whose brain weighed 67 oz. Dr. Ensor, district medical officer at Port Elizabeth, reports that the brain of Carey, the Irish informer, weighed 61 oz. In not a few instances the brains of very able men have been of average weight or of less than average weight. The brain of Samuel D. Gross, the surgeon, weighed 48 oz., the brain of Gambetta, the statesman, 40 $\frac{8}{10}$ oz., the brain of Walt Whitman, the poet, 43.3 oz., the brain of Hughes Bennett, the physician, 47 oz., the brain of Joseph Leidy, the naturalist and anatomist, 49.9 oz., and the brain of Döllinger, the physiologist, 42.6 oz. M. Nikiforoff has published an article in the *Novosti* on the subject of the weight of brains. According to him, the weight of the brain has no influence whatever on the mental faculties. It ought to be remembered that the significance of the weight of the brain should depend upon the proportion it bears to the dimensions of the whole body and to the age of the individual. There seems to be a relation between the weight of the brain and the body weight and stature. Quain gives the ratio between the brain weight and body weight as 1 to 41 in healthy individuals, but this proportion is by no means fixed and seems to vary widely in either direction. As the stature increases the brain weight increases, but, as Mills says,[2] "taller persons have relatively less brain matter than shorter ones, although absolutely they have more." The significance of the weight of the brain also depends upon the cause of death, for long illness or old age wastes the brain. To define the real degree of development of the brain, it is therefore necessary to have a knowledge of the condition of the whole body, and, as this is usually lacking, the mere record of weight possesses little significance. As Mills says:[3] "Apparently there is no invariable nor necessary relation between mere brain weight and the degree of individual intelligence; but high brain weights occur in larger proportions among civilized than among uncivilized races." Furthermore, it is to be remembered that a heavy brain may be a diseased brain. For instance, Byron's brain weighed nearly 64 oz. and showed evidences of disease.

The human brain is heavier than the brain of any of the lower animals, excepting the elephant and whale. The brain of the former weighs from eight to ten pounds; and that of a whale, in a specimen seventy-five feet long, weighed rather more than five pounds.

[1] The Nervous System and its Diseases. By Prof. Charles K. Mills. [2] Ibid. [3] Ibid.

CEREBRAL LOCALIZATION AND TOPOGRAPHY.

The cortex of the brain is highly specialized, and different regions represent special functions. In it are represented "the numerous manifestations associated with consciousness;" in it memories are stored up; and "in it occur the last and highest bodily processes concerned with sensations received from without, and with the setting free of impulses which are projected to lower centres and to the outside world."[1] A centre is an aggregation of nerve-cells and fibres, which "aggregation represents physiologically some action" (Mills). Physiological and pathological researches and surgical operations have proved that the surface of the brain may be mapped out into series of definite centres, each one of which is intimately connected with some well-defined function. A group of centres is known as a *zone*, an *area*, or a *region*. As Hughlings Jackson says, the study of centres is an investigation into the anatomical "substrata" of visual, motor, tactile, and other ideas; of "the parts which represent impressions of sight, of touch, of movement, and other functions" (Mills). Certain cortical centres are known as *motor centres*. Stimulation of these centres causes movement. Destruction of these centres renders movement impos-

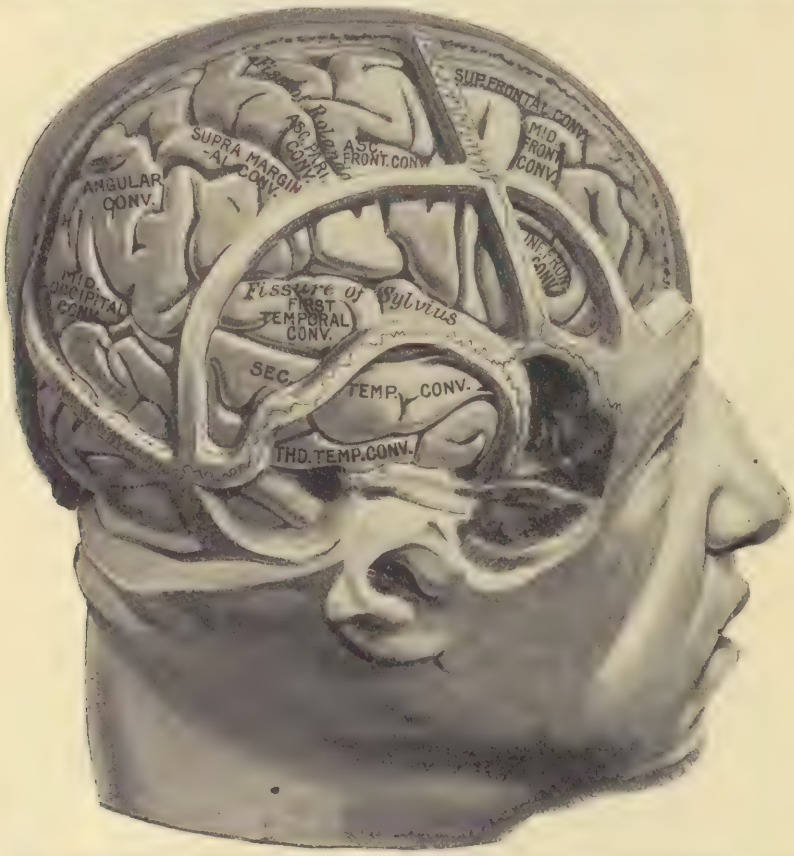

FIG. 614.—Drawing to illustrate cranio-cerebral topography. (Taken from a cast in the Museum of the Royal College of Surgeons of England, prepared by Professor Cunningham.)

sible. The centres are associated with contraction of muscular groups producing special movements not with the contraction of individual muscles. They represent movements rather than muscles. These centres are found particularly around the fissure of Rolando and on the mesial surface of the hemisphere, and they are associated with movements of the extremities of the opposite side of the body, and movements of the face, mouth, and tongue. Mills, von Monakow, and Sherrington are of the opinion that the motor areas are entirely in front of the fissure of Rolando (Figs. 615 and 616). This view is highly probable, but is not absolutely proved. Other observers hold that the motor areas occupy the entire ascending frontal and ascending parietal convolutions, extend a little way forward into the third frontal convolution and backward into the superior parietal convolution. The motor areas certainly extend on to the mesial surface in the paracentral lobule and pass perhaps into the marginal convolution. On the convexity of the hemi-

[1] The Nervous System and its Diseases. By Prof. Charles K. Mills.

sphere the highest centre is the leg area. Below this, in the order named, are the centres for the arm, face, lips, tongue, larynx, and pharynx. On the mesial surface from before backward are areas for the head, shoulder, trunk, hip, knee, leg, and foot. The centres for head and eye movements are in front of the arm centre. In a large motor area there are certain smaller areas. For instance, the area for the lower extremity contains separate centres, representing movements of the hip, knee, leg, foot, and toes.

The arm centre contains centres for movements of the shoulder, arm, wrist, thumb, and fingers. The face centre contains centres for movements of the upper face, the lower face, the

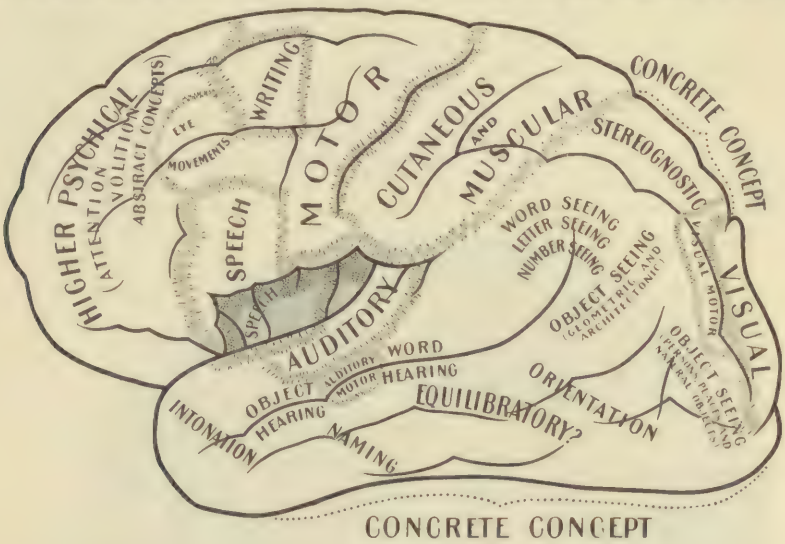

FIG. 615.—Side view of human brain, showing localization of functions. (Charles K. Mills.)

lips, and tongue. The *somaesthetic* area or the area of general sensation is not certainly marked out. Those who believe that the motor area is both front and back of the Rolandic fissure maintain that the area of general sensation largely corresponds to the motor area, but is of greater extent as it enters into the limbic lobe. Mills places it back of the fissure of Rolando in the convexity and also on the mesial surface of the hemisphere.

FIG. 616.—View of the mesial surface of human brain, showing localization of functions. (Charles K. Mills.)

The cortical centres are shown in Figs. 617 and 618. This is not the place, nor can space be given, to describe these localities.

Cranio-cerebral Topography.—The position of the principal fissures and convolutions of the cerebrum and their relation to the outer surface of the scalp (Fig. 614) have been the subject of

much investigation, and many systems have been devised by which one may localize these parts from an explanation of the external surface of the head.

These plans can only be regarded as approximately correct for several reasons; in the first place, because the relations of the convolutions and sulci to the surface are found to be very variable in different individuals; secondly, because the surface area of the scalp is greater than the surface area of the brain, so that lines drawn on the one cannot correspond exactly to sulci or convolutions on the other; and thirdly, because the sulci and convolutions in two individuals are never precisely alike. Nevertheless, the principal fissures and convolutions can be mapped out with sufficient accuracy for all practical purposes, so that any particular convolution can be generally exposed by removing with the trephine a certain portion of the skull's area.

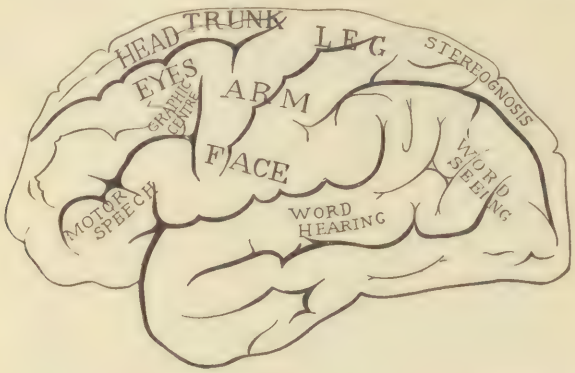

FIG. 617.—The localization of various centres on the outer surface of the left side of the human brain. (American Text-book of Surgery.)

The various landmarks on the outside of the skull, which can be easily felt, and which serve as indications of the position of the parts beneath, have been already referred to (see page 149), and the relation of the fissures and convolutions to these landmarks is as follows:

Longitudinal Fissure (Fig. 619). This corresponds to a line drawn from the glabella at the root of the nose to the external occipital protuberance.

The Fissure of Sylvius (Fig. 619). The position of the fissure of Sylvius and its posterior horizontal limb is marked by a line starting from a point one inch and a quarter horizontally behind the external angular process of the frontal bone to a point three-quarters of an inch below

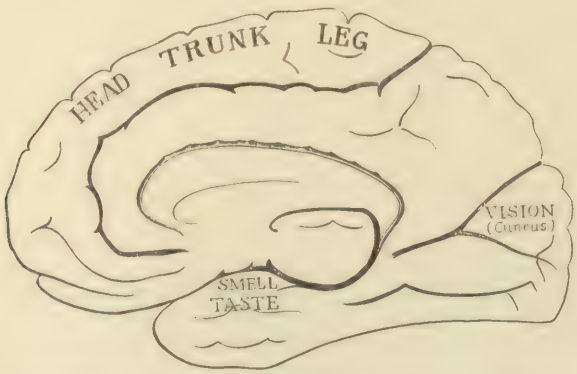

FIG. 618.—The localization of various centres on the median surface of the human brain. (American Text-book of Surgery.)

the most prominent point of the parietal eminence. The first three-quarters of an inch will represent the main fissure, the remainder the horizontal limb. The bifurcation of the fissure is therefore two inches behind and about a quarter of an inch above the level of the external angular process. The ascending limb of the fissure passes upward from this point parallel to, and immediately behind, the coronal suture.

The Transverse Fissure or Fissure of Bichat. This is between the cerebrum and cerebellum and corresponds to a line drawn from the inion to the external auditory meatus (the line *B C* in Fig. 619).

Fissure of Rolando.—To find the upper end of the fissure of Rolando, a measurement should be taken from the glabella to the external occipital protuberance. The position of the top of the sulcus will be, measuring from in front, 55.6 per cent. of the whole distance from the glabella to the external occipital protuberance. Professor Thane adopts a somewhat simpler method. He divides the distance from the glabella to the external occipital protuberance over the top of the head into two equal parts, and, having thus defined the middle point of the vertex, he takes half an inch behind it as the top of the sulcus. This is not quite so accurate as the former method, but it is sufficiently so for all practical purposes, and on account of its simplicity is very generally adopted. From this point the fissure runs downward and forward for 3¼ inches, its axis making an angle of 67° with the middle line. Cunningham states that this angle more nearly averages 71.5°. In order to mark this groove, two strips of metal may be employed—one, the shorter, being fixed to the middle of the other at the angle mentioned. If the longer strip is now placed along the sagittal suture so that the junction of the two strips is over the point corresponding to the top of the furrow, the shorter, oblique strip will indicate the direction and 3¾ inches will mark the length of the furrow. Dr. Wilson has devised an instrument, called a cyrtometer, which combines the scale of measurements for localizing the fissure with data for representing its length and direction.[1] Professor Thane gives the lower end of the furrow as

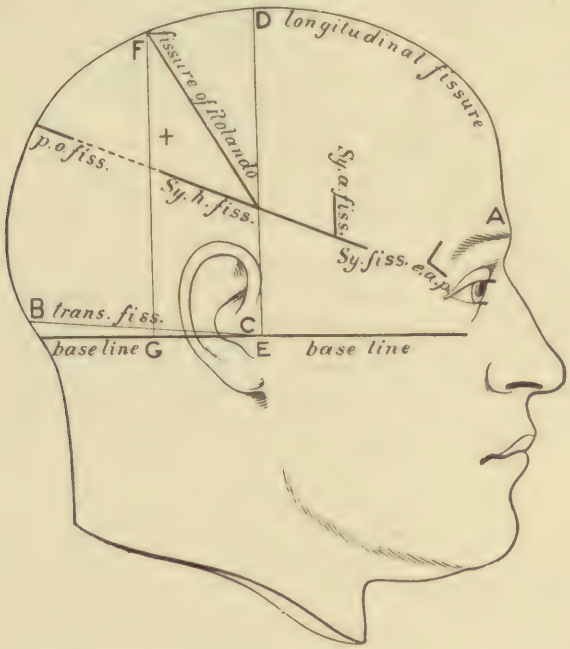

FIG. 619.—Relations of the principal fissures and convolutions of the cerebrum to the outer surface of the scalp. (Reid.)

"close to the posterior limb, and about half an inch behind the bifurcation of the fissure of Sylvius." So that, according to this anatomist, a line drawn from a point half an inch behind the mid-point between the glabella and external occipital protuberance to this spot would mark out the fissure of Rolando. Dr. Reid adopts a different method (Fig. 619). He first indicates on the surface the longitudinal fissure and the horizontal limb of the fissure of Sylvius (as above). He then draws two perpendicular lines from his "base-line" (that is, a line from the lowest part of the infraorbital margin through the middle of the external auditory meatus to the back of the head) to the top of the cranium, one (*D E*, Fig. 619) from the depression in front of the external auditory meatus, and the other (*F G*, Fig. 619) from the posterior border of the mastoid process at its root. He has thus described on the surface of the head a four-sided figure (*F D G E*, Fig. 619), and a diagonal line from the posterior superior angle to the anterior perpendicular line where it is crossed by the fissure of Sylvius will represent the furrow.

The **Parieto-occipital Fissure** on the upper surface of the cerebrum runs outward at right angles to the great longitudinal fissure for about an inch, from a point one-fifth of an inch in front of the lambda (posterior fontanelle). Reid states that if the horizontal limb of the fissure of Sylvius be continued onward to the sagittal suture, the last inch of this line will indicate the position of the sulcus (Fig. 619).

[1] Lancet, 1888, vol. i. p. 408.

The **Pre-central Sulcus** begins four-fifths of an inch in front of the middle of the fissure of Rolando, and extends nearly, but not quite, to the horizontal limb of the fissure of Sylvius.

The **Superior Frontal Fissure** runs backward from the supraorbital notch, parallel with the line of the longitudinal fissure to two-fifths of an inch in front of the line indicating the position of the fissure of Rolando.

The **Inferior Frontal Fissure** follows the course of the superior temporal ridge on the frontal bone.

The **Intraparietal Fissure** begins on a level with the junction of the middle and lower third of the fissure of Rolando, on a line carried across the head from the back of the root of one auricle to that of the other. After passing upward it curves backward, lying parallel to the longitudinal fissure, midway between it and the parietal eminence; it then curves downward to end midway between the posterior fontanelle and the parietal eminence.

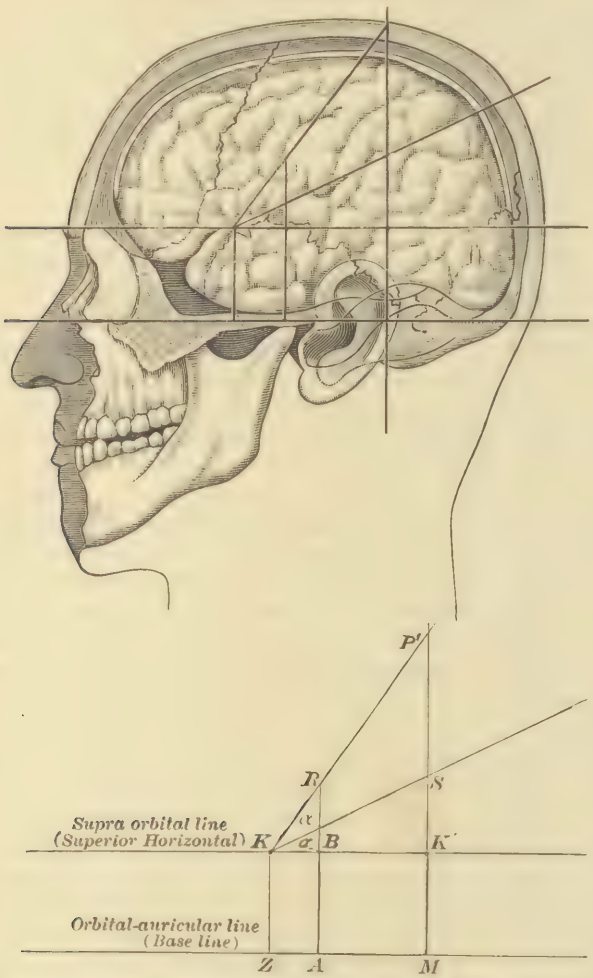

FIG. 620.—Kronlein's method for determining the portions of certain fissures of the brain.

Kronlein's method for determining the portions of certain fissures of the brain is very useful and easy of application (Fig. 620). It is as follows: (1) The base line, *Z M*, is a horizontal line running at the level of the lower border of the orbit and the upper border of the external auditory meatus. (2) Another horizontal line, *K K'*, is drawn parallel to *Z M*. The second horizontal line is on a level with the supraorbital ridge. (3) A vertical line, *Z K*, is erected from *Z M* at the middle of the zygoma and is carried to the line, *K K'*. (4) Another vertical line, *A R*, is erected from the base-line at the level of the articulation of the mandible and is carried to *R*. (5) A third vertical line, *M P*, is erected from the base-line at the posterior border of the mastoid process and is carried to the middle line of the skull, which is marked *P*. (6) A line is drawn from

K to *P*. The portion of this line between *R* and *P'* corresponds to the fissure of Rolando. (7) The angle *P K K'* is bisected by the line *K S*. *K S* corresponds to the fissure of Sylvius from its bifurcation to its termination posteriorly, and *K* is directly over the bifurcation. To reach the anterior branch of the middle meningeal, apply the trephine at *K;* to reach the posterior branch, apply it at *K'*. In abscess of the temporo-sphenoidal lobe the trephine should be applied, according to von Bergmann, in the region *A a K' M*.

THE NERVE-PATHS.

The anatomy of the various parts of the central nervous system having been described, a short account will now be given of the course taken by its more important nerve-paths, and of the direction in which impulses pass along them. Before doing so, however, it is necessary to refer to the methods employed in elucidating this complex subject. All nerve-fibres may be regarded as outgrowths from nerve-cells, and it is found that if a nerve-fibre be cut, the portion of it which is severed from the cell undergoes degeneration and becomes atrophied. Until recent years it was believed that the cell itself showed no change under such circumstances. This, however, is not the case, for if a nerve, the sciatic, for instance, be divided in an animal, and after an interval of some weeks the animal be injected with methylene blue and killed, it will be seen, on examining sections of the lumbar region of the spinal cord, that the cells are stained imperfectly or not at all, owing to a diminution, or, it may be, an entire disappearance of the chromatin, a substance which, in a normal cell, shows marked affinity for staining reagents. Further, the body of the cell is swollen, the nucleus displayed toward the periphery, and the part of the axone still attached to the altered cell is diminished in size and somewhat atrophied. Under favorable conditions the cell is capable of reassuming its normal appearance and the axone may commence to grow. This method of study by injection of methylene blue is of great value in determining the origin of nerve-fibres from their cells. Again, electrical stimulation of certain localized areas of the brain or of the tracts arising from them is followed by the contraction of the muscles of the body. The cortical centres of the motor tracts are situated in the convolutions adjacent to the fissure of Rolando (page 953). When the stimulus is applied to one part of the motor area the muscles of one limb of the opposite contract, while other portions control the movements of the other limb of the opposite side, etc. Destruction of these parts entails loss of function, paralysis of muscles, and degeneration of the tracts below the seat of injury. During life injury and disease may give rise to symptoms resembling either the effects of stimulation or those of destruction; and after death the tracts, or the centres of the tracts, are seen to be degenerated or otherwise altered. It was long believed by all and is still maintained by many that the motor area includes the ascending parietal, ascending frontal, and superior parietal convolutions. Mills, von Monakow, Sherrington and other high authorities now teach that the motor region is entirely *in front* of the central fissure, with the possible exception that the gyral mass between the foot of the fissure of Rolando and the Sylvian fissure, and extending a little back of the line of the central fissure, which may be included in the area for the face (Charles K. Mills) (Figs. 615 and 616). The motor areas are separated from each other and do not overlap, but probably interdigitate (Mills). The same is true of the areas for cutaneous sensibility. By observing the development of the nervous system during the growth of the embryo, the fact is disclosed that all axis-cylinders do not acquire a medullary sheath at one and the same time. Speaking generally, it may be said that afferent fibres become medullated before efferent, and that in the case of the latter myelination occurs earlier in the brain than in the cord. By watching the effects of these different processes the functions of a considerable part of the brain and of the nerves leading from or to it have been determined.

The Motor, Efferent, or Descending Tract (Figs. 621, 622, and 623).—The constituent fibres of this tract are the axis-cylinder processes of cells situated in the cortex of the convolutions about and probably solely in front of the fissure of Rolando. At first they are somewhat widely diffused, but as they

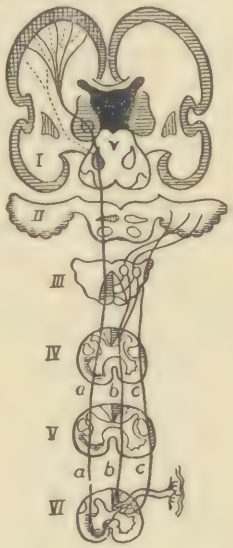

FIG. 622.—Scheme showing the course of the pyramidal tract. *I*, in the cerebrum and crus; *II*, in the pons; *III*, in the medulla oblongata; *IV*, decussation of the pyramids; *V*, in the cervical enlargement; *VI*, in the lumbar enlargement. (Jakob.)

descend through the corona radiata they gradually approach each other and pass between the lenticular nucleus and optic thalamus in the genu and anterior two-thirds of the posterior limb of the internal capsule. Proceeding downward they next occupy the middle three-fifths of the pes or crusta of the crus cerebri, and enter the pons Varolii, where the transverse fibres of this body not only conceal them, but divide them up into irregular bundles. Eventually they reach the medulla, and here the motor tracts form the anterior pyramids which lie one on each side of the median fissure. The transit of the fibres from the medulla is effected by two paths. The fibres nearest to the anterior median fissure cross the middle line, forming the **decussation of the pyramids** (Figs. 594, 605, 609, 621, 622, and 623), and descend in the opposite side of the cord as the **indirect** or **crossed pyramidal tract** (Figs. 605 and 623). Throughout the length of the spinal cord fibres from this column pass into the gray matter, to terminate by ramifying around the cells of the anterior horn. The more laterally placed portion of the motor tract does not decussate in the medulla, but descends as the **direct** or **uncrossed pyramidal tract** (Fig. 605); these fibres, however, end in the anterior gray horn of the opposite side of the spinal cord by passing across in the anterior white commissure. 1. *Motor* and *inhibiting influences* which reach the *spinal nerves* arise in the upper three-fourths of the motor area in front of the Rolandic fissure, pass along the fibres of the corona radiata

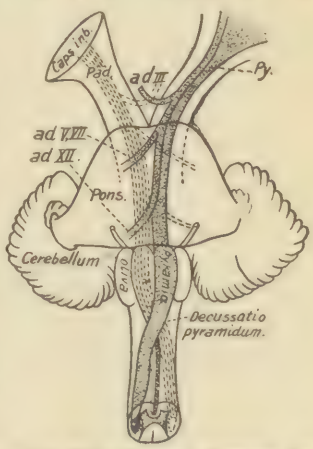

FIG. 623. Scheme showing the position of the pyramidal tract. *Py*, in the mesencephalon; *III*, *V*, *VII*, *XII*, central motor pathways to the corresponding cranial nerves. (Jakob.)

and of the anterior two-thirds of the posterior limb of the internal capsule, the middle three-fifths of the crusta, the anterior or ventral pontine fibres, and the medullary pyramids. From this point they may pass along either the crossed or the uncrossed pyramidal tract to reach the gray horn of the opposite side of the spinal cord. "By the former route the impulses cross over in the medulla through the decussation of the pyramids, and descend in the lateral column of the spinal cord; but by the uncrossed route they descend in the anterior column of the cord and decussate in succession through the white commissure. Impulses by either route finally reach the anterior gray cornu of the spinal cord, and, with the exception of a small percentage of them, they reach the cornu opposite to their Rolandic origin. The few undecussated fibres in the crossed pyramidal tract conduct uncrossed impulses to the anterior cornu of the same side."[1] 2. *Motor* and *inhibiting influences* which reach the *cranial nerves* arise in the lower portion of the motor area, pass through the corona radiata and posterior two-thirds of the internal capsule, but deviate from the pyramidal tract before reaching the medulla, and pass to the nuclei of cranial nerves (Fig. 623). On the same side fibres pass to the nuclei of the fourth nerve, but the balance of the fibres cross and pass to nuclei on the opposite side—viz., the nuclei of the third, fifth, sixth, seventh, ninth, tenth, eleventh, and twelfth cranial nerves.

The Cerebro-cortico-pontal Paths.—These paths pass through the cerebellum. Impulses from the prefrontal region pass along the corona radiata, through the anterior limb of the internal capsule and the inner portion of the crusta. Impulses from the temporal region pass along the corona radiata, through the posterior limb of the internal capsule and the outer portion of the crusta. The nucleus pontis and cranial nerve nuclei of the same side receive the impulses from both the frontal and the temporal paths, and from these depots the impulses are sent to cranial nerves or to spinal nerves. To cranial nerves they are sent direct from the synapses about the nuclei. In order to reach spinal nerves they pass to the cerebellar cortex by means of the middle peduncle of the cerebellum. From the cerebellar cortex the impulses pass through the inferior peduncles of the cerebellum and the lateral region of the medulla to reach the anterior gray horn (by way of the antero-lateral descending cerebellar tract).

The Intermediate Crusta Path (by Way of the Intermediate Bundle).—Some impulses which arise in the cerebral cortex pass to the corpus striatum, then to the nucleus pontis of the same side (chiefly), then by way of the middle peduncle of the cerebellum to the cerebellar cortex, and then along the antero-lateral descending cerebellar tract.

The Red Nucleus Path.—Impulses from the cerebral cortex may reach the red nucleus by way of the optic thalamus (direct route) and by way of the corpus striatum (indirect route).

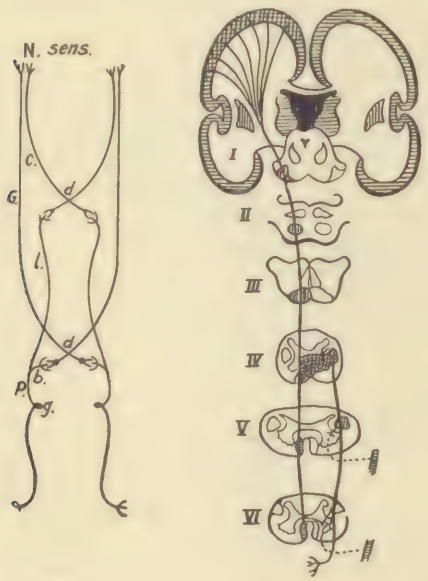
Impulses which reach the red nucleus by the direct route travel along the crossed descending tract of the red nucleus to the centre of the gray matter in the crescent of the opposite side of the cord. Impulses which reach the red nucleus by the indirect route pass to the cerebellar cortex of the opposite side and from the cortex along the descending cerebellar tract.

Short Fibre Paths (chiefly in the formatio reticularis).—Santee presents a concise explanation of the course of impulses along these paths.[2] He describes five paths: 1. Impulses having reached the ganglia of the cerebrum and mesencephalon, pass along the formatio reticularis and reach the antero-lateral ground bundle of the spinal cord to ultimately reach the spinal nerves. Impulses leaving the formatio reticularis may reach motor cranial nerve nuclei. 2. Impulses may pass from the formatio in the pons and by way of the middle cerebellar peduncle

[1] Anatomy of the Brain and Spinal Cord. By Harris E. Santee. [2] Ibid.

reach the cerebellar cortex. 3. Impulses which reach the cerebellar cortex may reach the antero-lateral ground bundle of the opposite side of the cord. 4. From the third cranial nerve nucleus fibres pass to the seventh nerve, and impulses come from the third nerve and are sent to the Occipito-fontalis, Corrugator supercilii, and Orbicularis palpebrarum muscles. 5. Fibres pass from the nucleus of the sixth cranial nerve to the nucleus of the opposite third nerve, and impulses pass from the nucleus of the sixth nerve of one side to the Internal rectus muscle of the opposite side.

The Sensory, Afferent, or Ascending Tract (Figs. 624, 625, and 626). **Path by the Columns of Goll and Burdach.**—The course taken by those fibres of the posterior nerve-roots which ascend has been arrived at by dividing the nerve-roots between their ganglia and their entrance into the spinal cord and subsequently examining the degenerated areas. It has been found that the fibres pursue an oblique course, being situated at first in the outer part of Burdach's column; higher up they occupy the



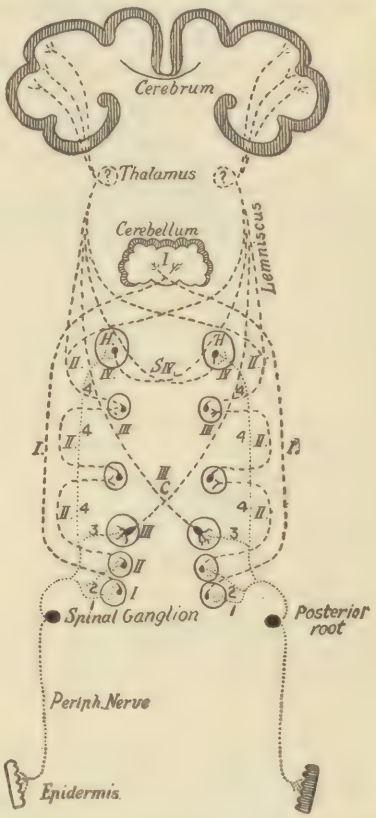


FIG. 624.—Scheme of the sensory pathway: *c*, central, *p*, peripheral, neurone; *g*, intervertebral ganglion cell; *b*, short, *l*, long, tract; *d*, decussation. (Jakob.)

FIG. 625.—Scheme showing the course of the sensory pathway: *I*, in the cerebrum and cerebral peduncles; *II*, pons and cerebellum; *III*, medulla oblongata; *IV*, upper portion of cervical cord; *V*, middle portion of cervical cord; *VI*, lumbar cord; *a*, fibres from the antero-lateral columns and fillet; *b*, fibres in the posterior columns; *c*, fibres from the cerebellum and lateral columns. (Jakob.)

FIG. 626.—Scheme of the sensory pathway. *Peripheral neurone* (dotted line): 1, 2, 3, short, 4, long, tracts. (Jakob.)

middle of this column, being displaced inward by the accession of other entering fibres, while still higher they enter and are continued upward in the column of Goll. The upper cervical fibres do not reach the column of Goll, but are entirely confined to that of Burdach. The degeneration method proves that the localization of these fibres is very precise: the sacral nerves lying to the inner side of Goll's column and near its periphery; the lumbar nerves to their outer side; the dorsal nerves still more laterally; while the cervical nerves are confined to the outer part of Burdach's column.

On reaching the medulla these ascending fibres end by arborizing around the cells in the gracile and cuneate nuclei, and the further upward course of the tract is effected by the axis-cylinder processes of these cells. There are two paths from this region, the **direct** and the **indirect**. The fibres of the **direct path** decussate in the medulla, dorsal to the crossing of the motor tract, in what is termed the **superior pyramidal decussation**, the **sensory decussation**, or the **decussation of the fillet** (Figs. 605, 610, 624, and 626), terms which are synonymous. Having crossed the middle line they ascend through the pons and tegmentum of the crus cerebri, and, reaching the ventral surface of the optic thalamus, from which they pass by the three systems of Flechsig to the cortex. The impulses ascending from the optic thalamus pass to the cortex through the internal capsule and corona radiata. Impulses which take the indirect path leave the medulla, pass to the cortex of the superior worm of the cerebellum,

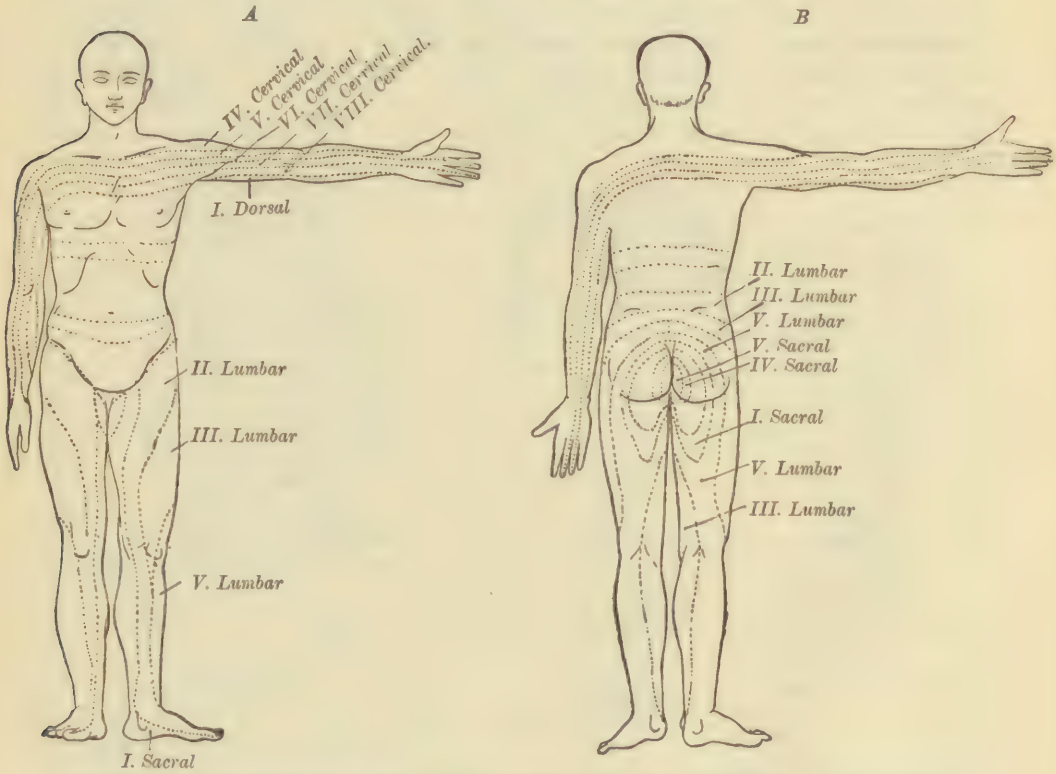

FIG. 627.—Cutaneous areas corresponding to the sensory segments of the spinal cord. *A*, anterior surface. *B*, posterior surface. (After Sticker.)

and then through the superior peduncle to the optic thalamus and the red nucleus of the opposite side. These fibres also reach the cortex by means of the systems of Flechsig. The fibres of the sensory path are arranged as follows in the internal capsule: those which go to the fronto-parietal cortex being situated in the extreme front part of the anterior limb of the internal capsule, while in the hinder extremity of the posterior limb other fibres pass to their distribution in the temporal and occipital cortex.

Path of Cranial Nerves and Medial Fillet.—Common sensory impulses passing along the fifth, the vestibular portion of the eighth, the ninth, and the tenth nerves are conveyed by the medial fillet to the ventral portion of the opposite optic thalamus, and from this region they are taken to the cortex by the systems of Flechsig.

Paths by the Direct Cerebellar Tract.—The direct cerebellar tract begins about the level of the second lumbar vertebra, and is the continuation upward of the axis-cylinders of Clarke's column. At the upper end of the cord it passes into the restiform body and through this reaches the cortex of the superior vermis of the cerebellum. This tract seems to lose some of its fibres in the cord, since the area of degeneration resulting from a section of the lower part of the cord diminishes from below upward; only some of its fibres therefore pass directly to the cerebellum. On the other hand, the tract is reinforced by an accession of fibres from the cord itself, so that its transverse area is greater above than below. Impulses of equilibrium pass from the posterior roots of the spinal nerves and ascend along the direct cerebellar tract, chiefly to the cerebellar cortex of the same side, partly to the cerebellar cortex of the opposite side. From the cerebellar cortex they pass to the cerebral cortex by the route previously referred to.

The Path by the Antero-lateral Ascending Cerebellar Tract.—Ordinary sensory and thermic impulses ascend along this tract to the cerebellar cortex of the opposite side (the superior worm) and partly to the optic thalamus and parietal cortex.

Short Fibre Paths.—According to Santee there are three of these paths: 1. One path is in the antero-lateral ground bundle and formatio reticularis. It conveys sensory impressions from the gray matter of the cord or from pontine and medullary nuclei which receive fibres of common sensation from cranial nerves to the opposite optic thalamus. 2. Another path takes impulses from the formatio reticularis to the cerebellar cortex and then to the red nucleus and optic thalamus. 3. Impulses may leave the antero-lateral ascending cerebellar tract along fibres which diverge in the medulla. These impulses reach the lateral nucleus, pass to the cerebellar cortex, and finally attain the cerebral cortex.[1]

Paths of Special Sensations.—(See the section on Cranial Nerves.)

Reflex Paths.—Reflex paths are almost infinite in number and only a few can be set forth. A spinal reflex action is produced as follows: A stimulus imparted to a sensory nerve ending is conveyed up the nerve to a centre or several centres in the spinal gray matter, from which it is transferred to a motor nerve, and by this to a muscle which responds to the stimulus by movement. Such a path is called a *reflex arc.*

Spinal Reflexes (Fig. 628) may be very simple or somewhat complicated. In the simple spinal reflex the cause of the stimulus is as indicated above. Among these simple spinal reflexes are the patellar reflex, the reflex withdrawal of a part when irritated, and the skin reflexes.

In a more complicated spinal reflex the "impulses traverse at least three neurones" (Santee). The more complicated reflexes are those of "defecation, micturition, parturition, vasomotor reflexes, cardio-accelerator reflexes, etc." (Santee).

A **Cranial Reflex** travels up a sensory cranial nerve and is transferred to a motor cranial nerve. Among these impulses are "watering" of the mouth on smelling a savory dish, the facial muscular contraction due to pain in the fifth nerve, coughing, sneezing, vomiting, and swallowing.

Spinal Cranial Reflexes are due to the ascent of impulses in the cord by way of the posterior longitudinal bundle or by Burdach's column, which impulses reach the nuclei of cranial motor nerves. "Thus is brought about the movement of the eyes toward the source of impulse, a change of facial expression to agree with the painful or pleasing character of the impulses, etc."[2] *Cranial spinal reflexes* are produced by impulses from cranial sensory nerves being transferred to spinal motor fibres. An example of one of these reflexes is the starting on hearing a sudden loud sound. Among these numerous reflexes are the respiratory, auditory, and pupillary.

Cutaneous Areas Corresponding to the Sensory Segments of the Spinal Cord.—These are shown in Figs. 627 and 628.

Muscular Supply from Motor Segments of the Cord.—This is shown in Fig. 628.

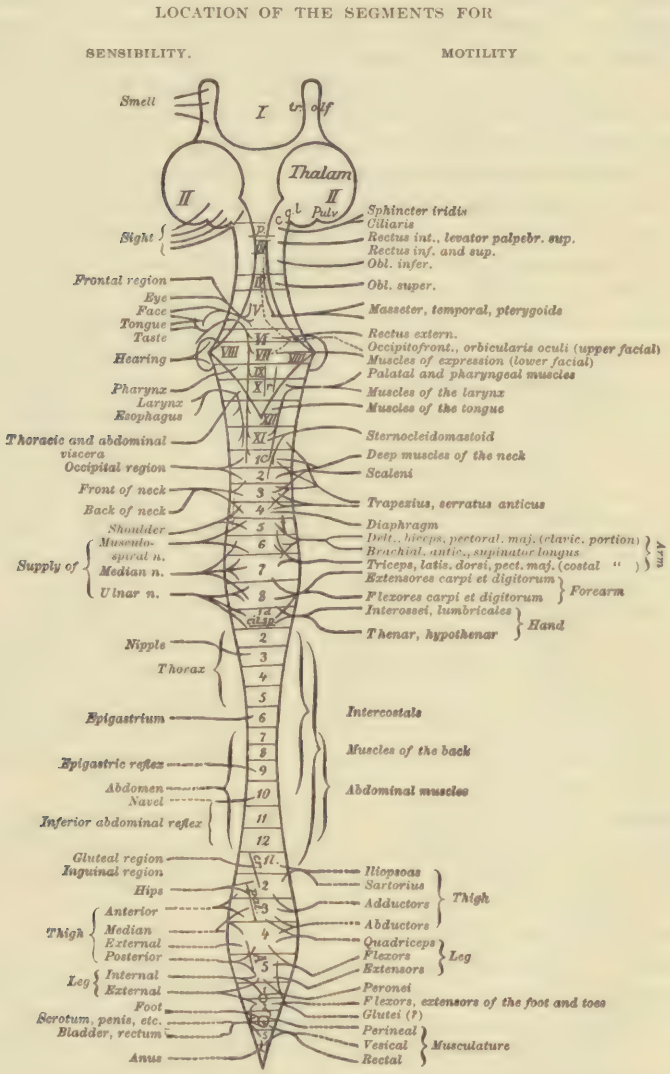

FIG. 628.—Explanation of abbreviations: *tr. olf.*, olfactory tract; *c. g. l.*, lateral geniculate body; *p*, *r*, *cr*, *A*, indicate approximately the location of the reflex centres for the pupillary (*p*), the respiratory (*r*), cremasteric (*cr*), patellar (*pat*), and tendo Achillis (*A*) reflexes. The vesical centre lies in the third and fourth sacral segments; the anal centre in the fourth and fifth (represented by circles); the centres for erection, ejaculation, labor pains (?) are probably also situated in this region. In reality, the divisions between the various segments are, of course, not so sharp as they are shown in the diagram, so that a given muscle or cutaneous region derives some of its controlling nerve-roots from the segments lying immediately above and below the principal segment. The sensory segment for any given region is regularly somewhat higher than the corresponding motor segment. (Jakob.)

THE SPINAL NERVES (NERVI SPINALES).

The spinal nerves are so called because they take their origin from the spinal cord, and are transmitted through the intervertebral foramina on either side of the spinal column. There are thirty-one pairs of spinal nerves, which are arranged

into the following groups, corresponding to the region of the spine through which they pass:

Cervical	8 pairs.
Thoracic or Dorsal	12 "
Lumbar	5 "
Sacral	5 "
Coccygeal	1 "

It will be observed that each group of nerves corresponds in number with the vertebrae in that region, except the cervical and coccygeal. Sometimes there is no thirty-first pair. Occasionally below the thirty-first pair there may be one or even two filamentous pairs which do not pass out of the spinal canal.

Each spinal nerve arises by two roots, an **anterior** or **motor root** and a **posterior or sensory root,** the latter being distinguished by a ganglion, termed the **spinal ganglion.**

The Roots of the Spinal Nerves (Figs. 538, 540, 541, 629, 630, 631).

The Anterior or Ventral Root (*radix anterior*).—The *superficial origin* is from the antero-lateral columns of the cord, corresponding to the situation of the anterior cornu of gray matter. Each root is composed of from four to eight filaments (*fila radicularia*).

The *deep origin* can be traced through the antero-lateral column; the roots, after penetrating horizontally through the longitudinal fibres of this tract, enter the gray substance, where their fibrils diverge in several directions: some passing inward, are continued across the anterior commissure in front of the central canal, to become continuous with the axis-cylinder processes of the large cells of the anterior cornu of the opposite side; others terminate in the mesial group of cells of the anterior column of the same side; other fibrils pass outward, to become continuous with the axis-cylinder processes of the group of cells in the lateral part of the anterior column.

The Posterior or Dorsal Root (*radix posterior*).—The *superficial origin* is by filaments (*fila radicularia*), from the postero-lateral fissure of the cord. The *real origin* of these fibres is from the nerve-cells in the posterior root ganglion, from which they can be traced into the cord in two main bundles, the course of which has already been studied (p. 847).

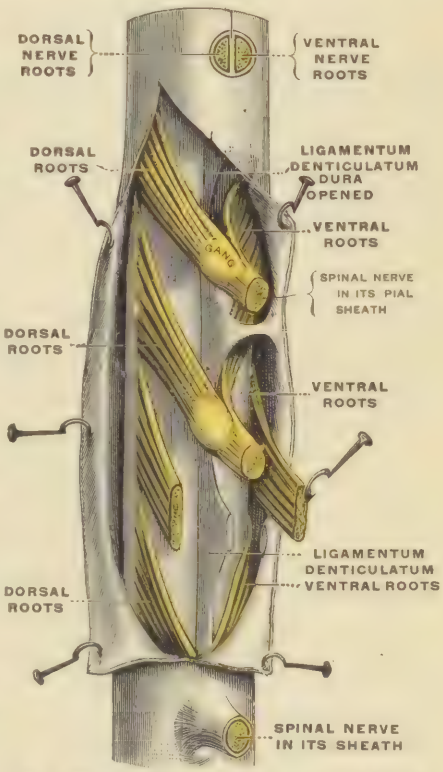

FIG. 629. A portion of the spinal cord, showing its right lateral surface. The dura is opened and arranged to show the nerve roots. (Testut.)

The *anterior roots* are smaller than the posterior, devoid of ganglionic enlargement, and their component fibrils are collected into two bundles near the intervertebral foramina.

The *posterior roots* of the nerves are larger, but the individual filaments are finer and more delicate than those of the anterior. As their component fibrils

pass outward toward the aperture in the dura mater, they coalesce into two bundles, receive a tubular sheath from that membrane, and enter the ganglion (Figs. 629, 630, and 631) which is developed upon each root.

The posterior root of the first cervical nerve forms an exception to these characters. It is smaller than the anterior, has occasionally no ganglion developed upon it, and when the ganglion exists, it is often situated within the dura mater. The first cervical may have a rudimentary posterior root or no posterior root.

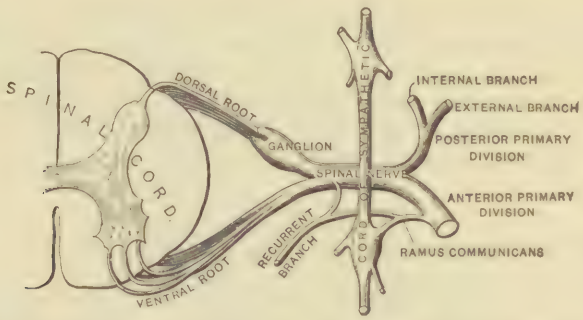

Fig. 630.—Plan of the constitution of a spinal nerve. (W. Keiller, in Gerrish's Text-book of Anatomy.)

Within the spinal canal the nerve-roots are separated from each other by the *ligamentum denticulatum* (Fig. 629). In the cervical region the spinal portion of the spinal accessory nerve separates the roots. Each root obtains a covering of pia mater, which becomes continuous with the neurilemma; "the arachnoid invests each root as far as the point where it meets with the dura mater; the two roots, after piercing the dura separately, are enclosed by it in a single tubular sheath, in which is included the spinal ganglion of the dorsal root."[1]

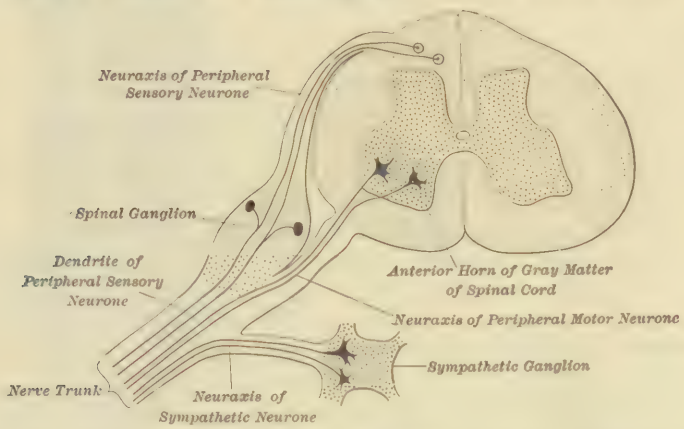

Fig. 631.—Diagram to show the composition of a peripheral nerve-trunk. (Böhm and Davidoff.)

The Ganglia of the Spinal Nerves (Ganglia Spinales) (Figs. 629, 630, 631).

A ganglion is developed upon the posterior root of each of the spinal nerves. The ganglion upon the posterior root of the first cervical nerve may be rudimentary or absent. These ganglia are of an oval form and of a reddish color; they bear a proportion in size to the nerves upon which they are formed, and are placed in the intervertebral foramina, external to the point where the nerves perforate

[1] Cunningham's Text-book of Anatomy.

the dura mater. Each ganglion is bifid internally, where it is joined by the two bundles of the posterior root, the two portions being united into a single mass externally. The ganglia upon the first and second cervical nerves form an exception to these characters, being placed on the arches of the vertebrae over which the nerves pass. The ganglia of the sacral nerves are placed within the spinal canal; and that on the coccygeal nerve, also in the canal, is situated at some distance from the origin of the posterior root.

The ganglion in an embryo is composed of bipolar nerve-cells. In an adult the bipolar nerve-cells by fusion of their two poles form unipolar nerve-cells. The process of each unipolar cell divides into two a short distance from the cell. One of the processes from each cell passes to the spinal cord, and the other passes into the spinal nerve. On the dorsal roots of the lumbar and sacral nerves, between the spinal ganglia and the cord, small cellular masses occasionally exist. They are called **accessory spinal ganglia** (*ganglia aberrantia*).

Distribution of the Spinal Nerves.

Immediately beyond the ganglion the two roots coalesce, their fibres intermingle, and the trunk thus formed constitutes the **spinal nerve**; it passes out of the intervertebral foramen, and divides into a **posterior primary division** for the supply of the posterior part of the body, and an **anterior primary division** for the supply of the anterior part of the body (Fig. 630). Each division contains fibres from both roots.

Before dividing, each spinal nerve gives off a small **recurrent** or **meningeal branch** (*ramus meningeus*) (Fig. 630), which is joined by a filament from the **communicating branch of the sympathetic** (*ramus communicans*) (Fig. 630), which connects the ganglion with the anterior division. The meningeal branches unite and form one nerve, which passes inward through the intervertebral foramen and supplies the dura mater, sending branches to the vertebrae and vertebral ligaments.

The Posterior Primary Divisions (*rami posteriores*) (Fig. 630).—The posterior primary divisions of the spinal nerves are generally smaller than the anterior; they arise from the trunk resulting from the union of the roots, in the intervertebral foramina; and, passing backward, divide into **internal** and **external branches**, which are distributed to the muscles and integument behind the spine. The posterior primary divisions of the spinal nerves form two small plexuses, the **posterior cervical plexus** and the **posterior sacral plexus**. The first cervical, the fourth and fifth sacral, and the coccygeal nerves do not divide into external and internal branches.

The Anterior Primary Divisions (*rami anteriores*) (Fig. 630).—The anterior primary divisions of the spinal nerves supply the parts of the body in front of the spine, including the limbs. They are for the most part larger than the posterior primary divisions. Each division, soon after its origin, receives a slender filament from the sympathetic, which is called the **gray ramus communicans**. In the dorsal region the anterior primary divisions of the spinal nerves are quite separate from each other, and are uniform in their distribution; but in the cervical, lumbar, and sacral regions they form intricate plexuses previous to their distribution. The anterior primary divisions of certain dorsal, lumbar, and sacral nerves give off a delicate collection of nerve filaments to the sympathetic cord. These are called the **white rami communicantes** or the **visceral branches of the spinal nerves.**

Points of Emergence of the Spinal Nerves.

The roots of the spinal nerves from their origin in the cord run obliquely downward to their point of exit from the intervertebral foramina, the amount of obliquity varying in different regions of the spine, and being greater in the lower

than the upper part. The level of their emergence from the cord is within certain limits variable, and of course does not correspond to the point of emergence of the nerve from the intervertebral foramina.

The following table, from Macalister, shows as accurately as can be shown the relation of these points of origin from the spinal cord to the bodies and spinous processes of the vertebrae:

THE CERVICAL NERVES (NN. CERVICALES).

The Roots of the Cervical Nerves.

The *roots* of the cervical nerves increase in size from the first to the fifth, and then remain the same size to the eighth. The posterior roots bear a proportion to the anterior as 3 to 1, which is much greater than in any other region, the individual filaments being also much larger than those of the anterior roots. The posterior root of the first cervical is an exception to this rule; it is smaller than the anterior root. In direction the roots of the cervical are less oblique than those of the other spinal nerves. The first cervical nerve is directed a little upward and outward; the second is horizontal; the others are directed obliquely downward and outward, the lowest being the most oblique, and consequently longer than the upper, the distance between their place of origin and their point of exit from the spinal canal never exceeding the depth of one vertebra.

The First Cervical or Suboccipital Nerve (*n. suboccipitalis*) (Fig. 632).—The posterior root may be rudimentary or absent. The trunk of the first cervical nerve leaves the spinal canal between the occipital bone and the posterior arch of the atlas (Figs. 16 and 202).

The **Trunk of the Second Cervical Nerve** leaves the spinal canal between the posterior arch of the atlas and the lamina of the axis; and the **Eighth** (the last), between the last cervical and first dorsal vertebrae.

Each nerve, at its exit from the intervertebral foramen, divides into a **posterior** and an **anterior division.** The anterior divisions of the four upper cervical nerves form the **cervical plexus.** The anterior divisions of the four lower cervical nerves, together with the first dorsal, form the **brachial plexus.**

The Posterior or Dorsal Divisions of the Cervical Nerves (Rami Posteriores) (Fig. 633).

The **Posterior Division of the First Cervical Nerve** (Figs. 632 and 633) differs from the posterior divisions of the other cervical nerves in not dividing into an internal and external branch. It is larger than the anterior division, and escapes from the spinal canal between the occipital bone and the posterior arch of the atlas,

lying beneath the vertebral artery. It enters the suboccipital triangle formed by the Rectus capitis posticus major, the Obliquus superior and Obliquus inferior, and, by **muscular branches,** supplies the Recti and Obliqui muscles, and the Complexus. From the branch which supplies the Inferior oblique a communicating filament is given off which joins the second cervical nerve. This nerve also occasionally gives off a cutaneous filament, which accompanies the occipital artery and communicates with the occipitalis major and minor nerves.

The **Posterior Division of the Second Cervical Nerve** is three or four times greater in diameter than the anterior division, and the largest of all the posterior cervical divisions. It emerges from the spinal canal between the posterior arch of the atlas and lamina of the axis, below the Inferior oblique. It supplies a twig to this muscle, and receives a communicating filament from the first cervical. It then divides into an **internal** and an **external branch.**

The **internal branch,** called, from its size and distribution, the **great occipital nerve** (*occipitalis major*) (Figs. 632 and 633), ascends obliquely inward between the Obliquus inferior and Complexus, and pierces the latter muscle and the Trapezius

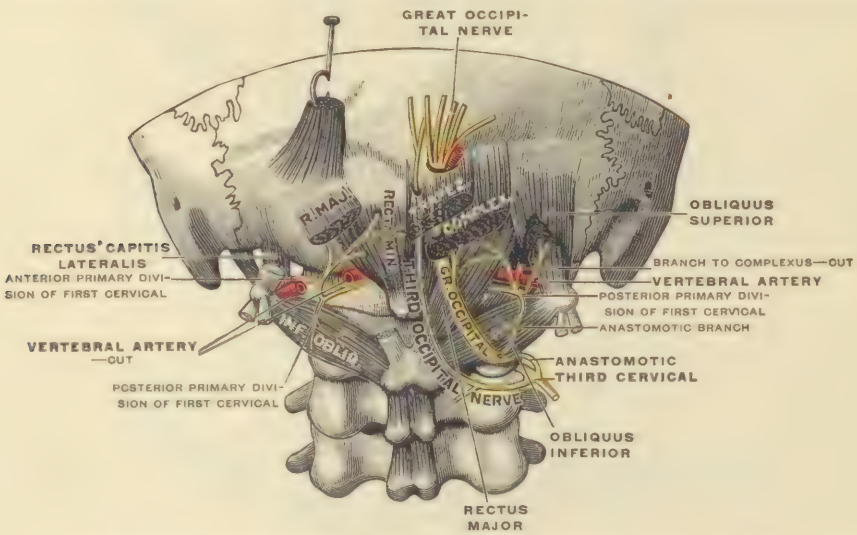

Fig. 632.—Dorsal primary divisions of the upper three cervical nerves. (Testut.)

near their attachments to the cranium. It is now joined by a filament from the posterior division of the third cervical nerve, the **anastomotic,** and, ascending on the back part of the head with the occipital artery, divides into two branches, which supply the integument of the scalp as far forward as the vertex, communicating with the occipitalis minor. It gives off an **auricular branch** to the back part of the ear and **muscular branches** to the Complexus.

The **external branch** is often joined by the external branch of the posterior division of the third cervical nerve, and supplies the Splenius, Trachelo-mastoid, and Complexus

The **Posterior Division of the Third Cervical Nerve** (Figs. 632 and 633) is smaller than the preceding, but larger than the fourth; it differs from the posterior divisions of the remaining cervical nerves in its supplying an additional filament, the **third occipital nerve,** to the integument of the occiput. The posterior division of the third nerve, like the others, divides into an **internal** and **external branch.**

The **internal** or **cutaneous branch** passes between the Complexus and Semispinalis, and, piercing the Splenius and Trapezius, supplies the skin over the latter muscle.

The **external branch** joins with that of the posterior division of the second to supply the Splenius, Trachelo-mastoid, and Complexus.

The **third** or **least occipital nerve** (*n. occipitalis minimus* or *n. occipitalis tertius*) (Fig. 632) *arises* from the internal or cutaneous branch of the posterior division of the third cervical nerve, beneath the Trapezius; it then pierces that muscle, and supplies the skin on the lower and back part of the head. It lies to the inner side of the occipitalis major, with which it is connected.

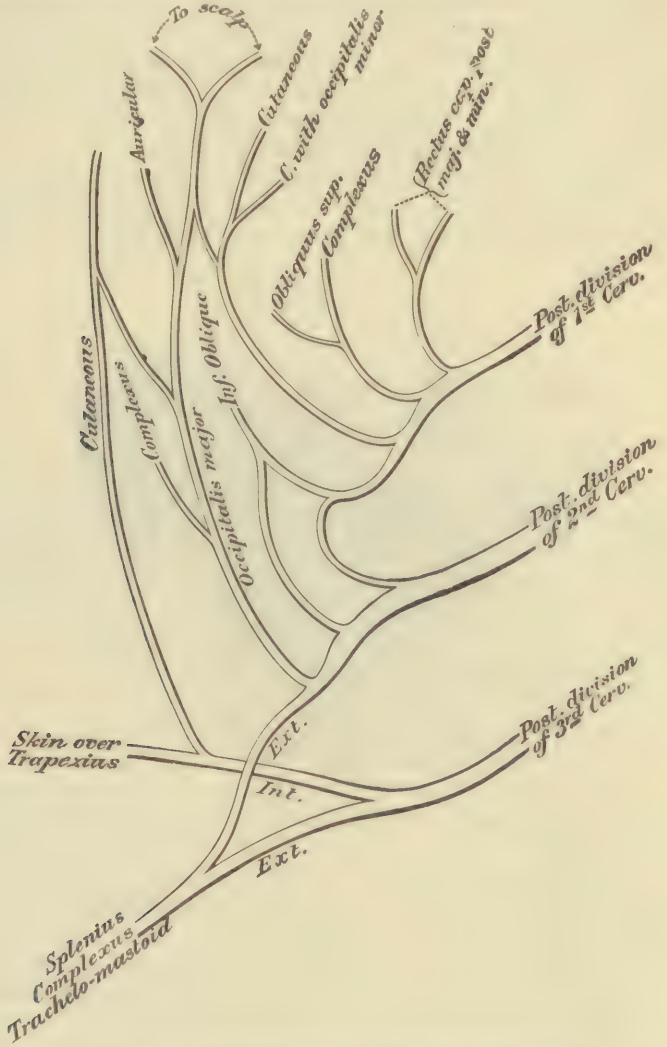

Fig. 633.—Posterior divisions of the upper cervical nerves.

The posterior division of the suboccipital nerve and the internal branches of the posterior divisions of the second and third cervical nerves are occasionally joined beneath the Complexus by communicating branches. This communication is described by Cruveilhier as the **posterior cervical plexus.**

The **Posterior Divisions of the Fourth, Fifth, Sixth, Seventh,** and **Eighth Cervical Nerves** pass backward, and divide, behind the Intertransversales muscles, into **internal** and **external branches.**

The **internal branches,** the larger, are distributed differently in the upper and lower part of the neck. Those derived from the fourth and fifth nerves pass

between the Complexus and Semispinalis muscles, and, having reached the spinous processes, perforate the aponeurosis of the Splenius and Trapezius, and are continued outward to the integument over the Trapezius, whilst those derived from the three lowest cervical nerves are the smallest, and are placed beneath the Semispinalis colli, which they supply, and then pass into the Interspinalis, Multifidus spinae, and Complexus, and send twigs through this latter muscle to supply the integument near the spinous processes (Hirschfeld).

The **external branches** supply the muscles at the side of the neck—viz., the Cervicalis ascendens, Transversalis colli, and Trachelo-mastoid.

The Anterior Divisions of the Cervical Nerves (Rami Anteriores).

The **Anterior Division of the First Cervical Nerve** (Fig. 635) is of small size. It escapes from the spinal canal through a groove upon the posterior arch of the atlas. In this groove it lies beneath the vertebral artery, to the inner side of the Rectus capitis lateralis. As it crosses the foramen in the transverse process of the atlas it receives a filament from the sympathetic. It then descends in front of the transverse process, to communicate with an ascending branch from the second cervical nerve.

Communicating filaments from the loop between this nerve and the second cervical nerve join the pneumogastric, the hypoglossal, and sympathetic, and some branches are distributed to the Rectus lateralis and the two Anterior recti. The fibres which communicate with the hypoglossal simply pass through the latter nerve to become for the most part the **descendens hypoglossi.** According to Valentin, the anterior division of the suboccipital nerve distributes filaments to the occipito-atlantal articulation and to the mastoid process of the temporal bone.

The **Anterior Division of the Second Cervical Nerve** (Fig. 635) escapes from the spinal canal, between the posterior arch of the atlas and the lamina of the axis, and, passing forward on the outer side of the vertebral artery, divides in front of the Intertransverse muscle into an **ascending branch,** which joins the first cervical; and one or two **descending branches,** which join the third cervical. It gives off the **small occipital**; a branch to assist in forming the **great auricular**; another to assist in forming the **superficial cervical**; one of the **communicantes hypoglossi,** and a filament to the Sterno-mastoid, which communicates in the substance of the muscle with the spinal accessory.

The **Anterior Division of the Third Cervical Nerve** (Fig. 635) is double the size of the preceding. At its exit from the intervertebral foramen it passes downward and outward beneath the Sterno-mastoid muscle, and divides into two branches. The **ascending branch** joins the anterior division of the second cervical; the **descending branch** passes down in front of the Scalenus anticus muscle and communicates with the fourth cervical. It gives off the larger part of the **great auricular** and **superficial cervical nerves**; one of the **communicantes hypoglossi**; a branch to the supraclavicular nerves; a filament to assist in forming the **phrenic**; and muscular branches to the Levator anguli scapulae and Trapezius; this latter nerve communicates beneath the muscle with the spinal accessory. Sometimes the nerve to the Scalenus medius is derived from this source.

The **Anterior Division of the Fourth Cervical Nerve** (Fig. 635) is of the same size as the preceding. It receives a branch from the third, sends a communicating branch to the fifth cervical, and, passing downward and outward, divides into numerous filaments, which cross the posterior triangle of the neck, forming the **supraclavicular nerves.** It gives a branch to the **phrenic nerve,** while it is contained in the intertransverse space, and sometimes a branch to the Scalenus medius muscle. It also gives a branch to the Levator anguli scapulae and to the Trapezius, which unites

with the branch given off from the third nerve, and communicates beneath the muscle with the spinal accessory.

The **Anterior Divisions of the Fifth, Sixth, Seventh,** and **Eighth Cervical Nerves** are remarkable for their size. They are much larger than the preceding nerves, and are all of equal dimensions. They assist in the formation of the brachial plexus.

The Cervical Plexus (Plexus Cervicalis) (Figs. 634 and 635).

The cervical plexus is formed by the anterior divisions of the four upper cervical nerves. It is situated opposite the four upper cervical vertebrae, resting upon the Levator anguli scapulae and Scalenus medius muscles, and covered in by the Sterno-mastoid.

Its branches may be divided into two groups, **superficial** and **deep,** which may be thus arranged:

- *Superficial*
  - Ascending
    - Occipitalis minor.
    - Auricularis magnus.
    - Superficialis colli.
  - Descending
    - Supraclavicular
      - Suprasternal.
      - Supraclavicular.
      - Supra-acromial.
- *Deep*
  - Internal
    - Communicating.
    - Muscular.
    - Communicantes hypoglossi.
    - Phrenic.
  - External
    - Communicating.
    - Muscular.

The Superficial Branches of the Cervical Plexus. The Small Occipital Nerve (*n. occipitalis minor*) (Fig. 634).—The small occipital nerve *arises* from the second cervical nerve, sometimes also from the third; it curves round the posterior border of the Sterno-mastoid, and ascends, running parallel to the posterior border of the muscle, to the back part of the side of the head. Near the cranium it perforates the deep fascia, and is continued upward along the side of the head behind the ear, supplying the integument, and communicating with the occipitalis major, the auricularis magnus, and with the posterior auricular branch of the facial.

This nerve gives off an **auricular branch,** which supplies the integument of the upper and back part of the auricle, communicating with the mastoid branch of the auricularis magnus. The auricular branch is occasionally derived from the great occipital nerve. The occipitalis minor varies in size; it is occasionally double.

The Great Auricular Nerve (*n. auricularis magnus*) (Fig. 634).—The great auricular nerve is the largest of the ascending branches. It arises from the second and third cervical nerves, winds around the posterior border of the Sterno-mastoid, and, after perforating the deep fascia, ascends upon that muscle beneath the Platysma to the parotid gland, where it divides into **facial, auricular,** and **mastoid branches.**

The **Facial Branches** pass across the parotid, and are distributed to the integument of the face over the parotid gland; others penetrate the substance of the gland and communicate with the facial nerve.

The **Auricular Branches** ascend to supply the integument of the back of the pinna, except at its upper part, communicating with the auricular branches of the facial and pneumogastric nerves. A filament pierces the pinna to reach its outer surface, where it is distributed to the lobule and lower part of the concha.

The **Mastoid Branch** communicates with the occipitalis minor and the posterior auricular branch of the facial, and is distributed to the integument behind the ear.

The Superficial Cervical Nerve or the Superficialis Colli (*n. cutaneus colli*) (Fig. 634).—The superficial cervical nerve or the superficialis colli *arises* from the second and third cervical nerves, turns around the posterior border of the Sterno-

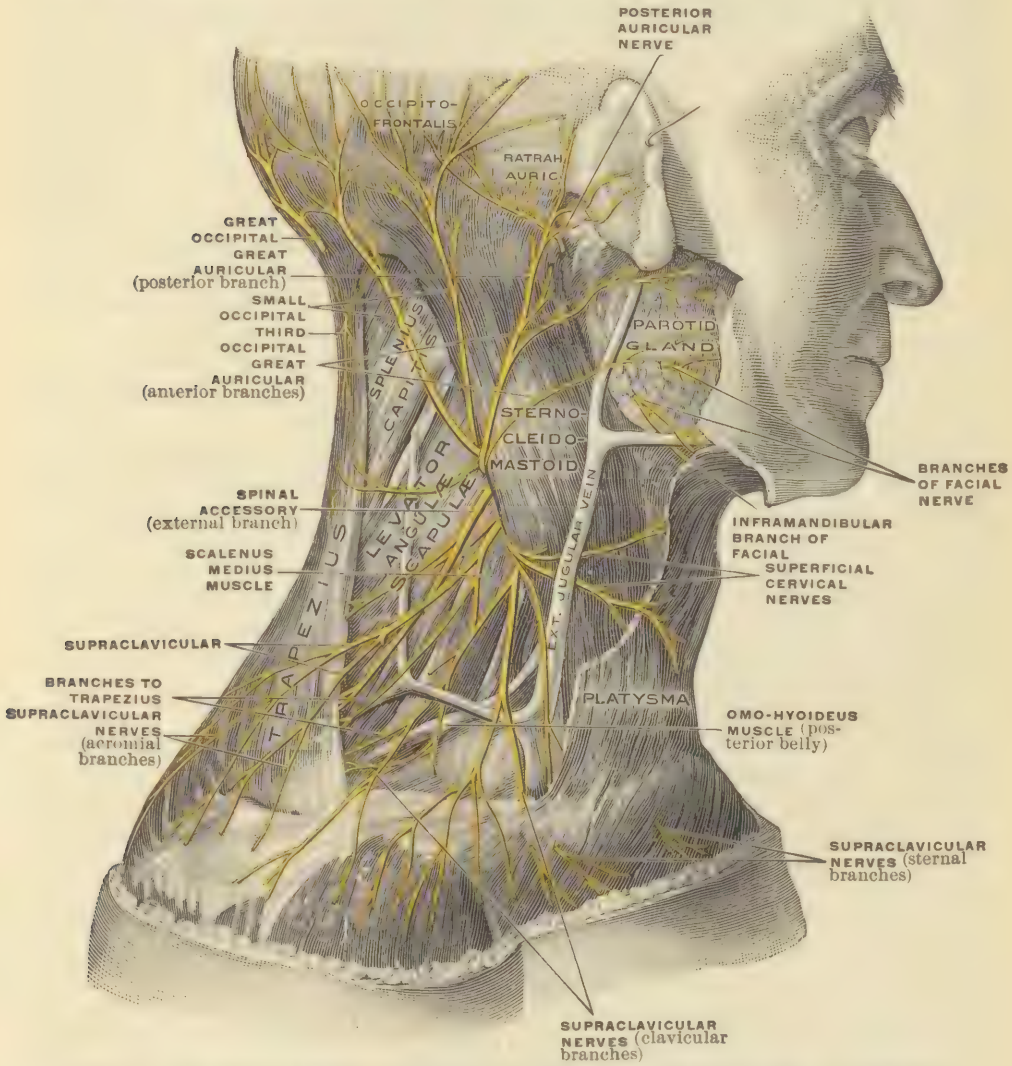

FIG. 634.—The cutaneous branches of the right cervical plexus, viewed from the right. The Platysma has been partly removed. (Spalteholz.)

mastoid about its middle, and, passing obliquely forward beneath the external jugular vein to the anterior border of the muscle, perforates the deep cervical fascia, and divides beneath the Platysma into two branches, which are distributed to the antero-lateral parts of the neck.

The **Ascending Branch** or **Branches** (*rami superiores*) gives a filament which accompanies the external jugular vein; it then passes upward to the submaxillary region, and divides into branches, some of which form a plexus with the cervical branches of the facial nerve beneath the Platysma; others pierce

that muscle and are distributed to the integument of the upper half of the neck, at its forepart, as high as the chin.

The **Descending Branches** (*rami inferiores*), usually represented by two or more filaments, pierce the Platysma, and are distributed to the integument of the side and front of the neck, as low as the sternum.

The Descending or Supraclavicular Branches (*nn. supraclaviculares*) (Fig. 634).—The descending or supraclavicular branches *arise* from the third and fourth cervical nerves; emerging beneath the posterior border of the Sterno-mastoid, they descend in the posterior triangle of the neck beneath the Platysma and deep cervical fascia. Near the clavicle they perforate the fascia and Platysma to become cutaneous, and are arranged, according to their position, into three groups.

The **Inner** or **Suprasternal Branches** (*nn. supraclaviculares anteriores*) cross obliquely over the external jugular vein and the clavicular and sternal attachments of the Sterno-mastoid muscle, and supply the integument as far as the median line. They furnish one or two filaments to the sterno-clavicular joint.

The **Middle** or **Supraclavicular Branches** (*nn. supraclaviculares medii*) cross the clavicle, and supply the integument over the Pectoral and Deltoid muscles, communicating with the cutaneous branches of the upper intercostal nerves.

The **External** or **Supra-acromial Branches** (*nn. supraclaviculares posteriores*) pass obliquely across the outer surface of the Trapezius and the acromion, and supply the integument of the upper and back part of the shoulder.

The Deep Branches of the Cervical Plexus (Fig. 635). **Internal Series. The Communicating Branches.**—The communicating branches consist of several filaments which pass from the loop between the first and second cervical nerves in front of the atlas to the pneumogastric, hypoglossal, and sympathetic; of branches from all four cervical nerves to the superior cervical ganglion of the sympathetic, together with a branch from the fourth to the fifth cervical.

Muscular Branches.—Muscular branches supply the Anterior recti and Rectus lateralis muscles; they proceed from the first cervical nerve, and from the loop formed between it and the second.

The Communicantes Hypoglossi (Fig. 635).—The communicantes hypoglossi consist usually of two filaments, one being derived from the second and the other from the third cervical. These filaments pass downward on the outer side of the internal jugular vein, cross in front of the vein a little below the middle of the neck, and form a loop with the descendens hypoglossi in front of the sheath of the carotid vessels. Occasionally, the junction of these nerves takes place within the sheath.

The Phrenic or the Internal Respiratory Nerve of Bell (*n. phrenicus*) (Figs. 635 and 636).—The **phrenic** or the **internal respiratory nerve of Bell** *arises* chiefly from the fourth cervical nerve, with a few filaments from the third and a communicating branch from the fifth. It descends to the root of the neck, running obliquely across the front of the Scalenus anticus muscle, and beneath the Sterno-mastoid muscle, the posterior belly of the Omohyoid muscle, and the Transversalis colli and suprascapular vessels. It next passes over the first part of the subclavian artery, between it and the subclavian vein, and, as it enters the chest, crosses the internal mammary artery near its origin. Within the chest it descends nearly vertically in front of the root of the lung and by the side of the pericardium, between it and the mediastinal portion of the pleura, to the Diaphragm, where it divides into branches, some few of which are distributed to its thoracic surface, but most of which separately pierce that muscle and are distributed to its under surface (*rami phrenicoabdominales*).

The two phrenic nerves differ in their length, and also in their relations at the upper part of the thorax.

The **right phrenic nerve** is situated more deeply, and is shorter and more vertical in direction than the left; it lies on the outer side of the right vena innominata and superior vena cava.

The **left phrenic nerve** is rather longer than the right, from the inclination of the heart to the left side, and from the Diaphragm being lower on this than on the opposite side. It enters the thorax behind the left innominate vein, and crosses in front of the vagus and the arch of the aorta and the root of the lung. In the thorax each phrenic nerve is accompanied by a branch of the internal mammary artery, the **comes nervi phrenici.**

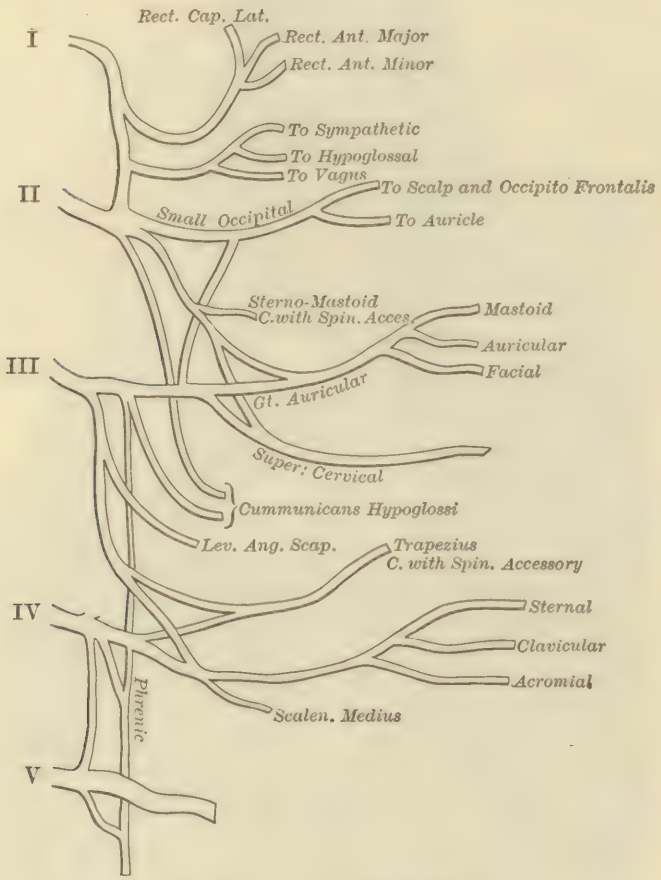

FIG. 635.—Plan of the cervical plexus.

Each nerve supplies filaments to the Diaphragm, pericardium, and pleura, and near the chest is joined by a filament from the sympathetic, and, occasionally, by one from the union of the descendens hypoglossi with the spinal nerves; this filament is found, according to Swan, only on the left side. The phrenic frequently receives a filament from the nerve to the Subclavian muscle. Branches have been described as passing to the peritoneum.

From the **right nerve** one or two filaments pass to join in a small ganglion with phrenic branches of the solar plexus; and branches from this ganglion are distributed to the hepatic plexus, the suprarenal capsule, and inferior vena cava.

From the **left nerve** filaments pass to join the phrenic plexus of the sympathetic, but without any ganglionic enlargement.

Surgical Anatomy.—Irritation of the phrenic nerve causes hiccough and persistent cough. Bilateral paralysis of the phrenic causes death from paralysis of the Diaphragm. This form of death is seen by the surgeon in fracture-dislocation of the third cervical vertebra. Division of the phrenic on one side is not fatal, and is occasionally practised by the surgeon in removing a tumor of the neck. In Hearn's and Franklin's cases of removal of the pneumogastric, the phrenic was also divided. Unilateral division of the phrenic nerve causes paralysis of the corresponding half of the Diaphragm, which is difficult of recognition, because, as Gowers points out, the patient can still take deep inspirations, the thoracic muscles not being paralyzed.

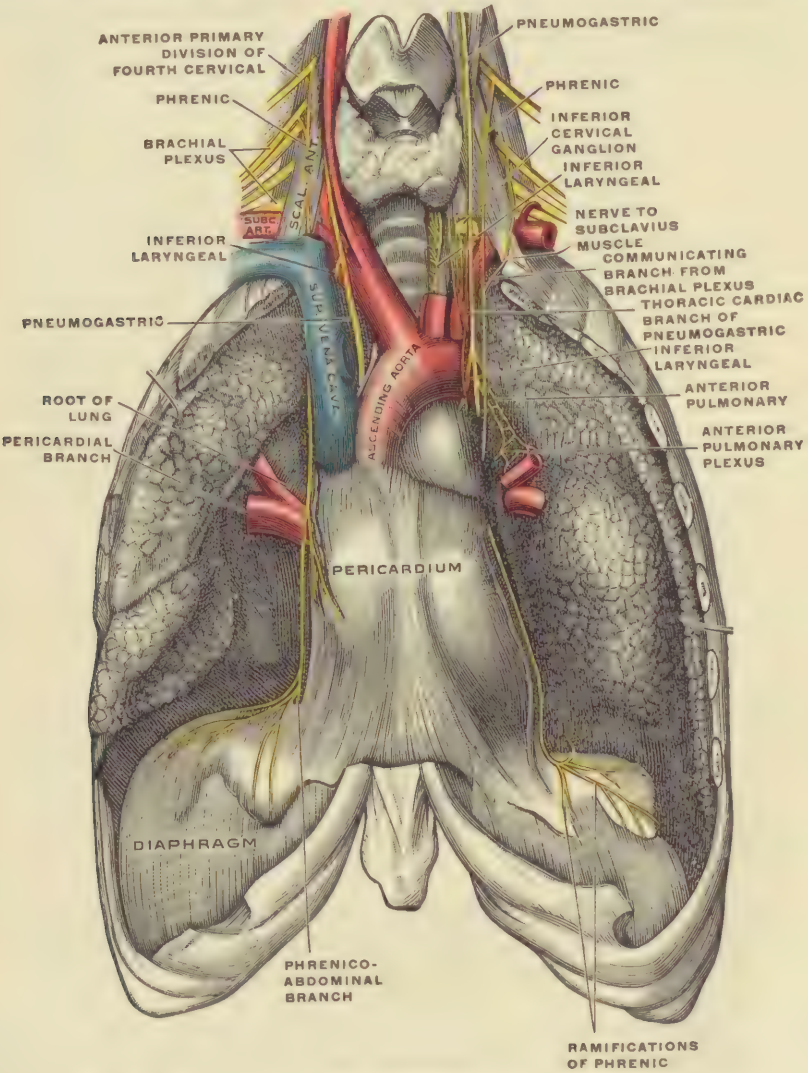

FIG. 636.—The phrenic nerve and its relations with the vagus nerve. (Toldt.)

The Deep Branches of the Cervical Plexus. External Series. Communicating Branches.—The deep branches of the external series of the cervical plexus communicate with the spinal accessory nerve, in the substance of the Sterno-mastoid muscle, in the posterior triangle, and beneath the Trapezius.

Muscular Branches.—Muscular branches are distributed to the Sterno-mastoid, Trapezius, Levator anguli scapulae, and Scalenus medius.

The branch for the Sterno-mastoid is derived from the second cervical; the Trapezius and Levator anguli scapulae receive branches from the third and fourth.

The Scalenus medius is derived sometimes from the third, sometimes the fourth, and occasionally from both nerves.

Surgical Anatomy.—The cervical plexus may be damaged by wounds or contusions, which may or may not be associated with fracture of the clavicle. Paralysis ensues, the extent depending on the degree of damage. After a contusion the paralysis is apt to be temporary and to be followed by pain and muscular spasm in the arm. Paralysis of the arm due to plexus injury may be partial or complete. In some cases there is complete motor palsy and partial sensory palsy, the sensory impulses passing along undamaged collaterals. In certain spasmodic difficulties the surgeon occasionally stretches the cervical plexus. It is reached by an incision at the posterior margin of the Sterno-cleido-mastoid muscle. This incision begins two inches below the level of the tip of the mastoid and is carried downward for three inches.

The Brachial Plexus (Plexus Brachialis) (Figs. 637, 638, 639).

The brachial plexus is formed by the union of the anterior divisions of the four lower cervical and the greater part of the first dorsal nerves, receiving usually

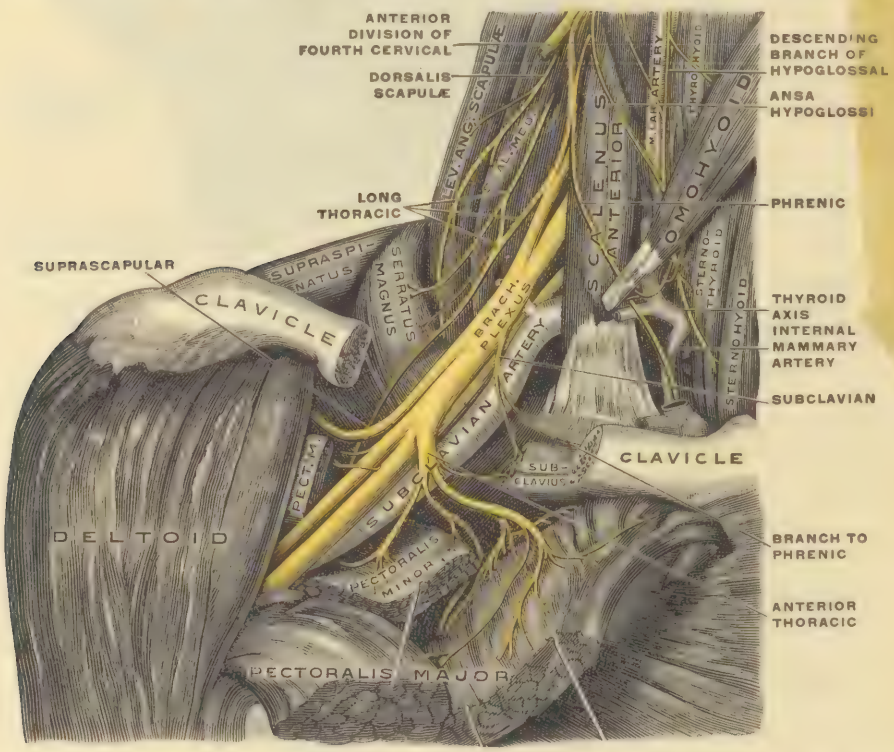

FIG. 637.—The right brachial plexus with its short branches, viewed from in front. The sterno-cleido-mastoid and trapezius muscles have been completely, the omohyoid and subclavian have been partially, removed; a piece has been sawed out of the clavicle; the pectoralis muscles have been incised and reflected. (Spalteholz.)

a fasciculus from the fourth cervical nerve, and frequently one from the second dorsal nerve. It extends from the lower part of the side of the neck to the axilla. It is very broad, and presents little of a plexiform arrangement at its commencement. It is narrow opposite the clavicle, becomes broad and forms a more dense interlacement in the axilla, and divides opposite the coracoid process into numerous branches for the supply of the upper limb. The nerves which form the plexus are all similar in size, and their mode of communication is subject to considerable variation, so that no one plan can be given as applying to every case. The following appears, however, to be the most constant arrangement: **above the clavicle**

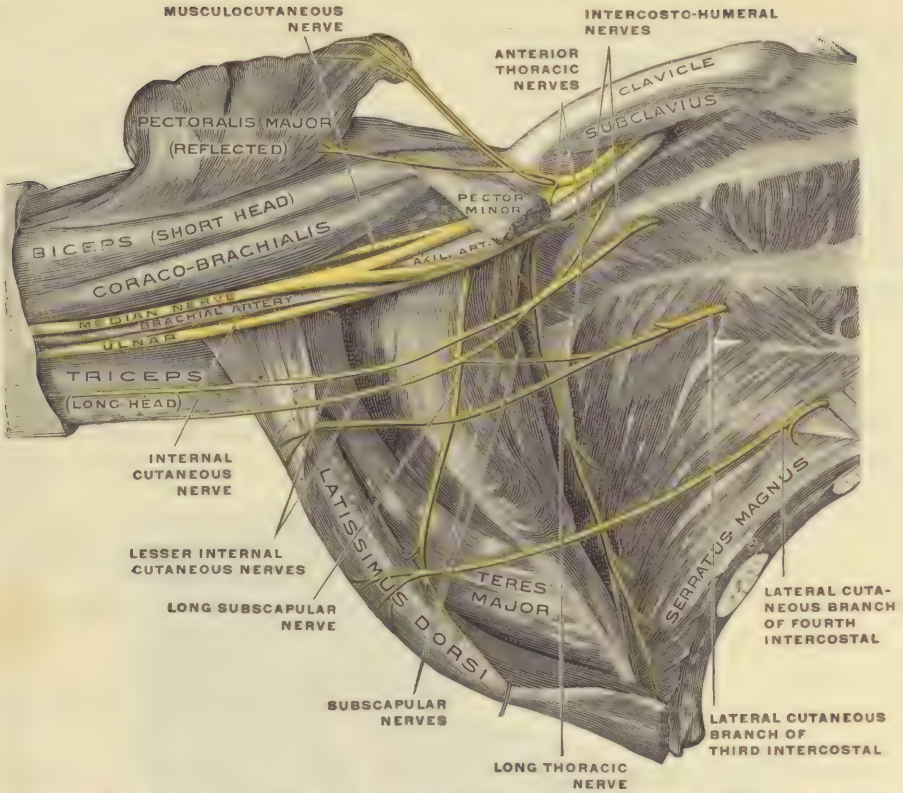

FIG. 638.—The right brachial plexus (infraclavicular portion) in the axilliary fossa, viewed from below and in front. The Pectoralis major and minor muscles have been in large part removed; their attachments have been reflected. (Spalteholz.)

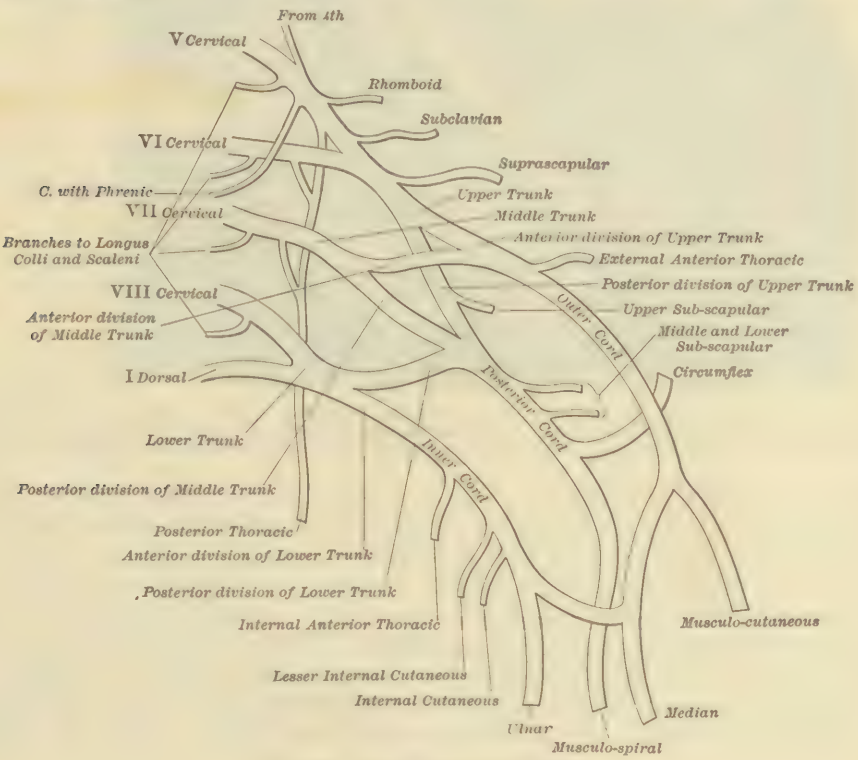

FIG. 639.—Plan of the brachial plexus.

(*pars supraclavicularis*) the fifth and sixth cervical unite together soon after their exit from the intervertebral foramina to form a common trunk. The eighth cervical and first dorsal also unite to form one trunk. So that the nerves forming the plexus, as they lie on the Scalenus medius external to the outer border of the

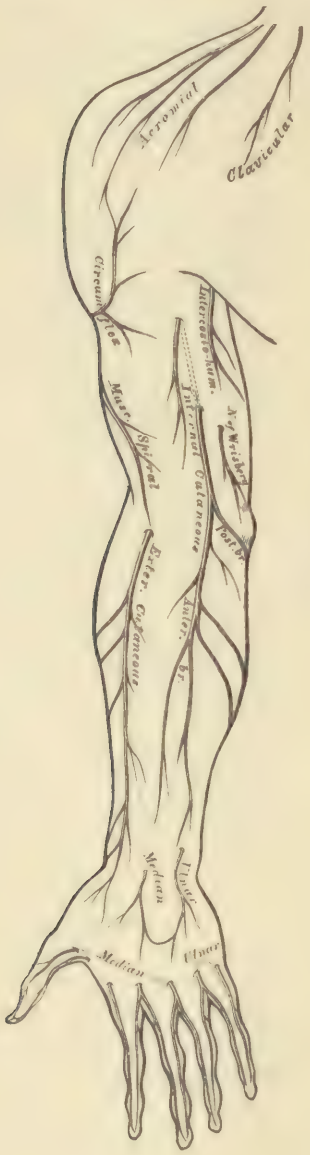

FIG. 640.—Cutaneous nerves of right upper extremity. Anterior view.

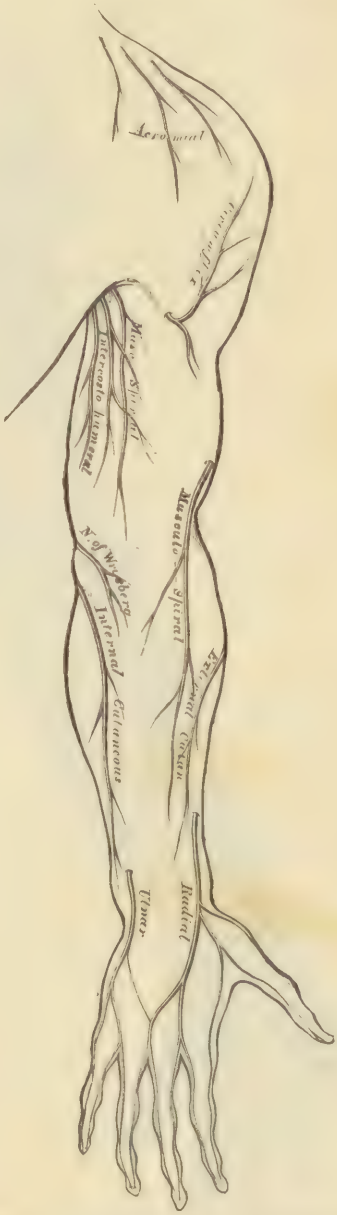

FIG. 641.—Cutaneous nerves of right upper extremity. Posterior view.

Scalenus anticus muscle, are blended into three trunks—an **upper one,** formed by the junction of the fifth and sixth cervical nerves; a **middle one,** consisting of the seventh cervical nerve; and a **lower one,** formed by the junction of the eighth cervical and first dorsal nerves. As they pass beneath the clavicle, to compose the infraclavicular **part of the plexus** (*pars infraclavicularis*), each of

these three trunks divides into two branches, an **anterior** and a **posterior**.[1] The anterior divisions of the upper and middle trunks then unite to form a common cord, which is situated on the outer side of the middle part of the axillary artery, and is called the **outer cord of the brachial plexus** (*fasciculus lateralis*). The anterior division of the lower trunk passes down on the inner side of the axillary artery in the middle of the axilla, and forms the **inner cord of the brachial plexus** (*fasciculus medialis*). The posterior divisions of all three trunks unite to form the **posterior cord of the brachial plexus** (*fasciculus posterior*), which is situated behind the second portion of the axillary artery. From this posterior cord are given off the two lower subscapular nerves, the upper subscapular nerve being given off from the posterior division of the upper trunk prior to its junction with the posterior division of the lower and middle trunks. The posterior cord divides into the circumflex and musculo-spiral nerves.

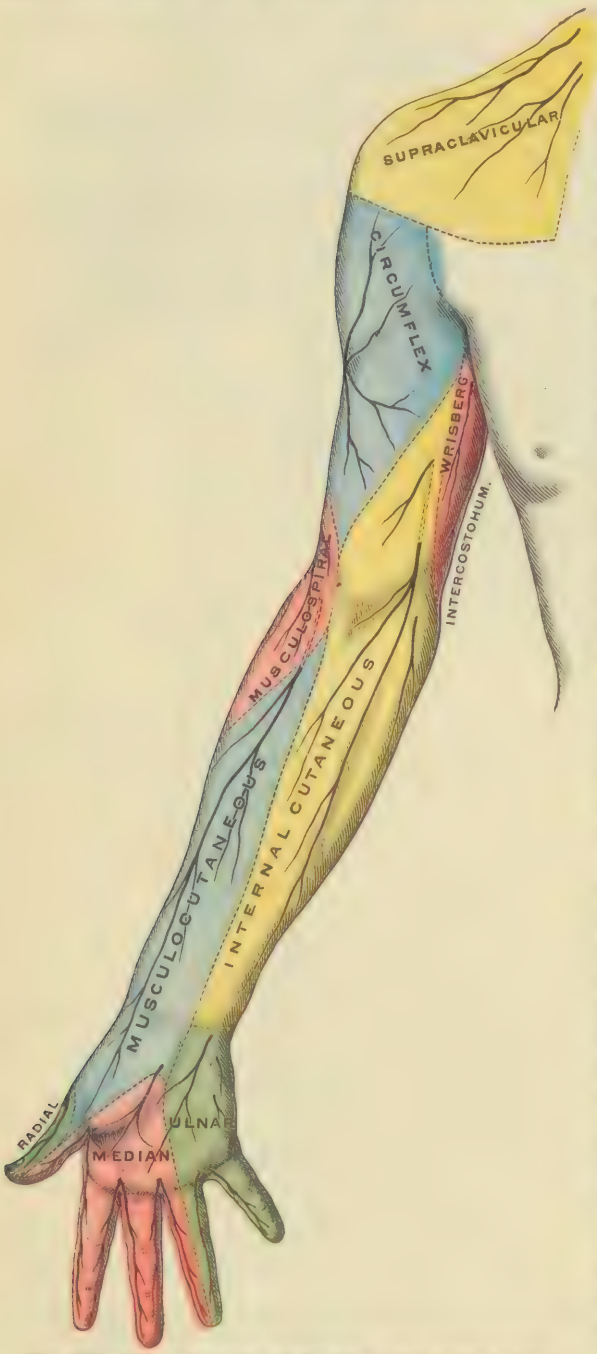

Fig. 642.—Cutaneous nerves of the upper limb, ventral aspect. (W. Keiller, in Gerrish's Text-book of Anatomy.)

The brachial plexus communicates with the cervical plexus by a branch from the fourth to the fifth cervical nerve, and with the phrenic nerve by a branch from the fifth cervical, which joins that nerve on the Anterior scalenus muscle; the fifth and sixth cervical nerves are joined by filaments to the middle cervical ganglion of the sympathetic, the seventh and eighth cervical to its inferior ganglion, and the first dorsal nerve to its first thoracic ganglion. Close to their exit from the intervertebral foramina the nerves give off the filaments to the ganglia.

Relations.—**In the neck**, the brachial plexus lies in the posterior triangle, being covered by the skin, Platysma, and deep fascia; it is crossed by the posterior belly

[1] The posterior division of the lower trunk is very much smaller than the others, and is frequently derived entirely from the eighth cervical nerve.—Ed. of 15th English edition.

of the Omo-hyoid muscle and by the transversalis colli artery. When the posterior scapular artery arises from the third part of the subclavian it usually passes between the roots of the plexus. The plexus lies at first between the Anterior and Middle scaleni muscles, and then above and to the outer side of the subclavian artery; it next passes behind the clavicle and Subclavius muscle, lying upon the first serration of the Serratus magnus, and the Subscapularis muscles. It is in close relation with the apex of the lung (Luschka). **In the axilla** it is placed on the outer side of the first portion of the axillary artery; it surrounds the artery in the second part of its course, one cord lying upon the outer side of that vessel, one on the inner side, and one behind it, and at the lower part of the axillary space gives off its terminal branches to the upper extremity.

Branches.—The branches of the brachial plexus are arranged in two groups—viz., those given off **above the clavicle,** and those **below the clavicle.**

Branches above the Clavicle (Figs. 637 and 639).—The branches above the clavicle, from the *pars supraclavicularis,* are—the

Communicating.
Muscular.
Posterior thoracic.
Suprascapular.

The Communicating Branch (Figs. 636 and 639).—The communicating branch with the **phrenic** is derived from the fifth cervical nerve or from the loop between the fifth and sixth; it joins the phrenic on the Anterior scalenus muscle. The communications with the sympathetic have already been referred to.

FIG. 643.—Cutaneous nerve of the upper limb, dorsal aspect. (W. Keiller, in Gerrish's Text-book of Anatomy.)

The Muscular Branches (*rami musculares*).—The muscular branches supply the Longus colli, Scaleni, Rhomboidei, and Subclavius muscles. Those for the Longus colli and Scaleni arise from the four lower cervical nerves at their exit

from the intervertebral foramina. The Rhomboid branch is called the **posterior scapular nerve** (*n. dorsalis scapulae*) (Figs. 637 and 639), *arises* from the fifth

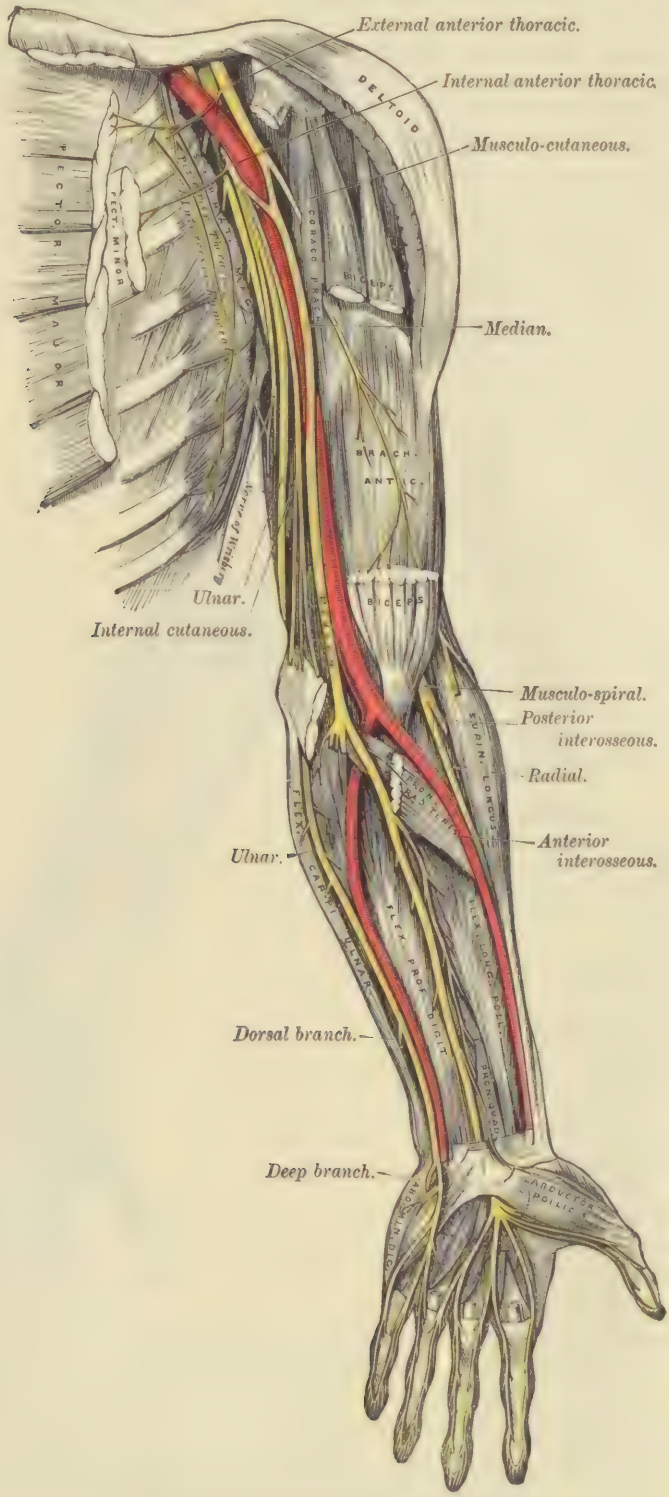

FIG. 644.—Nerves of the left upper extremity.

cervical, pierces the Scalenus medius, and passes beneath the Levator anguli scapulae, which it occasionally supplies, to the Rhomboid muscles. The nerve to the Subclavius (*n. subclavius*) is a small filament which arises from the fifth cervical at its point of junction with the sixth nerve; it descends in front of the third part of the subclavian artery to the Subclavius muscle, and is usually connected by a filament with the phrenic nerve.

The Posterior Thoracic, the Long Thoracic, or the External Respiratory Nerve of Bell (*n. thoracalis longus*) (Figs. 637, 638, 639, and 644).—The posterior thoracic, the long thoracic, or the external respiratory nerve of Bell supplies the Serratus magnus muscle, and is remarkable for the length of its course. It sometimes arises by two roots from the fifth and sixth cervical nerves immediately after their exit from the intervertebral foramina, but generally by three roots from the fifth, sixth, and seventh nerves. These unite in the substance of the Middle scalenus muscle, and, after emerging from it, the nerve passes down behind the brachial plexus and the axillary vessels, resting on the outer surface of the Serratus magnus. It extends along the side of the chest to the lower border of that muscle, supplying filaments to each of the muscular digitations.

The Suprascapular Nerve (*n. suprascapularis*) (Figs. 637, 639, and 645).—The suprascapular nerve arises from the cord formed by the fifth and sixth cervical nerves; passing obliquely outward beneath the Trapezius and the Omo-hyoid, it enters the supraspinous fossa below the transverse or suprascapular ligament, and, passing beneath the Supraspinatus muscle, curves around the external border of the spine of the scapula to the infraspinous fossa. In the supraspinous fossa it gives off two branches to the Supraspinatus muscle, and an articular filament to the shoulder-joint; and in the infraspinous fossa it gives off two branches to the Infraspinatus muscle, besides some filaments to the shoulder-joint and scapula

Branches below the Clavicle (Figs. 638 and 639).—The branches below the clavicle, that is, the branches from the *pars subclavicularis* of the brachial plexus, are derived from the three cords of the brachial plexus, in the following manner:

From the Outer Cord.—From the outer cord *arise* the external anterior thoracic nerve, the musculo-cutaneous, and the outer head of the median.

From the Inner Cord.—From the inner cord *arise* the internal anterior thoracic nerve, the internal cutaneous, the lesser internal cutaneous (nerve of Wrisberg), the ulnar, and inner head of the median.

From the Posterior Cord.—From the posterior cord *arise* two of the three subscapular nerves, the third taking origin from the posterior division of the trunk formed by the fifth and sixth cervical nerves; the cord then divides into the musculo-spiral and circumflex nerves.

These branches from below the clavicle may be arranged according to the parts they supply:

To the chest	Anterior thoracic.
To the shoulder	Subscapular. Circumflex.
To the arm, forearm, and hand .	Musculo-cutaneous. Internal cutaneous. Lesser internal cutaneous. Median. Ulnar. Musculo-spiral.

The fasciculi of which these nerves are composed may be traced through the plexus to the spinal nerves from which they originate. They are as follows:

External anterior thoracic	from	5th, 6th, and 7th cervical.
Internal anterior thoracic	"	8th cervical and 1st dorsal.
Subscapular	"	5th, 6th, 7th, and 8th cervical.
Circumflex	"	5th and 6th cervical.
Musculo-cutaneous	"	5th and 6th cervical.
Internal cutaneous	"	8th cervical and 1st dorsal.
Lesser internal cutaneous	"	1st dorsal.
Median	"	6th, 7th, and 8th cervical, and 1st dorsal.
Ulnar	"	8th cervical and 1st dorsal.
Musculo-spiral	"	6th, 7th, and 8th cervical, sometimes also from the 5th.

The Anterior Thoracic Nerves (*nn. thoracales anteriores*) (Figs. 637, 638, and 639).—The anterior thoracic nerves, two in number, supply the Pectoral muscles.

The **External** or **Superficial Anterior Thoracic Nerve** (Figs. 637 and 644), the larger of the two, *arises* from the outer cord of the brachial plexus, through which its fibres may be traced to the fifth, sixth, and seventh cervical nerves. It passes inward, across the axillary artery and vein, pierces the costo-coracoid membrane, and is distributed to the under surface of the Pectoralis major muscle. It sends down a communicating filament to join the internal anterior thoracic nerve, and this communicating filament forms a loop around the inner side of the axillary artery.

The **Internal** or **Deep Anterior Thoracic Nerve** *arises* from the inner cord, and through it from the eighth cervical and first dorsal nerves. It passes behind the first part of the axillary artery, then curves forward between the axillary artery and vein, and joins with the filament from the anterior nerve. It then passes to the under surface of the Pectoralis minor muscle, where it divides into a number of branches, which supply the muscle on its under surface. Some two or three branches pass through the muscle and reach the Pectoralis major.

The Subscapular Nerves (*nn. subscapulares*) (Figs. 638 and 639).—The subscapular nerves *arise* from the posterior cord of the plexus. There are three subscapular nerves, and they supply the Subscapularis, Teres major, and Latissimus dorsi muscles, and give filaments to the shoulder-joint. The fasciculi of which they are composed may be traced to the fifth, sixth, seventh, and eighth cervical nerves.

The **First, Short** or **Upper Subscapular Nerve**, the smallest, *arises* from the posterior division of the upper trunk of origin of the brachial plexus, and enters the upper part of the Subscapularis muscle; this nerve is frequently represented by two branches.

The **Second** or **Lower Subscapular Nerve** arises from the posterior end of the brachial plexus, enters the axillary border of the Subscapularis and terminates in the Teres major. The latter muscle is sometimes supplied by a separate branch.

The **Third, Middle** or **Long Subscapular Nerve** (*n. thoracodorsalis*) (Fig. 638), the largest of the three, *arises* from the posterior end of the brachial plexus and follows the course of the subscapular artery, along the posterior wall of the axilla to the Latissimus dorsi muscle, through which it may be traced as far as its lower border.

The Circumflex Nerve (*n. axillaris*) (Figs. 639 and 645).—The circumflex nerve supplies some of the muscles, the shoulder-joint, and the integument of the shoulder (Figs. 640 and 641). It *arises* from the posterior cord of the brachial plexus, in common with the musculo-spiral nerve, and its fibres may be traced through the posterior cord to the fifth and sixth cervical nerves. It is at first placed behind the axillary artery, between it and the Subscapularis muscle, and passes downward

and outward to the lower border of that muscle. It then winds backward in company with the posterior circumflex artery, through a **quadrilateral space** bounded above by the Teres minor muscle, below by the Teres major muscle, internally by the long head of the Triceps muscle, and externally by the neck of the humerus. The nerve then divides into two branches.

The **Upper Branch** (Fig. 645) winds backward around the surgical neck of the humerus, beneath the Deltoid, with the posterior circumflex vessels, as far as the anterior border of that muscle, supplying it, and giving off cutaneous branches, which pierce the muscle and ramify in the integument covering its lower part (Fig. 642).

The **Lower Branch** (Fig. 645), at its origin, distributes filaments to the Teres minor and back part of the Deltoid muscles. Upon the filaments to the former muscle an oval enlargement usually exists. The nerve then pierces the deep fascia, and supplies the integument over the lower two-thirds of the posterior surface of the Deltoid (*n. cutaneus brachii lateralis*), as well as that covering the long head of the Triceps (*caput longum n. tricipitis brachii*) (Fig. 643).

The circumflex nerve, before its division, gives off an **articular filament,** which enters the shoulder-joint below the Subscapularis muscle.

The Musculo-cutaneous or the External Cutaneous Nerve or the Perforating Nerve of Casserius[1] (*n. musculocutaneus*) (Figs. 638, 639, and 644).—The musculo-cutaneous, or the external cutaneous nerve, supplies some of the muscles of the arm and the integument of the forearm. It *arises* from the outer cord of the brachial plexus, opposite the lower border of the Pectoralis minor muscle, receiving filaments from the fifth, sixth, and seventh cervical nerves. It perforates the **Coraco-brachialis muscle** (Fig. 644), passes obliquely between the Biceps and Brachialis anticus muscles to the outer side of the arm, and, a little above the elbow, winds around the outer border of the tendon of the Biceps, and, perforating the deep fascia, becomes cutaneous (Fig. 640). This nerve, in its course through the arm, supplies the Coraco-brachialis, Biceps, and the greater part of the Brachialis anticus muscles. The branch to the Coraco-brachialis is given off from the nerve close to its origin, and in some instances, as a separate filament from the outer cord of the plexus. The branches to the Biceps and Brachialis anticus are given off after the nerve has pierced the Coraco-brachialis. The nerve also sends a small branch to the humerus, which enters the **nutrient foramen** with the accompanying artery, and a filament, from the branch supplying the Brachialis anticus, goes to the elbow-joint. The musculo-cutaneous furnishes the chief nerve supply to this joint.

The **Cutaneous Portion of the Musculo-cutaneous Nerve** (*n. cutaneus antibrachii lateralis*) passes behind the median cephalic vein, and divides, opposite the elbow-joint, into an **anterior** and a **posterior branch.**

The **anterior branch** descends along the radial border of the forearm to the wrist, and supplies the integument over the outer half of the anterior surface. At the wrist-joint it is placed in front of the radial artery, and some filaments, piercing the deep fascia, accompany that vessel to the back of the wrist, supplying the carpus. The nerve then passes downward to the ball of the thumb, where it terminates in cutaneous filaments. It communicates with a branch from the radial nerve and with the palmar cutaneous branch of the median.

The **posterior branch** passes downward along the back part of the radial side of the forearm to the wrist. It supplies the integument of the lower third of the forearm, communicating with the radial nerve and the external cutaneous branch of the musculo-spiral. The cutaneous areas supplied by the musculo-cutaneous nerve are indicated in Figs. 642 and 643.

The musculo-cutaneous nerve presents frequent irregularities. It may adhere

[1] See foot-note, page 1027.

for some distance to the median and then pass outward, beneath the Biceps, instead of through the Coraco-brachialis. Frequently some of the fibres of the median run for some distance in the musculo-cutaneous and then leave it to join their proper trunk. Less frequently the reverse is the case, and the median sends a branch to join the musculo-cutaneous. Instead of piercing the Coraco-brachialis muscle the nerve may pass under it or through the Biceps. Occasionally it gives a filament to the Pronator radii teres muscle, and it has been seen to supply the back of the thumb when the radial nerve was absent.

The Internal Cutaneous Nerve (*n. cutaneus antibrachii medialis*) (Figs. 638, 639, and 644).—The internal cutaneous nerve is one of the smallest branches of the brachial plexus. It *arises* from the inner cord in common with the ulnar nerve and internal head of the median nerve, and, at its commencement, is placed on the inner side of the axillary artery, and afterward of the brachial artery. It derives its fibres from the eighth cervical and first dorsal nerves. It passes down the inner side of the arm, pierces the deep fascia with the basilic vein, about the middle of the limb, and, becoming cutaneous, divides into two branches, **anterior** and **posterior**.

This nerve gives off, near the axilla, a cutaneous filament, which pierces the fascia and supplies the integument covering the Biceps muscle nearly as far as the elbow. This filament lies a little external to the common trunk, from which it arises.

The **anterior branch**, the larger of the two, passes usually in front of, but occasionally behind, the median basilic vein. It then descends on the anterior surface of the ulnar side of the forearm, distributing filaments to the integument as far as the wrist, and communicating with a cutaneous branch of the ulnar nerve (Fig. 640).

The **posterior branch** passes obliquely downward on the inner side of the basilic vein, passes in front of, or over, the internal condyle of the humerus to the back of the forearm, and descends on the posterior surface of its ulnar side as far as the wrist, distributing filaments to the integument (Fig. 641). It communicates, above the elbow, with the lesser internal cutaneous nerve, and above the wrist with the dorsal cutaneous branch of the ulnar nerve (Swan). The cutaneous areas supplied by the internal cutaneous nerve are indicated in Figs. 642 and 643.

The Lesser Internal Cutaneous Nerve or the Nerve of Wrisberg (*n. cutaneus brachii medialis*) (Figs. 638, 639, and 644).—The lesser internal cutaneous nerve is distributed to the integument on the inner side of the arm. It is the smallest of the branches of the brachial plexus, and, arising from the inner cord, receives its fibres from the first dorsal nerve. It passes through the axillary space, at first lying behind, and then on the inner side of, the axillary vein, and communicates with the intercosto-humeral nerve. It descends along the inner side of the brachial artery to the middle of the arm, where it pierces the deep fascia, and is distributed to the integument of the back part of the lower third of the arm, extending as far as the elbow (Figs. 640, 641, and 642), where some filaments are lost in the integument in front of the inner condyle, and others over the olecranon. It communicates with the posterior branch of the internal cutaneous nerve.

In some cases the nerve of Wrisberg and the **intercosto-humeral nerve** are connected by two or three filaments which form a plexus at the back part of the axilla. In other cases the intercosto-humeral is of large size, and takes the place of the nerve of Wrisberg, receiving merely a filament of communication from the brachial plexus, which filament represents the latter nerve. In other cases this filament is wanting, the place of the nerve of Wrisberg being supplied entirely by the intercosto-humeral.

The Median Nerve (*n. medianus*) (Figs. 638, 639, and 644).—The median nerve has received its name from the course it takes along the middle of the arm and forearm to the hand, lying between the ulnar and musculo-spiral nerves, and the ulnar and

the radial nerves. It *arises* by two roots, one from the outer, and one from the inner, cord of the brachial plexus; these embrace the lower part of the axillary artery, uniting either in front or on the outer side of that vessel. The median nerve receives filaments from the sixth, seventh, and eighth cervical and the first dorsal nerves. As it descends through the arm, it lies at first on the outer side of the brachial artery, crosses that vessel in the middle of its course, usually in front, but occasionally behind it, and lies on its inner side to the bend of the elbow, where it is placed beneath the bicipital fascia, and is separated from the elbow-joint by the Brachialis anticus muscle. **In the forearm** it passes between the two heads of the Pronor radii teres muscle, and descends beneath the Flexor sublimis muscle, lying on the Flexor profundus muscle, to within two inches above the annular ligament, where it becomes more superficial, lying between the tendons of the Flexor sublimis and Flexor carpi radialis muscles, beneath, and rather to the radial side or under the tendon of the Palmaris longus, covered by the integument and fascia. It then passes through the **carpal canal** (*canalis carpi*) beneath the annular ligament into the hand. In its course through the forearm it is accompanied by a branch of the *anterior interosseous artery*.

Branches.—With the exception of the *nerve to the Pronator radii teres muscle*, which sometimes arises above the elbow-joint, and filaments to the elbow-joint, the median nerve gives off no branches in the arm. **In the forearm** its branches are **muscular, anterior interosseous,** and **palmar cutaneous,** and, according to Rüdinger and Macalister, two **articular twigs to the elbow-joint.**

The **Muscular Branches** (*rami musculares*) supply all the superficial muscles on the front of the forearm except the Flexor carpi ulnaris. These branches are derived from the nerve near the elbow.

The **Anterior Interosseous** (*n. interosseus* [*antibrachii*] *volaris*) (Fig. 644) supplies the deep muscles on the front of the forearm, except the inner half of the Flexor profundus digitorum. It accompanies the anterior interosseous artery along the interosseous membrane, in the interval between the Flexor longus pollicis and Flexor profundus digitorum muscles, both of which it supplies, and terminates below in the Pronator quadratus muscle sending filaments to the inferior radio-ulnar articulation and the wrist-joint.

The **Palmar Cutaneous Branch** (*ramus cutaneus palmaris n. mediani*) *arises* from the median nerve at the lower part of the forearm. It pierces the fascia above the annular ligament, and, descending over that ligament, divides into two branches; of which the **outer branch** supplies the skin over the ball of the thumb, and communicates with the anterior cutaneous branch of the musculo-cutaneous nerve; and the **inner branch** supplies the integument of the palm of the hand, communicating with the cutaneous branch of the ulnar.

In the palm of the hand the median nerve is covered by the integument and palmar fascia and is crossed by the superficial palmar arch. It rests upon the tendons of the flexor muscles. In this situation it becomes enlarged, somewhat flattened, of a reddish color, and divides into two branches. Of these, the **external branch** supplies a muscular branch to some of the muscles of the thumb and digital branches to the thumb and index finger; the **internal branch** supplies digital branches to the contiguous sides of the index and middle and of the middle and ring fingers. The digital branches, before they subdivide, are called **common palmar digital branches of the median nerve** (*nn. digitales volares communes*).

The **branch to the muscles of the thumb** (*ramus muscularis*) is a short nerve which divides to supply the Abductor, Opponens, and the superficial head of the Flexor brevis pollicis muscles, the remaining muscles of this group being supplied by the ulnar nerve.

The **Collateral Palmar Digital** or the **Digital Branches** (*nn. digitales volares proprii*) are five in number. The **first** and **second** pass along the borders of the thumb,

the external branch communicating with branches of the radial nerve. The **third** passes along the radial side of the index finger, and supplies the First lumbricalis muscle. The **fourth** subdivides to supply the adjacent sides of the index and middle fingers, and sends a branch to the Second lumbricalis muscle. The **fifth** supplies the adjacent sides of the middle and ring fingers, and communicates with a branch from the ulnar nerve.

Each digital nerve, opposite the base of the first phalanx, gives off a dorsal branch, which joins the dorsal digital nerve from the radial nerve and runs along the side of the dorsum of the finger, to end in the integument over the last phalanx. At the end of the finger the digital nerve divides into a palmar and a dorsal branch, the former of which supplies the extremity of the finger, and the latter ramifies around and beneath the nail. The digital nerves, as they run along the fingers, are placed superficial to the digital arteries. The cutaneous areas supplied by the median nerve are shown in Figs. 642 and 643.

The Ulnar Nerve (*n. ulnaris*) (Figs. 638, 639, and 644).—The ulnar nerve is placed along the inner or ulnar side of the upper limb, and is distributed to the muscles and integument of the forearm and hand. It is smaller than the median, behind which it is placed, diverging from it in its course down the arm. It arises from the inner cord of the brachial plexus, in common with the inner head of the median and the internal cutaneous nerve, and derives its fibres from the eighth cervical and first dorsal nerves. At its commencement it lies to the inner side of the axillary artery, and holds the same relation with the brachial artery to the middle of the arm. From this point it runs obliquely across the internal head of the Triceps, pierces the internal intermuscular septum, and descends to the groove between the internal condyle and the olecranon, accompanied by the inferior profunda artery. **At the elbow** it rests upon the back of the inner condyle, and passes into the forearm between the two heads of the Flexor carpi ulnaris muscle. **In the forearm** it descends in a perfectly straight course along the ulnar side of the extremity, lying upon the Flexor profundus digitorum muscle, its upper half being covered by the Flexor carpi ulnaris muscle, its lower half lying on the outer side of the muscle, being covered by the integument and fascia. The ulnar artery, in the upper third of its course, is separated from the ulnar nerve by a considerable interval, but in the rest of its extent the nerve lies to its inner side. **At the wrist** the ulnar nerve crosses the annular ligament on the outer side of the pisiform bone, to the inner side of and a little behind the ulnar artery, and immediately beyond this bone divides into two branches, the superficial and the deep palmar.

Branches.—The branches of the ulnar nerve are—

In the forearm	Articular. Muscular. Cutaneous. Dorsal cutaneous.	In the hand	Superficial palmar. Deep palmar.

The **Articular Branches** distributed to the elbow-joint consist of several small filaments. They arise from the nerve as it lies in the groove between the inner condyle of the humerus and the olecranon process of the ulnar.

The **Muscular Branches** (*rami musculares*) are two in number—one supplying the Flexor carpi ulnaris; the other, the inner half of the Flexor profundus digitorum. They arise from the trunk of the nerve near the elbow.

The **Cutaneous Branch** arises from the ulnar nerve about the middle of the forearm, and divides into two branches.

One branch (frequently absent) pierces the deep fascia near the wrist, and is distributed to the integument, communicating with a branch of the internal cutaneous nerve.

The second branch, the **palmar cutaneous** (*ramus cutaneus palmaris*) lies on the

ulnar artery, which it accompanies to the hand, some filaments entwining around the vessel; it ends in the integument of the palm, communicating with branches of the median nerve.

The **Dorsal Cutaneous Branch** (*ramus dorsalis manus*) *arises* about two inches above the wrist; it passes backward beneath the Flexor carpi ulnaris muscle, perforates the deep fascia, and, running along the ulnar side of the back of the wrist and hand, divides into branches (*nn. digitales dorsales*); one of these supplies the inner side of the little finger; a second supplies the adjacent sides of the little and ring fingers; a third joins the branch of the radial nerve which supplies the adjoining sides of the middle and ring fingers, and assists in supplying these parts; a fourth is distributed to the metacarpal region of the hand, communicating with a branch of the radial nerve.

On the little finger the dorsal digital branches extend only as far as the base of the terminal phalanx, and on the ring finger as far as the base of the second phalanx; the more distal parts of these digits are supplied by dorsal branches derived from the palmar digital branches of the ulnar.

The **Superficial Palmar Branch** (*ramus superficialis n. ulnaris*) supplies the Palmaris brevis and the integument on the inner side of the hand, and terminates in two digital branches, which are distributed, one to the ulnar side of the little finger, the other to the adjoining sides of the little and ring fingers, the latter communicating with a branch from the median. The digital branches are distributed to the fingers in the same manner as the digital branches of the median.

The **Deep Palmar Branch** (*ramus profundus n. ulnaris*), accompanied by the deep branch of the ulnar artery, passes between the Abductor and Flexor brevis minimi digiti muscles; it then perforates the Opponens minimi digiti and follows the course of the deep palmar arch beneath the flexor tendons. At its origin it supplies the muscles of the little finger. As it crosses the deep part of the hand it sends two branches to each interosseous space, one for the Dorsal and one for the Palmar interosseous muscle, the branches to the Second and Third palmar interossei supplying filaments to the two inner Lumbrical muscles. At its termination between the thumb and index finger, it supplies the Adductores transversus et obliquus pollicis and the inner head of the Flexor brevis pollicis. It also sends articular filaments to the wrist-joint, and to the bones and joints of the hand.

It will be remembered that the inner part of the Flexor profundus digitorum muscle is supplied by the ulnar nerve; the two inner Lumbricales, which are connected with the tendons of this part of the muscle, are therefore supplied by the same nerve. The outer part of the Flexor profundus is supplied by the median nerve; the two outer Lumbricales, which are connected with the tendons of this part of the muscles, are therefore supplied by the same nerve. Brooks states that in twelve instances out of twenty-one he found that the third lumbrical received a twig from the median nerve, in addition to its branch from the ulnar. The palmar branches of the ulnar which go to the fingers are called by Toldt before division **common palmar digital branches**, and after division **collateral palmar digital branches**. The cutaneous areas supplied by the ulnar nerve are shown in Figs. 642 and 643.

The Musculo-spiral Nerve (*n. radialis*) (Figs. 639, 644, and 645).—The musculo-spiral nerve, the largest branch of the brachial plexus, supplies the muscles of the back part of the arm and forearm, and the integument of the same parts, as well as that of the back of the hand (Figs. 642 and 643). It *arises* from the posterior cord of the brachial plexus, of which it may be regarded as the continuation. It receives filaments from the sixth, seventh, and eighth, and sometimes also from the fifth cervical nerves. At its commencement it is placed behind the axillary artery and the upper part of the brachial artery, passing down in front of the tendons of the Latissimus dorsi and Teres major muscles. It winds around the humerus in the musculo-spiral

groove with the superior profunda artery, passing from the inner to the outer side of the bone, between the internal and external heads of the Triceps muscle (Fig. 645). It pierces the external intermuscular septum, and descends between the Brachialis anticus and Supinator longus muscles to the front of the external condyle of the humerus, where it sends filaments to the elbow-joint and divides into the radial and posterior interosseous nerves.

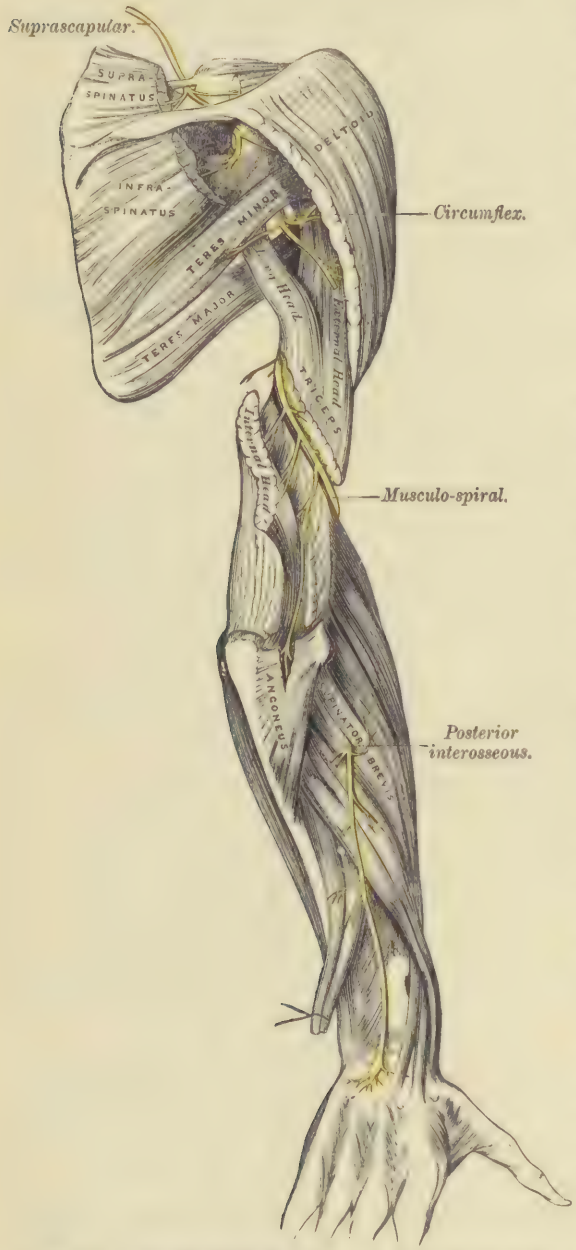

FIG. 645.—The suprascapular, circumflex, and musculo-spiral nerves.

Branches.—The branches of the musculo-spiral nerve are—

Muscular.
Cutaneous.
Radial.
Posterior interosseous.

The **Muscular Branches** (*rami musculares n. radialis*) are divided into **internal, posterior,** and **external**; they supply the Triceps, Anconeus, Supinator longus, Extensor carpi radialis longior, and Brachialis anticus muscles. These branches are derived from the nerve at the inner side, back part, and outer side of the arm.

The **internal muscular branches** supply the inner and middle heads of the Triceps muscle. That to the inner head of the Triceps is a long, slender filament which lies close to the ulnar nerve, as far as the lower third of the arm, and is therefore frequently spoken of as the **ulnar collateral** branch.

The **posterior muscular branch,** of large size, arises from the nerve in the groove between the Triceps muscle and the humerus. It divides into branches which supply the outer and inner heads of the Triceps and the Anconeus muscles. The branch for the latter muscle is a long, slender filament which descends in the substance of the Triceps to the Anconeus.

The **external muscular branches** supply the Supinator longus, Extensor carpi radialis longior, and (usually) the outer part of the Brachialis anticus muscles.

The **Cutaneous Branches** are three in number, one **internal** and two **external**.

The **internal cutaneous branch** (*n. cutaneus brachii posterior*) *arises* in the axillary space with the inner muscular branch. It is of small size, and passes through

the axilla to the inner side of the arm, supplying the integument on its posterior aspect nearly as far as the olecranon. In its course it crosses beneath the intercosto-humeral nerve, with which it communicates.

The **external cutaneous branch** (*n. cutaneus antibrachii dorsalis*) divides into two branches, and each one perforates the outer head of the Triceps muscle at its attachment to the humerus. The **upper** and smaller one passes to the front of the elbow, lying close to the cephalic vein, and supplies the integument of the lower half of the arm on its anterior aspect. The **lower branch** pierces the deep fascia below the insertion of the Deltoid muscle, and passes down along the outer side of the arm and elbow, and then along the back part of the radial side of the forearm to the wrist, supplying the integument in its course, and joining, near its termination, with the posterior cutaneous branch of the musculo-cutaneous nerve.

The **Radial Nerve** (*ramus superficialis n. radialis*) (Fig. 644), passes along the front of the radial side of the forearm to the commencement of its lower third. It lies at first a little to the outer side of the radial artery, concealed beneath the Supinator longus muscle. In the middle third of the forearm it lies beneath the same muscle, in close relation with the outer side of the artery. It leaves the artery about three inches above the wrist, passes beneath the tendon of the Supinator longus muscle, and, piercing the deep fascia at the outer border of the forearm, divides into two branches.

The **external branch**, the smaller of the two, supplies the integument of the radial side and ball of the thumb, joining with the anterior branch of the musculo-cutaneous nerve.

The **internal branch** communicates, above the wrist, with the posterior cutaneous branch from the musculo-cutaneous, and on the back of the hand forms an arch with the dorsal cutaneous branch of the ulnar nerve. It then divides into four **digital nerves** (*nn. digitales dorsales*), which are distributed as follows: The first supplies the ulnar side of the thumb; the second, the radial side of the index finger; the third, the adjoining sides of the index and middle fingers; and the fourth, the adjacent borders of the middle and ring fingers.[1] The latter nerve communicates with a filament from the dorsal branch of the ulnar nerve.

The Posterior Interosseous Nerve (*ramus profundus n. radialis*) (Figs. 644 and 645).—The posterior interosseous nerve winds to the back of the forearm around the outer side of the radius, passes between the two planes of fibres of the Supinator brevis muscle, and is prolonged downward between the superficial and deep layer of muscles, to the middle of the forearm. Considerably diminished in size, it descends on the interosseous membrane, beneath the Extensor longus pollicis muscle, to the back of the carpus, where it presents a gangliform enlargement from which filaments are distributed to the inferior radio-ulnar articulation, to the wrist-joint, and to the ligaments and articulations of the carpus. It supplies all the muscles of the radial and posterior brachial regions, excepting the Anconeus, Supinator longus, and Extensor carpi radialis longior.

Surgical Anatomy.—The brachial plexus may be ruptured by traction on the limb, leading to complete paralysis. Bristow[2] has reported three cases of avulsion of the plexus and has described twenty-four cases. In these cases it is generally believed that the lesion is rather a tearing away of the nerves from the spinal cord than a solution of continuity of the nerve-fibres themselves. In a case operated upon by Bristow it was found that the plexus had given way where the four cervical nerves and the first dorsal nerve unite to form three trunks. In supraclavicular division of the brachial plexus, not only will there be motor and sensory paralysis in the limb, but the Serratus magnus muscle will probably be paralyzed, because of injury to the posterior thoracic nerve. In the axilla any of the nerves forming the brachial plexus may be injured by a wound of this part, the median being the one which is most frequently damaged from its exposed

[1] According to Hutchinson, the digital nerve to the thumb reaches only as high as the root of the nail; the one to the forefinger as high as the middle of the second phalanx, and the one to the middle and ring fingers not higher than the first phalangeal joint (London Hospital Gazette, vol. iii. p. 319).—Ed. of 15th English edition.

[2] Annals of Surgery, September, 1902.

position. The musculo-spiral, on account of its sheltered and deep position, is least often wounded. The brachial plexus in the axilla is often damaged from the pressure of a crutch, producing the condition known as *crutch paralysis*. In these cases the musculo-spiral is the nerve most frequently implicated; the ulnar nerve being the one that appears to suffer next in frequency.

The *circumflex nerve* is of particular surgical interest. On account of its course around the surgical neck of the humerus, it is liable to be torn in fractures of this part of the bone, and in dislocations of the shoulder-foint, leading to paralysis of the deltoid, and, according to Erb, inflammation of the shoulder-joint is liable to be followed by a neuritis of this nerve from extension of the inflammation to it.

Mr. Hilton takes the circumflex nerve as an illustration of a law which he lays down, that "the same trunks of nerves whose branches supply the groups of muscles moving a joint furnish also a distribution of nerves to the skin over the insertions of the same muscles, and the interior of the joint receives its nerves from the same source." In this way he explains the fact that an inflamed joint becomes rigid, because the same nerves which supply the interior of the joint supply the muscles which move that joint.

The *median nerve* is liable to injury in wounds of the forearm. When paralyzed, there is loss of flexion of the second phalanges of all the fingers and of the terminal phalanges of the index and middle fingers. Flexion of the terminal phalanges of the ring and middle fingers can still be effected by that portion of the Flexor profundus digitorum which is supplied by the ulnar nerve. There is power to flex the proximal phalanges through the Interossei. The thumb cannot be flexed or opposed, and is maintained in a position of extension and adduction. All power of pronation is lost. The wrist can be flexed, if the hand is first adducted, by the action of the Flexor carpi ulnaris. There is loss or impairment of sensation on the palmar surface of the thumb, index, middle, and outer half of the ring fingers, and on the dorsal surface of the same fingers over the last two phalanges; except in the thumb, where the loss of sensation is limited to the back of the last phalanx. In order to expose the median nerve for the purpose of *stretching* it an incision should be made along the radial side of the tendon of the Palmaris longus muscle, which serves as a guide to the nerve.

The *ulnar nerve* is liable to be injured in wounds of the forearm. When paralyzed, there is loss of power of flexion in the ring and little fingers; there is impaired power of ulnar flexion and adduction of the hand; there is inability to spread out the fingers from paralysis of the Interossei; and there is inability to adduct the thumb. The fingers cannot be flexed at the first joints, and cannot be extended at the other joints. A *claw-hand* develops, the first phalanges being overextended and the others flexed. Sensation is lost or impaired in the skin of the ulnar side of the hand anteriorly and posteriorly, involving the little finger, the ring finger, and the ulnar half of the middle finger posteriorly, and anteriorly involving the little finger and the ulnar half of the ring finger. In order to expose the nerve in the lower part of the forearm, an incision should be made along the outer border of the tendon of the Flexor carpi ulnaris, and the nerve will be found lying on the ulnar side of the ulnar artery.

The *musculo-spiral nerve* is probably more frequently injured than any other nerve of the upper extremity. In consequence of its close relationship to the humerus as it lies in the musculo-spiral groove, it is frequently torn or injured in fractures of this bone, or subsequently involved in the callus that may be thrown out around a fracture, and thus pressed upon and its functions interfered with. It is also liable to be squeezed against the bone by kicks or blows and it may be divided by wounds of the arm. When paralyzed, the hand is flexed at the wrist and lies flaccid. This condition is known as *drop-wrist*. The fingers are also flexed, and on an attempt being made to extend them the last two phalanges only will be extended through the action of the Interossei, the first phalanges remaining flexed. There is no power of extending the wrist. Supination is completely lost when the forearm is extended on the arm, but is possible to a certain extent if the forearm is flexed so as to allow of the action of the Biceps. The power of extension of the forearm is lost on account of paralysis of the Triceps. Loss of sensation may be considerable or slight. Its area is shown in Fig. 643. The best position in which to expose the nerve for the purpose of stretching is to make an incision along the inner border of the Supinator longus muscle, just above the level of the elbow-joint. The skin and superficial structures are to be divided and the deep fascia exposed. The white line in this structure indicating the border of the muscle is to be defined, and the deep fascia divided in this line. By now raising the Supinator longus the nerve will be found lying beneath it, on the Brachialis anticus muscle.

Post-anæsthetic paralysis. When a person emerges from the influence of a general anæsthetic palsy of the arm may be found to exist. The brachial plexus may have been compressed during the operation by drawing the arm strongly from the body or elevating it by the side of the head. In such a case the plexus was compressed by the head of the humerus (Braun).

The median nerve is stretched when the arm is rotated externally and drawn backward and outward. The ulnar nerve is stretched when the forearm is flexed and supinated (Braun). Garrigues believes that in most cases of post-anæsthetic paralysis the brachial plexus was squeezed between the collar bone and the first rib by the head of the patient being drawn to the opposite side or being allowed to fall back.

THE THORACIC OR DORSAL NERVES (NN. THORACALES.)

The thoracic or dorsal nerves are twelve in number on each side. The first appears between the first and second dorsal vertebrae, and the last between the last dorsal and first lumbar.

The Roots of the Thoracic or Dorsal Nerves.

The roots of the thoracic or dorsal nerves are of small size, and vary but slightly from the second to the last. Both roots are very slender, the posterior roots slightly exceeding the anterior in thickness. They gradually increase in length from above downward, and in the lower part of the dorsal region pass down in contact with the spinal cord for a distance equal to the height of at least two vertebrae, before they emerge from the spinal canal. They then join in the intervertebral foramen, and at their exit divide into two primary divisions, a posterior (dorsal) and an anterior (intercostal).

The Posterior Divisions of the Thoracic or Dorsal Nerves (Rami Posteriores) (Fig. 646).

The posterior divisions of the thoracic or dorsal nerves are smaller than the anterior, pass backward between the transverse processes, and divide into **internal** and **external branches.**

Each internal branch is called a **ramus medialis**; each external branch is called a **ramus lateralis.**

The Internal Branches.—The internal branches of the six upper nerves pass inward between the Semispinalis dorsi and Multifidus spinae muscles, which they supply, and then, piercing the origins of the Rhomboidei and Trapezius muscles, become cutaneous by the side of the spinous processes and ramify in the integument. The internal branches of the six lower nerves are distributed to the Multifidus spinae, without giving off any cutaneous filaments.

The External Branches.—The external branches increase in size from above downward. They pass through the Longissimus dorsi muscle to the cellular interval between it and the Iliocostalis muscle, and supply those muscles, as well as their continuations upward to the head, and also the Levatores costarum muscles; the five or six lower nerves also give off cutaneous filaments, which pierce the Serratus posticus inferior and Latissimus dorsi muscles in a line with the angles of the ribs, and then ramify in the integument.

The Cutaneous Branches.—The cutaneous branches of the posterior primary divisions of the dorsal nerves are twelve in number. From each *ramus medialis* of the upper six nerves comes a *ramus cutaneus medialis*, and from each *ramus lateralis* of the lower six nerves comes a *ramus cutaneus lateralis*. The six upper cutaneous nerves are derived from the internal branches of the posterior divisions of the dorsal nerves. They pierce the origins of the Rhomboidei and Trapezius muscles, and become cutaneous by the side of the spinous processes, and then ramify in the integument. They are frequently furnished with gangliform enlargements. The six lower cutaneous nerves are derived from the external branches of the posterior divisions of the dorsal nerves. They pierce the Serratus posticus inferior and Latissimus dorsi muscles in a line with the angles of the ribs, and then ramify in the integument.

The Anterior Divisions of the Thoracic or Dorsal Nerves or the Intercostal Nerves (Rami Anteriores).

The anterior divisions of the dorsal nerves or the **intercostal** nerves (*nn. intercostales*) are twelve in number on each side. They are, for the most part,

distributed to the parietes of the thorax and abdomen, separately from each other, without being joined in a plexus; in which respect they differ from the

FIG. 646.—Superficial and deep distribution of the posterior divisions of the spinal nerves. (After Hirschfeld and Leveillé.) On the left side the cutaneous branches are represented lying on the superficial layer of muscles. On the right side the superficial muscles have been removed, the Splenius capitis and Complexus divided in the neck, and the Erector spinae divided and partly removed in the back, so as to expose the posterior divisions of the spinal nerves near their origin. *a a*. Lesser occipital nerve from the cervical plexus. 1. External muscular branches of the first cervical nerve, and union by a loop with the second. 2, placed on the Rectus capitis posticus major muscle, marks the great occipital nerve, passing round the short muscles and piercing the Complexus : the external branch is seen to the outside. 3. External branch from the posterior division of the third nerve. 3′. Its internal branch, sometimes called the third occipital. 4′ to 8′. The internal branches of the several corresponding nerves on the left side. The external branches of these nerves, proceeding to muscles, are displayed on the right side, *d* 1 to *d* 6, and thence to *d* 12. External muscular branches of the posterior divisions of the twelve dorsal nerves on the right side, *d* 1′ to *d* 6′. The internal cutaneous branches of the six upper dorsal nerves on the left side, *d* 7′ to *d* 12′. Cutaneous twigs from the external branches of the six lower dorsal nerves. *l l*. External branches from the posterior divisions of several lumbar nerves on the right side, piercing the muscles, the lower descending over the gluteal region *l′ l′*. The same, more superficially, on the left side. *s s*. The issue and union by loops of the posterior divisions of four sacral nerves on the right side *s′ s′*. Some of those distributed to the skin on the left side.

other spinal nerves. Each nerve is connected with the adjoining **ganglion of the sympathetic** by one or two filaments (*ramus communicans*). The intercostal nerves may be divided into two sets, from the difference they present in their distribution. The six upper, with the exception of the first and the intercosto-humeral branch of the second, are limited in their distribution to the parietes of the chest. The six lower supply the parietes of the chest and abdomen, the last one sending a cutaneous filament to the buttock.

The Anterior Division of the First Thoracic or First Dorsal Nerve.—The anterior division of the first dorsal nerve divides into two branches: one, the larger, leaves the thorax in front of the neck of the first rib, and enters into the formation of the **brachial plexus**; the other and smaller branch runs along the first intercostal space, forming the **first intercostal nerve** (*n. intercostalis I*), giving off muscular branches, and terminates on the front of the chest by forming the **first anterior cutaneous nerve** (*ramus cutaneus anterior n. intercostalis I*) of the thorax. Occasionally this anterior cutaneous branch is wanting. The first intercostal nerve, as a rule, gives off no lateral cutaneous branch, but sometimes a small branch is given off which communicates with the intercosto-humeral. It frequently receives a connecting twig from the second dorsal nerve, which passes upward over the neck of the second rib.

The Anterior Divisions of the Upper Thoracic or Dorsal Nerves (*nn. intercostales*) (Fig. 646).—The anterior divisions of the second, third, fourth, fifth, and sixth dorsal nerves and the small branch from the first dorsal are confined to the parietes of the thorax, and are named **upper** or **pectoral intercostal nerves.** They pass forward in the intercostal spaces with the intercostal vessels, being situated below them. At the back of the chest they lie between the pleura and the External intercostal muscle, but are soon placed between the two planes of Intercostal muscles as far as the middle of the rib. They then enter the substance of the Internal intercostal muscles, and, running amidst their fibres as far as the costal cartilages, they gain the inner surface of the muscles and lie between them and the pleura. Near the sternum, they cross in front of the internal mammary artery and Triangularis sterni muscle, pierce the Internal intercostal muscles, the anterior intercostal membrane, and Pectoralis major muscle, and supply the integument of the front of the chest and over the mammary gland, forming the anterior cutaneous nerves of the thorax; the branch from the second nerve is joined with the supraclavicular nerves of the cervical plexus.

Branches.—Numerous slender **muscular filaments** (*rami musculares*) supply the Intercostals, the Infracostales, the Levatores costarum, Serratus posticus superior, and Triangularis sterni muscles. Some of these branches, at the front of the chest, cross the costal cartilages from one to another intercostal space.

Lateral Cutaneous Nerves of the Thorax (*rami cutanei laterales* [*pectorales*]) (Fig. 638).—These are derived from the intercostal nerves, midway between the vertebrae and sternum; they pierce the External intercostal and Serratus magnus muscles, and divide into two branches, **anterior** and **posterior.**

The **Anterior Branches** (*rami anteriores*) are reflected forward to the side and the forepart of the chest, supplying the integument of the chest and mamma; those of the fifth and sixth nerves supply the upper digitations of the External oblique muscle.

The **Posterior Branches** (*rami posteriores*) are reflected backward to supply the integument over the scapula and over the Latissimus dorsi muscle.

The **Lateral Cutaneous Branch of the Second Intercostal Nerve** (*n. intercosto-brachialis*) is of large size, and does not divide, like the other nerves, into an anterior and posterior branch. It may unite with a branch of the third intercostal. The single nerve or the united nerve is named, from its origin and distribution, the **intercosto-humeral nerve** (Figs. 638 and 644). It pierces the External intercostal

muscle, crosses the axilla to the inner side of the arm, and joins with a filament from the nerve of Wrisberg. It then pierces the fascia, and supplies the skin of the upper half of the inner and back part of the arm (Figs. 642 and 643), communicating with the internal cutaneous branch of the musculo-spiral nerve. The size of this nerve is in inverse proportion to the size of the other cutaneous nerves, especially the nerve of Wrisberg. A **second intercosto-humeral nerve** is frequently given off from the third intercostal. It supplies filaments to the armpit and inner side of the arm. It may or may not send a branch to the intercosto-humeral.

The Anterior Divisions of the Lower Thoracic or Dorsal Nerves.—The anterior divisions of the seventh, eighth, ninth, tenth, and eleventh dorsal nerves are continued anteriorly from the intercostal spaces into the abdominal wall, and the twelfth dorsal is continued throughout its whole course in the abdominal wall, since it is placed below the last rib; hence these nerves are named **lower** or **abdominal intercostal nerves**. They have (with the exception of the last) the same arrangement as the upper ones as far as the anterior extremities of the intercostal spaces, where they pass behind the costal cartilages, and between the Internal oblique and Transversalis muscles, to the sheath of the Rectus, which they perforate. They supply the Rectus muscle, and terminate in branches which become subcutaneous near the linea alba. These branches are named the **anterior cutaneous nerves** of the **abdomen**. They are directed outward as far as the lateral cutaneous nerves, supplying the integument of the front of the belly. The lower intercostal nerves supply the Intercostals, Serratus posticus inferior, and Abdominal muscles, and, about the middle of their course, give off **lateral cutaneous branches** which pierce the External intercostal and External oblique muscles, in the same line as the lateral cutaneous nerves of the thorax, and divide into **anterior** and **posterior branches**, which are distributed to the integument of the abdomen and back; the anterior branches supply the digitations of the External oblique muscle and extend downward and forward nearly as far as the margin of the Rectus muscle; the posterior branches pass backward to supply the skin over the Latissimus dorsi muscle.

The Last Thoracic or Dorsal Nerve.—The last dorsal is larger than the other dorsal nerves. Its anterior division runs along the lower border of the last rib, and passes under the external arcuate ligament of the Diaphragm. It then runs in front of the Quadratus lumborum muscle, perforates the Transversalis muscle, and passes forward between it and the Internal oblique muscle, to be distributed in the same manner as the lower intercostal nerves. It communicates with the ilio-hypogastric branch of the lumbar plexus, and is frequently connected with the first lumbar nerve by a slender branch, the **dorsi-lumbar nerve**, which descends in the substance of the Quadratus lumborum muscle. It gives a branch to the Pyramidalis muscle.

The Cutaneous Branches.—There are two cutaneous branches, an **anterior** and a **lateral**.

The **Anterior Cutaneous Branch** is a terminal branch and is a direct prolongation from the intercostal. It supplies an area of skin of the abdominal wall between the umbilicus and pubis.

The **Lateral Cutaneous Branch** (*ramus cutaneus lateralis* [*abdominalis*] *intercostalis XII*) is remarkable for its large size; it perforates the Internal and External oblique muscles, passes downward over the crest of the ilium in front of the iliac branch of the ilio-hypogastric, and is distributed to the integument of the front part of the gluteal region, some of its filaments extending as low down as the trochanter major. It does not divide into an anterior and a posterior branch, like the other lateral cutaneous branches of the intercostal nerves.

Surgical Anatomy.—The lower seven intercostal nerves and the ilio-hypogastric from the first lumbar nerve supply the skin of the abdominal wall. They run downward and inward

fairly equidistant from each other. The sixth and seventh supply the skin over the "pit of the stomach;" the eighth corresponds to about the position of the middle linea transversa; the tenth to the umbilicus; and the ilio-hypogastric supplies the skin over the pubes and external abdominal ring. There are several points of surgical significance about the distribution of these nerves, and it is important to remember their origin and course, for in many diseases affecting the nerve-trunks at or near their origin the pain is referred to their peripheral terminations. Thus in *Pott's disease of the spine* children will often be brought to the surgeon suffering from pain in the belly. This is due to the fact that the nerves are irritated at the seat of disease as they issue from the spinal canal. When the irritation is confined to a single pair of nerves, the sensation complained of is often a feeling of constriction, as if a cord were tied around the abdomen; and in these cases the situation of the sense of constriction may serve to localize the disease in the spinal column. In other cases, where the bone disease is more extensive and two or more nerves are involved, a more diffused pain in the abdomen is complained of. A similar conditon is sometimes present in affections of the cord itself, as in *tabes dorsalis*.

Again, it must be borne in mind that the same nerves which supply the skin of the abdomen supply also the muscles which constitute the greater part of the abdominal wall. Hence, it follows that any irritation applied to the peripheral terminations of the cutaneous branches in the skin of the abdomen is immediately followed by reflex contraction of the abdominal muscles. A good practical illustration of this may sometimes be seen in watching two surgeons examine the abdomen of the same patient. One, whose hand is cold, causes the muscles of the abdominal wall to at once contract and the belly to become rigid, and thus not nearly so suitable for examination; the other, who has taken the precaution to warm his hand, examines the abdomen without exciting any reflex contraction. The supply of both muscles and skin from the same source is of importance in protecting the abdominal viscera from injury. A blow on the abdomen, even of a severe character, will do no injury to the viscera if the muscles are in a condition of firm contraction; whereas in cases where the muscles have been taken unawares, and the blow has been struck while they were in a state of rest, an injury insufficient to produce any lesion of the abdominal wall has been attended with rupture of some of the abdominal contents. The importance, therefore, of immediate reflex contraction upon the receipt of an injury cannot be overestimated, and the intimate association of the cutaneous and muscular fibres in the same nerve produces a much more immediate response on the part of the muscles to any peripheral stimulation of the cutaneous filaments than would be the case if the two sets of fibres were derived from independent sources.

Again, the nerves supplying the abdominal muscles and skin are derived from the lower intercostal nerves and are intimately connected with the sympathetic supplying the abdominal viscera through the lower thoracic ganglia from which the splanchnic nerves are derived. In consequence of this, in rupture of the abdominal viscera and in acute peritonitis the muscles of the belly-wall become firmly contracted, and thus as far as possible preserve the abdominal contents in a condition of rest.

THE LUMBAR NERVES (NN. LUMBALES).

The lumbar nerves are five in number on each side. The first lumbar nerve appears between the first and second lumbar vertebrae, and the last between the last lumbar vertebra and the base of the sacrum.

The Roots of the Lumbar Nerves.

The roots of the lumbar nerves are the largest, and their filaments the most numerous, of all the spinal nerves, and they are closely aggregated together upon the lower end of the cord. The anterior roots are the smaller, but there is not the same disproportion between them and the posterior roots as in the cervical nerves. The roots of these nerves have a vertical direction, and are of considerable length, more especially the lower ones, since the spinal cord does not extend beyond the first lumbar vertebra. The roots become joined in the intervertebral foramina, and the nerves so formed divide at their exit into two divisions, posterior and anterior.

The Posterior Divisions of the Lumbar Nerves (Rami Posteriores) (Fig. 646).

The posterior divisions of the lumbar nerves diminish in size from above downward; they pass backward between the transverse processes, and divide into **internal** and **external branches.**

The Internal Branches (*rami mediales*).—The internal branches, the smaller, pass inward close to the articular processes of the vertebrae, and supply the Multifidus spinae and Interspinales muscles.

The External Branches (*rami laterales*).—The external branches supply the Erector spinae and Intertransverse muscles. From the three upper branches cutaneous nerves are derived which pierce the aponeurosis of the Latissimus dorsi muscle and descend over the back part of the crest of the ilium, to be distributed to the integument of the gluteal region, some of the filaments passing as far as the trochanter major (Fig. 652).

The posterior division of the fifth lumbar nerve usually sends a branch which forms a loop with the posterior division of the first sacral nerve.

The Anterior Divisions of the Lumbar Nerves (Rami Anteriores).

The anterior divisions of the lumbar nerves increase in size from above downward. At their origin they communicate with the **lumbar ganglia** of the sympathetic by long, slender filaments, which accompany the lumbar arteries around the sides of the bodies of the vertebrae, beneath the Psoas muscle. The nerves pass obliquely outward behind the Psoas magnus or between its fasciculi, distributing filaments to it and the Quadratus lumborum. The anterior divisions of the five lumbar, five sacral, and first coccygeal nerve constitute the **lumbo-sacral plexus** (*plexus lumbosacralis*). This is subdivided into the **lumbar plexus**, the **sacral plexus**, and the **pudendal plexus**. The anterior divisions of the four upper nerves are connected together in this situation by anastomotic loops, and form the **lumbar plexus**. The anterior division of the fifth lumbar, joined with a branch from the fourth, descends across the base of the sacrum to join the anterior division of the first sacral nerve and assist in the formation of the sacral plexus. The cord resulting from the union of the fifth lumbar and the branch from the fourth is called the **lumbo-sacral cord** (*truncus lumbosacralis*) (Figs. 648 and 655).

The Lumbar Plexus (Plexus Lumbalis) (Figs. 647, 648).

The lumbar plexus is formed by the loops of communication between the anterior divisions of the four upper lumbar nerves. The plexus is narrow above, and often connected with the last dorsal nerve by a slender branch, the **dorsi-lumbar nerve**. The plexus is broad below, where it is joined to the sacral plexus by the lumbo-sacral cord. The lumbar plexus is situated in the substance of the Psoas muscle near its posterior part, in front of the transverse processes of the lumbar vertebrae.

The mode in which the plexus is arranged varies in different subjects. It differs from the brachial plexus in not forming an intricate interlacement, but the several nerves of distribution arise from one or more of the spinal nerves in the following manner: The first lumbar nerve receives a branch from the last dorsal, and gives off a larger branch, which subdivides into the **ilio-hypogastric** and **ilio-inguinal nerves**; the first lumbar also gives off a **communicating branch** which passes down to the second lumbar nerve, and a third branch which unites with a branch of the second lumbar, to form the **genito-crural nerve**. The second, third, and fourth lumbar nerves divide into **anterior** and **posterior divisions**. The anterior division of the second divides into two branches, one of which joins with the above-mentioned branch of the first nerve to form the genito-crural; the other unites with the anterior division of the third nerve, and a part of the anterior division of the fourth nerve to form the **obturator nerve**. The remainder of the anterior division of the fourth nerve passes down to communicate with the fifth lumbar nerve. The posterior divisions of the second and third nerves divide into two

branches, a smaller branch from each uniting to form the **external cutaneous nerve,** and a larger branch from each, which join with the whole of the posterior division of the fourth lumbar nerve to form the **anterior crural.** The **accessory obturator,** when it exists, is formed by the union of two small branches given off from the third and fourth nerves.

From this arrangement it follows that the ilio-hypogastric and ilio-inguinal are derived entirely from the first lumbar nerve; the genito-crural from the first and second nerves; the external cutaneous from the second and third; the anterior crural and obturator by fibres derived from the second, third, and fourth; and the accessory obturator, when it exists, from the third and fourth.

Branches (Figs. 647 and 648).—The branches of the lumbar plexus are—the

Ilio-hypogastric.	Obturator.
Ilio-inguinal.	Accessory obturator.
Genito-crural.	Anterior crural.
External cutaneous.	

The Ilio-hypogastric Nerve (*n. iliohypogastricus*) (Figs. 647 and 648).—The ilio-hypogastric nerve *arises* from the first lumbar nerve. It emerges from the outer border of the Psoas muscle at its upper part, and crosses obliquely in front of the Quadratus lumborum to the crest of the ilium. It then perforates the Transversalis muscle at its posterior part near the crest of the ilium. It gives off **muscular branches** (*rami musculares*) to the abdominal wall, and divides between the transversalis and the Internal oblique into two cutaneous branches, **iliac** and **hypogastric.**

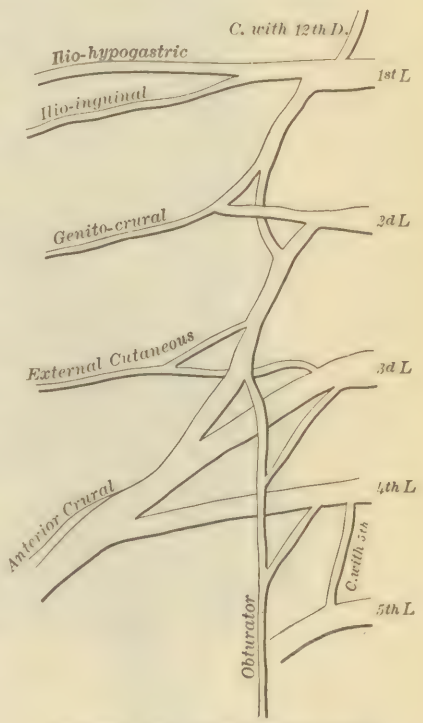

FIG. 647.—Plan of the lumbar plexus.

The **Iliac Branch** (*ramus cutaneus lateralis*) pierces the Internal and External oblique muscles immediately above the crest of the ilium, and is distributed to the integument of the gluteal region, behind the lateral cutaneous branch of the last dorsal nerve (Figs. 652 and 656). The size of this nerve bears an inverse proportion to that of the cutaneous branch of the last dorsal nerve.

The **Hypogastric Branch** (*ramus cutaneus anterior*) (Fig. 649) continues onward between the Internal oblique and Transversalis muscles. It then pierces the Internal oblique, and becomes cutaneous by perforating the aponeurosis of the External oblique, about an inch above and a little to the outer side of the external abdominal ring, and is distributed to the integument of the hypogastric region. The ilio-hypogastric nerve communicates with the last dorsal and ilio-inguinal nerves.

The Ilio-inguinal Nerve (*n. ilioinguinalis*) (Figs. 647, 648, and 649).—The ilio-inguinal nerve, smaller than the preceding, *arises* with it from the first lumbar nerve. It emerges from the outer border of the Psoas muscle just below the ilio-hypogastric nerve, and, passing obliquely across the Quadratus lumborum and Iliacus muscles, perforates the Transversalis near the forepart of the crest of the ilium, and communicates with the ilio-hypogastric nerve between that muscle and the Internal oblique. The nerve then pierces the Internal oblique, distribu-

ting **muscular branches** (*rami musculares*) to it, and, accompanying the spermatic cord through the external abdominal ring, is distributed to the integument of the upper and inner part of the thigh, and to the scrotum in the male (*nn. scrotales anteriores*) (Fig. 651), and to the labium majus in the female (*nn. labiales anteriores*). The size of this nerve is in inverse proportion to that of the ilio-hypogastric. Occasionally it is very small, and ends by joining the ilio-hypogastric; in such cases a branch from the ilio-hypogastric takes the place of the ilio-inguinal, or the ilio-inguinal nerve may be altogether absent.

The **Genito-crural Nerve** (*n. genitofemoralis*) (Figs. 647 and 648) *arises* from the first and second lumbar nerves. It passes obliquely through the substance

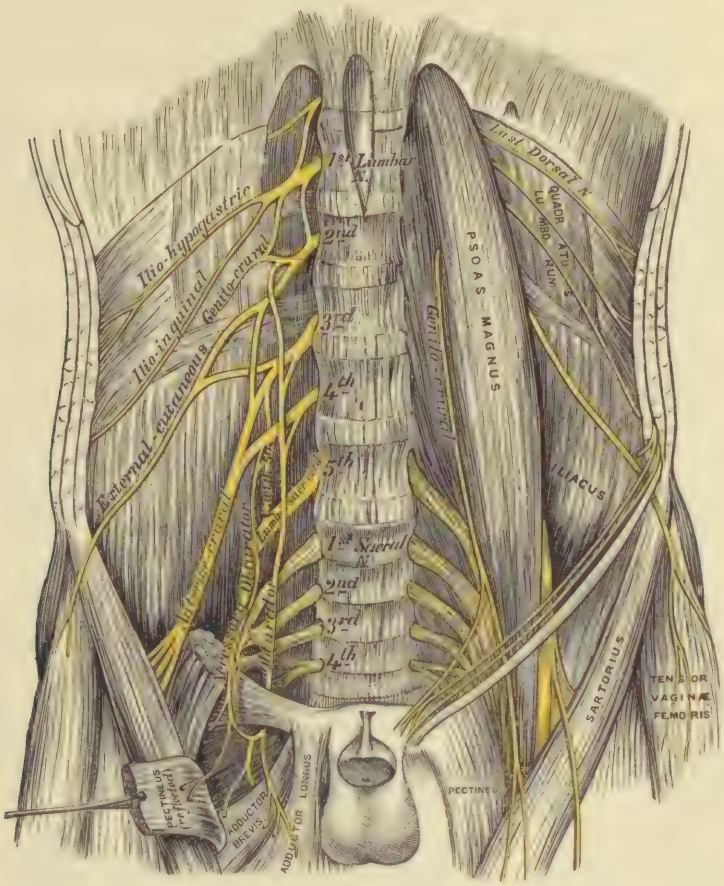

Fig. 648.—The lumbar plexus and its branches.

of the Psoas muscle, and emerges from its inner border at a level corresponding to the intervertebral substance between the third and fourth lumbar vertebrae; it then descends on the surface of the Psoas muscle, under cover of the peritoneum, and divides into a **genital** and a **crural branch.**

The **Genital Branch** (*n. spermaticus externus*) passes outward on the Psoas magnus, and pierces the fascia transversalis, or passes through the internal abdominal ring; in the male it then descends along the back part of the spermatic cord to the scrotum, and supplies the Cremaster muscle. In the female it accompanies the round ligament, and is lost upon it.

The **Crural Branch** (*n. lumboinguinalis*) (Fig. 649) descends on the external iliac artery, sending a few filaments around it, and, passing beneath Poupart's ligament

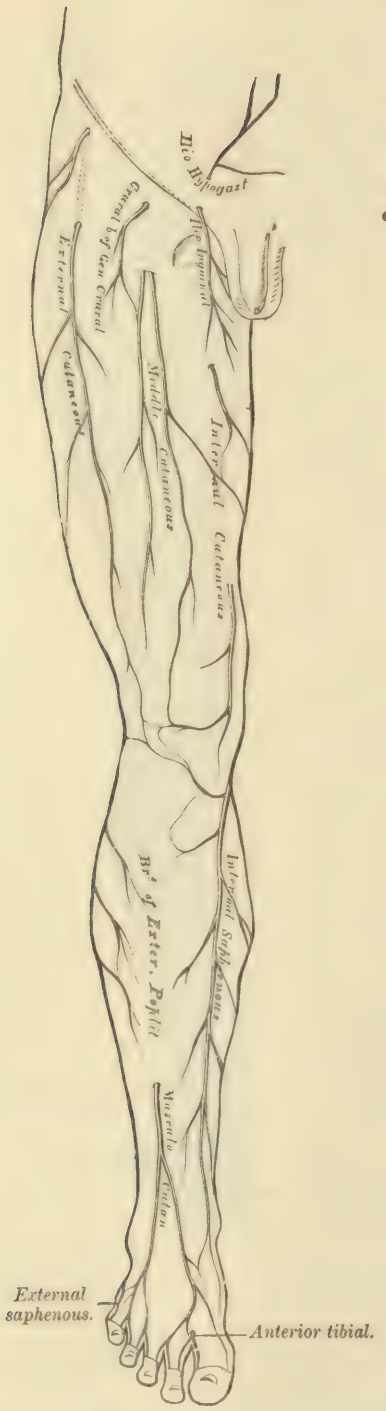

Fig. 649.—Cutaneous nerves of lower extremity. Front view.

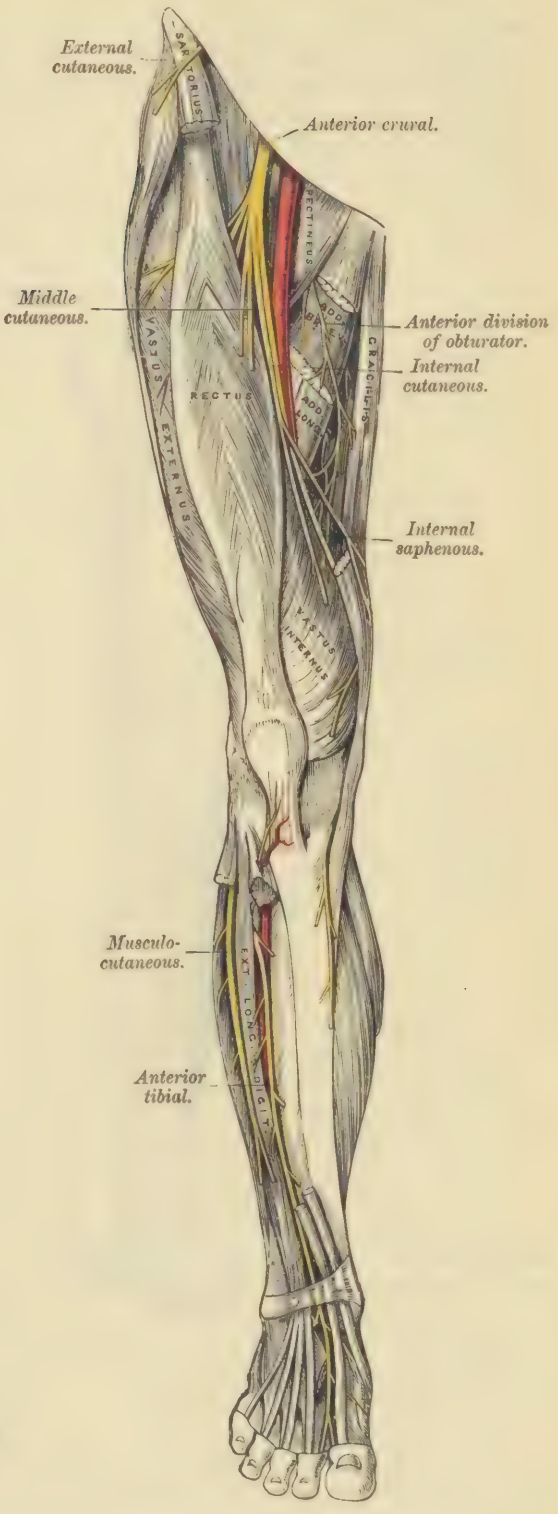

Fig. 650.—Nerves of the lower extremity. Front view.

to the thigh, enters the sheath of the femoral vessels, lying superficial and a little external to the femoral artery. It pierces the anterior layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and

Fig. 651.—Areas of distribution of the cutaneous nerves of the front of the lower limb. (W. Keiller, after Testut, in Gerrish's Text-book of Anatomy.)

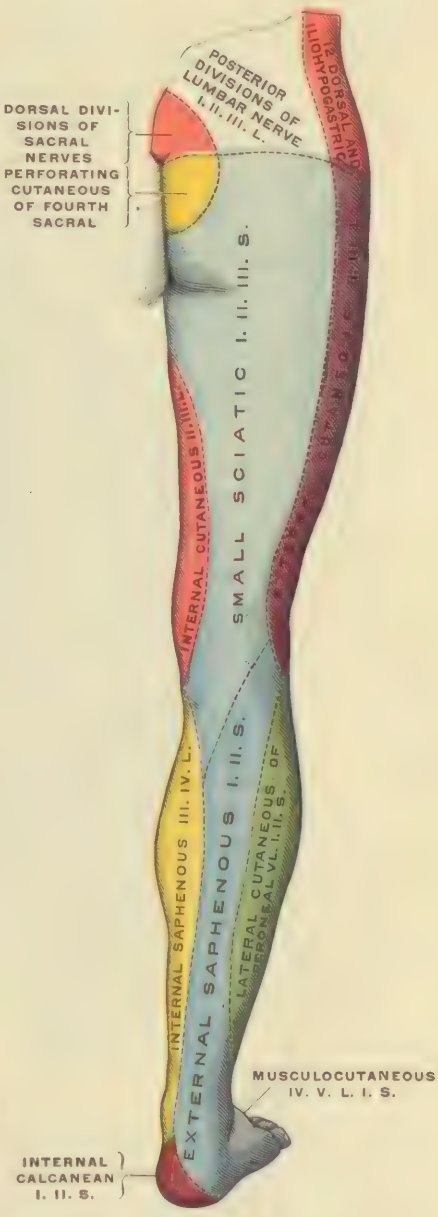

Fig. 652.—Areas of distribution of the cutaneous nerves of the back of the lower limb. (W. Keiller, after Testut, in Gerrish's Text-book of Anatomy.)

knee (Fig. 651). On the front of the thigh it communicates with the outer branch of the middle cutaneous nerve, derived from the anterior crural.

A few filaments from this nerve may be traced on to the femoral artery; they are derived from the nerve as it passes beneath Poupart's ligament.

The External Cutaneous Nerve (*n. cutaneus femoris lateralis*) (Figs. 647, 648, 649, and 650).—The external cutaneous nerve *arises* from the second and third lumbar nerves. It emerges from the outer border of the Psoas muscle about its middle, and crosses the Iliacus muscle obliquely, toward the anterior superior spine of the ilium. It then passes under Poupart's ligament and over the Sartorius muscle into the thigh, where it divides into two branches, **anterior** and **posterior.**

The **Anterior Branch** descends in an aponeurotic canal formed in the fascia lata, becomes superficial about four inches below Poupart's ligament, and divides into branches which are distributed to the integument along the anterior and outer part of the thigh, as far down as the knee (Fig. 651). This nerve occasionally communicates with a branch of the long saphenous nerve in front of the knee-joint.

The **Posterior Branch** pierces the fascia lata, and subdivides into branches which pass backward across the outer and posterior surface of the thigh, supplying the integument from the crest of the ilium as far as the middle of the thigh (Fig. 652).

The Obturator Nerve (*n. obturatorius*) (Figs. 647, 648, and 650).—The obturator nerve supplies the Obturator externus and Adductor muscles of the thigh, the articulations of the hip and knee, and occasionally the integument of the thigh and leg. It arises by three branches—from the second, the third, and the fourth lumbar nerves. Of these, the branch from the third is the largest, while that from the second is often very small. It descends through the inner fibres of the Psoas muscle, and emerges from its inner border near the brim of the pelvis; it then runs along the lateral wall of the pelvis, above the obturator vessels, to the upper part of the obturator foramen, where it enters the thigh, and divides into an anterior and a posterior branch, separated by some of the fibres of the Obturator externus muscle, and lower down by the Adductor brevis muscle.

The **Anterior Branch** (*ramus anterior*) (Fig. 650) passes down in front of the Adductor brevis, being covered by the Pectineus and Adductor longus, and at the lower border of the latter muscle communicates with the internal cutaneous and internal saphenous nerves, forming a kind of plexus. It then descends upon the femoral artery, upon which it is finally distributed. The nerve, near the obturator foramen, gives off an articular branch to the hip-joint. Behind the Pectineus it distributes muscular branches to the Adductor longus and Gracilis, and usually to the Adductor brevis, and in rare cases to the Pectineus, and receives a communicating branch from the accessory obturator nerve.

Occasionally the communicating branch to the internal cutaneous and internal saphenous nerves is continued down, as a **cutaneous branch** (*ramus cutaneus*), to the thigh and leg. When this is so, this *occasional cutaneous* branch emerges from beneath the lower border of the Adductor longus, descends along the posterior margin of the Sartorius to the inner side of the knee, where it pierces the deep fascia, communicates with the long saphenous nerve, and is distributed to the integument of the inner side of the leg as low down as its middle. When this communicating branch is small its place is supplied by the internal cutaneous nerve.

The **Posterior Branch** (*ramus posterior*) pierces the Obturator externus, sending branches to supply it, and passes behind the Adductor brevis on the front of the Adductor magnus, where it divides into numerous muscular branches, which supply the Adductor magnus, and the Adductor brevis when the latter does not receive a branch from the anterior division of the nerve. One of the branches gives off a filament to the knee-joint.

The **Articular Branch for the Knee-joint** is sometimes absent; it perforates the lower part of the Adductor magnus, and enters the popliteal space; it then descends upon the popliteal artery, as far as the back part of the knee-joint, where it perforates the posterior ligament, and is distributed to the synovial membrane. It gives filaments to the popliteal artery in its course.

The Accessory Obturator Nerve or the Accessory Anterior Crural Nerve of Winslow (*n. obturatorius accessorius* (Fig. 648).—The accessory obturator nerve is not constantly present. It is of small size, and arises by separate filaments from the third and fourth lumbar nerves. It descends along the inner border of the Psoas muscle, crosses the ascending ramus of the os pubis, and passes under the outer border of the Pectineus muscle, where it divides into numerous branches. One of these supplies the Pectineus, penetrating its under surface; another is distributed to the hip-joint; while a third communicates with the anterior branch of the obturator nerve. When this nerve is absent the hip-joint receives two branches from the obturator nerve. Occasionally the articular branch is very small, and becomes lost in the capsule of the hip-joint.

The Anterior Crural Nerve (*n. femoralis*) (Figs. 647, 648, and 650).—The anterior crural nerve is the largest branch of the lumbar plexus. It supplies muscular branches to the Iliacus, Pectineus, and all the muscles on the front of the thigh, excepting the Tensor fasciae femoris; cutaneous filaments to the front and inner side of the thigh, and to the leg and foot (Figs. 651 and 652); and articular branches to the hip and knee. It arises from the second, third, and fourth lumbar nerves. It descends through the fibres of the Psoas muscle, emerging from muscle at the lower part of its outer border, and passes down between it and the Iliacus muscle, and beneath Poupart's ligament, into the thigh, where it becomes somewhat flattened, and divides into an anterior and a posterior part. Under Poupart's ligament it is separated from the femoral artery by a portion of the Psoas muscle, and lies beneath the iliac fascia.

Within the abdomen the anterior crural nerve gives off from its outer side some small **muscular branches** to the Iliacus, and a branch to the femoral artery which is distributed upon the upper part of that vessel. The origin of this branch varies; it occasionally arises higher than usual, or it may arise lower down in the thigh.

External to the pelvis the following branches are given off:

From the Anterior Division.	*From the Posterior Division.*
Middle cutaneous.	Long saphenous.
Internal cutaneous.	Muscular.
Muscular.	Articular.

The middle and internal cutaneous branches of the anterior crural nerve are the **rami cutanei anteriores n. femoralis** of the new nomenclature.

The **Middle Cutaneous Nerve** (Figs. 649 and 650) pierces the fascia lata (generally the Sartorius muscle also) about three inches below Poupart's ligament, and divides into two branches (Fig. 649), which descend in immediate proximity along the forepart of the thigh, to supply the integument as low as the front of the knee (Fig. 651), where it communicates with the internal cutaneous nerve and the patellar branch of the internal saphenous nerve, to form the **patellar plexus.** In the upper part of the thigh the outer division of the middle cutaneous nerve communicates with the crural branch of the genito-crural nerve.

The **Internal Cutaneous Nerve** (Fig. 649) passes obliquely across the upper part of the sheath of the femoral artery, and divides in front or at the inner side of that vessel into two branches, **anterior** and **posterior** or **internal.**

The **anterior branch** runs downward on the Sartorius, perforates the fascia lata at the lower third of the thigh, and divides into two branches, one of which supplies the integument as low down as the inner side of the knee; the other crosses to the outer side of the patella, communicating in its course with the nervus cutaneus patellae, a branch of the internal saphenous nerve.

The **posterior** or **internal branch** descends along the inner border of the Sartorius muscle to the knee, where it pierces the fascia lata, communicates with the long saphenous nerve, and gives off several cutaneous branches. The nerve then

passes down the inner side of the leg, to the integument of which it is distributed. This nerve, beneath the fascia lata, at the lower border of the Adductor longus, joins in a plexiform network by uniting with branches of the long saphenous and obturator nerves (Fig. 650). When the communicating branch from the obturator nerve is large and continued to the integument of the leg, the inner branch of the internal cutaneous is small and terminates at the plexus, occasionally giving off a few cutaneous filaments.

The internal cutaneous nerve, before dividing, gives off a few filaments, which pierce the fascia lata, to supply the integument of the inner side of the thigh (Figs. 651 and 652). One of these filaments passes through the saphenous opening; a second becomes subcutaneous about the middle of the thigh (Fig. 649); and a third pierces the fascia at its lower third (Fig. 649).

The Muscular Branches of the Anterior Division (*rami musculares*).—The **nerve to the Pectineus** is often duplicated; it arises from the anterior crural immediately below Poupart's ligament, and passes inward behind the femoral sheath to enter the anterior surface of the muscle. The **nerve to the Sartorius** arises in common with the middle cutaneous.

The **Long** or **Internal Saphenous Nerve** (*n. saphenus*) (Figs. 649 and 650) is the largest of the cutaneous branches of the anterior crural. It approaches the femoral artery where this vessel passes beneath the Sartorius, and lies in front of it, beneath the aponeurotic covering of Hunter's canal, as far as the opening in the lower part of the Abductor magnus. It then leaves the artery, and descends vertically along the inner side of the knee, beneath the Sartorius muscle, pierces the fascia lata opposite the interval between the tendons of the Sartorius and Gracilis muscles, and becomes subcutaneous. The nerve then passes along the inner side of the leg (Fig. 649), accompanied by the internal saphenous vein, descends behind the internal border of the tibia, and, at the lower third of the leg divides into two branches: one continues its course along the margin of the tibia, terminating at the inner ankle; the other passes in front of the ankle, and is distributed to the integument along the inner side of the foot, as far as the great toe, communicating with the internal branch of the musculo-cutaneous nerve.

The long saphenous nerve **about the middle of the thigh** gives off a communicating branch which joins the plexus formed by the obturator and internal cutaneous nerves.

At the inner side of the knee it gives off a large patellar branch, the **nervus cutaneus patellae** (*ramus infrapatellaris*), which pierces the Sartorius and fascia lata, and is distributed to the integument in front of the patella. This nerve communicates above the knee with the anterior branch of the internal cutaneous and with the middle cutaneous; below the knee, with other branches of the long saphenous; and on the outer side of the joint, with branches of the external cutaneous nerve, forming a plexiform network, the **patella plexus** (*plexus patellae*). The cutaneous nerve of the patella is occasionally small, and terminates by joining the internal cutaneous, which supplies its place in front of the knee.

Below the knee the branches of the long saphenous nerves are distributed to the integument of the front and inner side of the leg (Figs. 651 and 652), communicating with the cutaneous branches from the internal cutaneous or from the obturator nerve. The nerve also sends filaments to the ankle-joint.

The Muscular Branches of the Posterior Division.—The muscular branches of the posterior division supply the four parts of the Quadriceps extensor muscle.

The **branch to the Rectus muscle** enters its under surface high up, sending off a small filament to the hip-joint.

The **branch to the Vastus externus muscle**, of large size, follows the course of the descending branch of the external circumflex artery to the lower part of the muscle. It gives off an articular filament to the knee-joint.

The **branch to the Vastus internus muscle** is a long branch which runs down on the outer side of the femoral vessels in company with the internal saphenous nerve for its upper part. It enters the muscle about its middle, and gives off a filament which can usually be traced downward on the surface of the muscle to the knee-joint.

The **branch to the Crureus muscle** enters the muscle on its anterior surface about the middle of the thigh, and sends a filament through the muscle to the Subcrureus and the knee-joint.

The **articular branch to the hip-joint** is derived from the nerve to the Rectus muscle.

The **articular branches to the knee-joint** are three in number. One, a long, slender filament, is derived from the nerve to the Vastus externus muscle; it penetrates the capsular ligament of the joint on its anterior aspect. Another is derived from the nerve to the Vastus internus muscle. It can usually be traced downward on the surface of this muscle to near the joint; it then penetrates the muscle and accompanies the deep branch of the anastomotica magna artery, pierces the capsular ligament of the joint on its inner side, and supplies the synovial membrane. The third branch is derived from the nerve to the Crureus.

THE SACRAL AND COCCYGEAL NERVES (NN. SACRALES ET COCCYGEUS).

The sacral nerves are five in number on each side. The four upper ones pass from the sacral canal through the sacral foramina; the fifth through the foramen between the sacrum and coccyx.

The Roots of the Upper Sacral Nerves.

The roots of the upper sacral nerves are the largest of all the spinal nerves; while those of the lowest sacral and the coccygeal nerve are the smallest. They are longer than those of any of the other spinal nerves, on account of the spinal cord not extending beyond the first lumbar vertebra. From their great length, and the appearance they present in connection with their attachment to the spinal cord, the roots of origin of these nerves are called collectively the **cauda equina**.

Each sacral and coccygeal nerve separates into two divisions, posterior and anterior.

The Posterior Divisions of the Sacral Nerves (Rami Posteriores) (Fig. 653).

The posterior divisions of the sacral nerves are small, diminish in size from above downward, and emerge, except the last, from the sacral canal by the posterior sacral foramina.

The Upper Sacral Nerves.—Each of the *three upper ones* is covered, at its exit from the sacral canal, by the Multifidus spinae muscle, and divides into an **internal branch** (*ramus medialis*) and an **external branch** (*ramus lateralis*).

The Internal Branches.—The internal branches are small, and supply the Multifidus spinae muscle.

The External Branches.—The external branches join with one another, and with the last lumbar and fourth sacral nerves, in the form of loops on the posterior surface of the sacrum, constituting the **posterior sacral plexus**. From these loops branches pass to the outer surface of the great sacro-sciatic ligament, where they form a second series of loops beneath the Gluteus maximus muscle. Cutaneous branches from this second series of loops, usually two or three in number, pierce the Gluteus maximus muscle along a line drawn from the posterior superior spine

of the ilium to the tip of the coccyx. They supply the integument over the posterior part of the gluteal region (Fig. 652).

The Lower Sacral Nerves.—The posterior divisions of the two lower sacral nerves are situated below the Multifidus spinae muscle. They are of small size, and do not divide into internal and external branches, but join with each other,

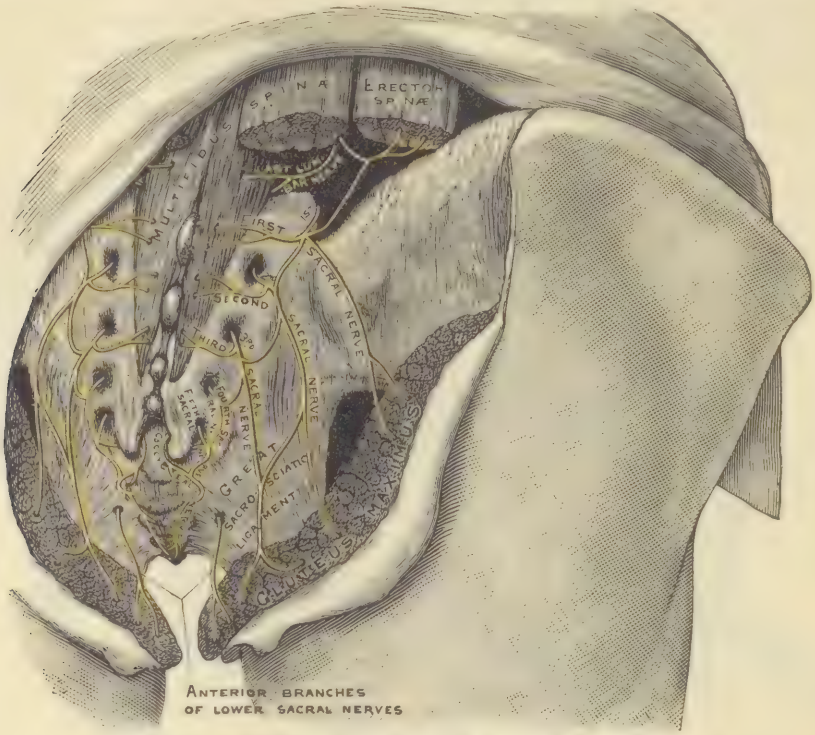

FIG. 653.—The posterior sacral nerves.

and with the posterior division of the coccygeal nerve to form the **posterior sacro-coccygeal nerve**, which passes through the sacro-sciatic ligament, and forms loops on the back of the sacrum, filaments from which supply the Extensor coccygeus and the integument over the coccyx (Fig. 652).

The Anterior Divisions of the Sacral Nerves (Rami Anteriores) (Fig. 655).

The anterior divisions of the sacral nerves diminish in size from above downward. The four upper ones emerge from the anterior sacral foramina; the anterior division of the fifth, after emerging from the spinal canal through its terminal opening, curves forward between the sacrum and the coccyx. All the anterior sacral nerves at their exit from the sacral foramina communicate with the **sacral ganglia of the sympathetic.** The **first nerve** (Fig. 654), of large size, unites with the **lumbo-sacral cord** (*truncus lumbosacralis*), formed by the fifth lumbar, and a branch from the fourth lumbar (*n. furcalis*). The **second** (Fig. 654), equal in size to the preceding, and the **third** (*n. bigeminus*) (Fig. 654), about one-fourth the size of the second, unite with this trunk, and form, with a small fasciculus from the fourth, the **sacral plexus**, a visceral branch being given off from the third nerve to the bladder (Fig. 655).

The **Fourth Anterior Sacral Nerve** sends a branch to join the sacral plexus. The remaining portion of the nerve divides into **visceral** and **muscular branches**, and a communicating filament descends to join the fifth sacral nerve.

The **visceral branches** are distributed to the viscera of the pelvis, communicating with the sympathetic nerve. These branches ascend upon the rectum and bladder, and in the female upon the vagina, communicating with branches of the sympathetic from the pelvic plexus. The visceral branches of the third and fourth sacral do not join the gangliated cord.

The **muscular branches** are distributed to the Levator ani, Coccygeus, and Sphincter ani. The branch to the Sphincter ani pierces the Levator ani, so as to reach the ischio-rectal fossa, where it is found lying in front of the coccyx. Cutaneous filaments arise from the latter branch, which supply the integument between the anus and coccyx. Another cutaneous branch is frequently given off from this

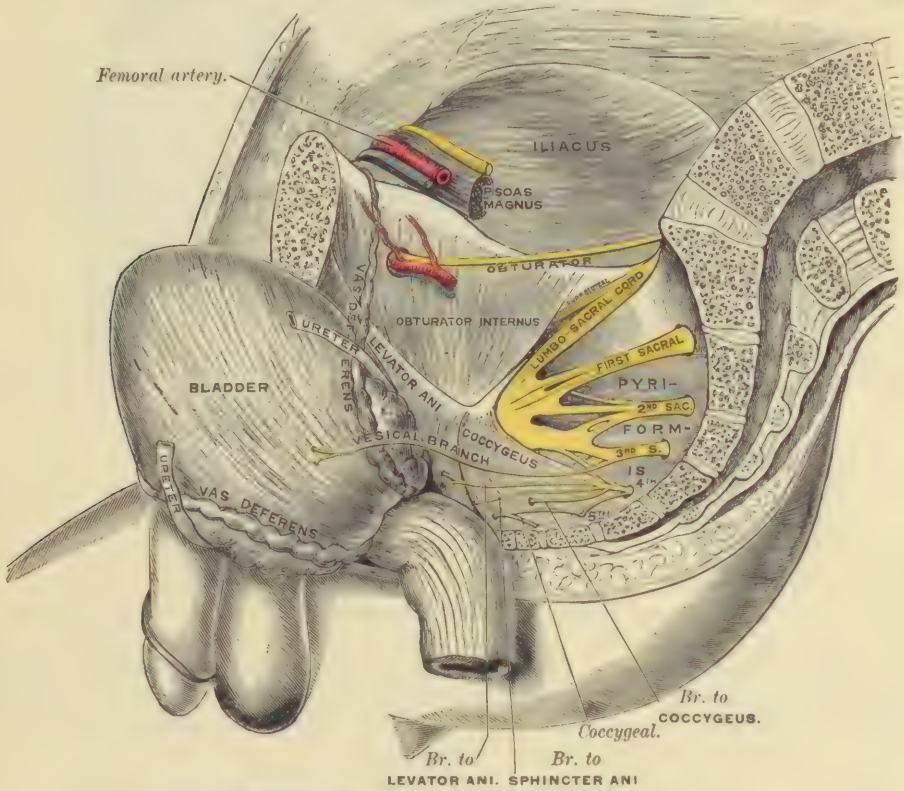

FIG. 654.—Side view of pelvis, showing sacral nerves.

nerve, though sometimes from the pudic (Schwalbe). It perforates the great sacro-sciatic ligament, and, winding around the lower border of the Gluteus maximus, supplies the skin over the lower and inner part of this muscle.

The **Fifth Anterior Sacral Nerve,** after passing from the lower end of the sacral canal, curves forward through the fifth sacral foramen, formed between the lower part of the sacrum and the transverse process of the first piece of the coccyx. It pierces the Coccygeus muscle, and descends upon its anterior surface to near the tip of the coccyx, where it again perforates the muscle, to be distributed to the integument over the back part and side of the coccyx. This nerve communicates above with the fourth sacral and below with the coccygeal nerve, and supplies the Coccygeus muscle.

The Posterior Division of the Coccygeal Nerve.

The coccygeal nerve divides into its anterior and posterior divisions in the spinal canal. The posterior division is the smaller. It does not divide, but

receives, as already mentioned, a communicating branch from the last sacral, and is lost in the integument over the back of the coccyx.

The Anterior Division of the Coccygeal Nerve.

The anterior division of the coccygeal nerve is a delicate filament which escapes at the termination of the sacral canal; it passes downward behind the rudimentary transverse process of the first piece of the coccyx, and curves forward through the notch between the first and second pieces, piercing the Coccygeus muscle, and descending on its anterior surface to near the tip of the coccyx, where it again pierces the muscle, to be distributed to the integument over the back part and side of the coccyx. It is joined by a branch from the fifth anterior sacral as it descends on the surface of the Coccygeus muscle.

The **Pudendal Plexus** (*plexus pudendus*).—The pudendal plexus is formed by fibres obtained from the anterior divisions of the first three sacral nerves and by the anterior divisions of the two lower sacral nerves and the coccygeal nerve. It is, so to speak, interpolated in the sacral plexus and is considered as a portion of it.

The Sacral or Sciatic Plexus (Plexus Sacralis) and the Pudic or Pudendal Plexus (Plexus Pudendalis) (Fig. 655).

The sacral plexus is formed by the lumbo-sacral cord, the anterior divisions of the three upper sacral nerves and a branch from the fourth. The pudic or pudendal plexus is considered with the sacral plexus. It is usually composed of

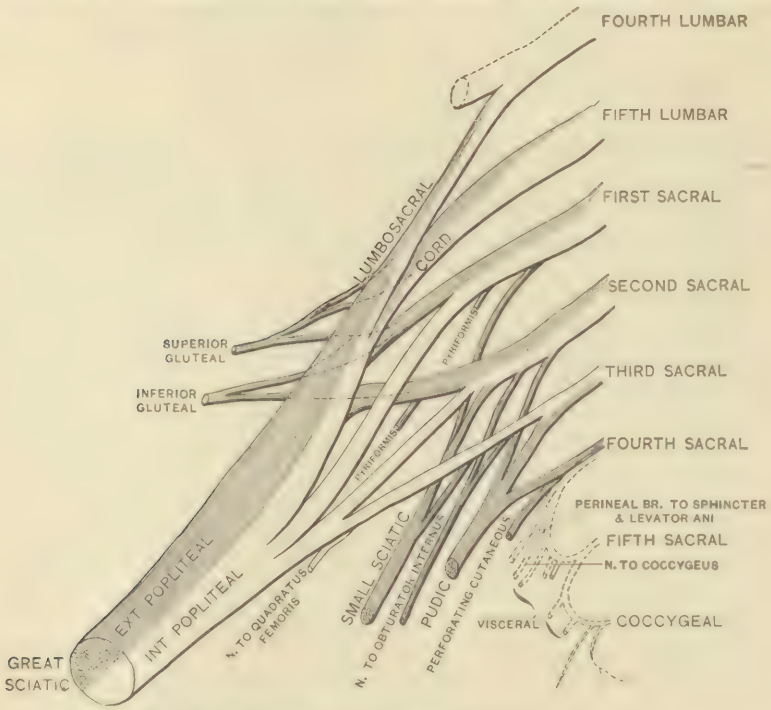

FIG. 655.—Plan of sacral plexus with the pudendal plexus. (Gerrish.)

the anterior divisions of the second, third, fourth, and fifth sacral nerves and the coccygeal nerve. It is irregular in composition. Prof. Cunningham says: "There is no distinct point of separation between the two plexuses. On the contrary, there is considerable overlapping, so that two and sometimes three of the principal nerves derived from the pudendal plexus have their origin in common with nerves of the

sacral plexus." The nerves of these two plexuses proceed in different directions: the upper ones obliquely downward and outward, the lower ones nearly horizontally outward, and they all unite into two cords; an **upper** and **larger cord**, which is formed by the lumbo-sacral cord with the first, second, and the greater part of the third sacral nerves; and a **lower** and **smaller cord**, formed by the remainder of the third, with a portion of the fourth sacral nerve. The upper cord is prolonged into the great sciatic nerve and the lower into the pudic. Frequently a small filament is given off from the second sacral nerve to join the lower cord.

Each of the nerves which form the plexus joins the sympathetic by *gray rami communicantes*. *White rami communicantes* join the third sacral and sometimes also the second and fourth sacrals to the sympathetic.

The sacro-pudendal plexus is triangular in form, its base corresponding with the exit of the nerves from the sacrum, its apex with the lower part of the great sacro-sciatic foramen. It rests upon the anterior surface of the Pyriformis, and is covered in front by the pelvic fascia, which separates it from the sciatic and pudic branches of the internal iliac artery and from the viscera of the pelvis. The sacral plexus proper sends branches to the lower extremity; the pudendal plexus proper is largely limited to supplying the perineum.

Branches.—The branches of the sacro-pudendal plexus are divided into **collateral** and **terminal branches.**

Collateral branches	Muscular. Superior gluteal. Inferior gluteal. Small sciatic Perforating cutaneous.
Terminal branches	Pudic. Great sciatic.

The Muscular Branches (*rami musculares*).—The muscular branches supply the Pyriformis, Obturator internus, the two Gemelli, and the Quadratus femoris. The branch to the Pyriformis muscle *arises* from the upper two sacral nerves before they enter the plexus; the branch to the Obturator internus muscle arises at the junction of the lumbo-sacral and first sacral nerves; it passes out of the pelvis through the great sacro-sciatic foramen below the Pyriformis, crosses the spine of the ischium, and re-enters the pelvis through the lesser sacro-sciatic foramen to enter the inner surface of the Obturator internus; the branch to the Gemellus superior muscle *arises* in common with the nerve to the Obturator internus muscle; it enters the muscle at the upper part of its posterior surface; the small branch to the Gemellus inferior and Quadratus femoris muscles also *arises* from the upper part of the plexus; it passes through the great sacro-sciatic foramen below the Pyriformis, and courses down beneath the great sciatic nerve, the Gemelli and tendon of the Obturator internus, supplies the muscles on their deep or anterior surface and gives off an articular branch to the hip-joint. A second articular branch is occasionally derived from the upper part of the sacral plexus.

The Superior Gluteal Nerve (*n. glutæus superior*) (Figs. 655 and 657).—The superior gluteal nerve *arises* from the back part of the lumbo-sacral cord, with some filaments from the first sacral nerve; it passes from the pelvis through the great sacro-sciatic foramen above the Pyriformis muscle, accompanied by the gluteal vessels, and divides into a **superior** and an **inferior branch.**

The **Superior Branch** follows the line of origin of the Gluteus minimus, and supplies the Gluteus medius muscle.

The **Inferior Branch** crosses obliquely between the Gluteus minimus and medius, distributing filaments to both these muscles, and terminates in the Tensor fasciæ femoris muscle, extending nearly to its lower end.

The Inferior Gluteal Nerve (*n. glutaeus inferior*) (Fig. 655).—The inferior gluteal nerve *arises* from the lumbo-sacral cord and first and second sacral nerves, and is intimately connected with the small sciatic at its origin. It passes out of the pelvis through the great sciatic notch, beneath the Pyriformis muscle, and, dividing into a number of branches, enters the Gluteus maximus muscle on its under surface.

The Small Sciatic Nerve (*n. cutaneus femoris posterior*) (Figs. 655, 656, and 657).—The small sciatic nerve supplies the integument of the perineum and back part of the thigh and leg. It is usually formed by the union of two branches, which arise from the second and third nerves of the sacral plexus. It issues from the pelvis through the great sacro-sciatic foramen below the Pyriformis muscle, descends beneath the Gluteus maximus with the sciatic artery, and at the lower border of that muscle passes along the back part of the thigh, beneath the fascia lata and over the long head of the Biceps, to the lower part of the popliteal region, where it pierces the fascia and becomes cutaneous. It then accompanies the external saphenous vein to about the middle of the leg, its terminal filaments communicating with the external saphenous nerve.

The **Branches** of the small sciatic nerve are all cutaneous, and are grouped as follows: **gluteal, perineal,** and **femoral.**

The **Gluteal Cutaneous Branches** (*nn. clunium inferiores* [*laterales*]) consist of two or three ascending filaments, which turn upward around the lower border of the Gluteus maximus to supply the integument covering the lower and outer part of that muscle (Fig. 652).

The **Perineal Cutaneous Branches** (*rami perineales*) are distributed to the skin at the upper and inner side of the thigh, on its posterior aspect. One branch, longer than the rest, the **inferior pudendal** or **long scrotal nerve** (Fig. 657), curves forward below the tuber ischii, pierces the fascia lata, and passes forward beneath the superficial fascia of the perineum to be distributed to the integument of the scrotum in the male (Fig. 652) and the labium in the female, communicating with the superficial perineal and inferior hemorrhoidal nerves.

The **Femoral Cutaneous Branches** are numerous descending filaments, derived from both sides of the nerves, which are distributed to the back, inner, and outer sides of the thigh, to the skin covering the popliteal space, and to the upper part of the leg (Fig. 652).

The Perforating Cutaneous Nerve (*n. clunium inferior medialis*) (Fig. 655).—The perforating cutaneous nerve usually arises from the second and third sacral nerves, and is of small size. It is continued backward through the great sacro-sciatic ligament, and, winding around the lower border of the Gluteus maximus, supplies the integument covering the inner and lower part of that muscle.

The Pudic Nerve (*n. pudendus*) (Figs. 655 and 657).—The pudic nerve is the direct continuation of the lower cord of the sacral plexus, and derives its fibres from the third and fourth sacral nerves, and frequently from the second also. It leaves the pelvis through the great sacro-sciatic foramen, below the Pyriformis. It then crosses the spine of the ischium, and re-enters the pelvis through the lesser sacro-sciatic foramen. It accompanies the pudic vessels upward and forward along the outer wall of the ischio-rectal fossa, being contained in a sheath of the obturator fascia, termed **Alcock's canal,** and divides into two terminal branches, the **perineal nerve** and the **dorsal nerve of the penis** or **clitoris.** Before its division it gives off the inferior hemorrhoidal nerve.

The **Inferior Haemorrhoidal Nerve** (*n. haemorrhoidalis inferior*) is occasionally derived separately from the sacral plexus. It passes across the ischio-rectal fossa, with its accompanying vessels, toward the lower end of the rectum, and is distributed to the Sphincter ani externus and to the integument around the anus. Branches of this nerve communicate with the inferior pudendal and superficial perineal nerves at the forepart of the perineum.

FIG. 656.—Cutaneous nerves of lower extremity. Posterior view.

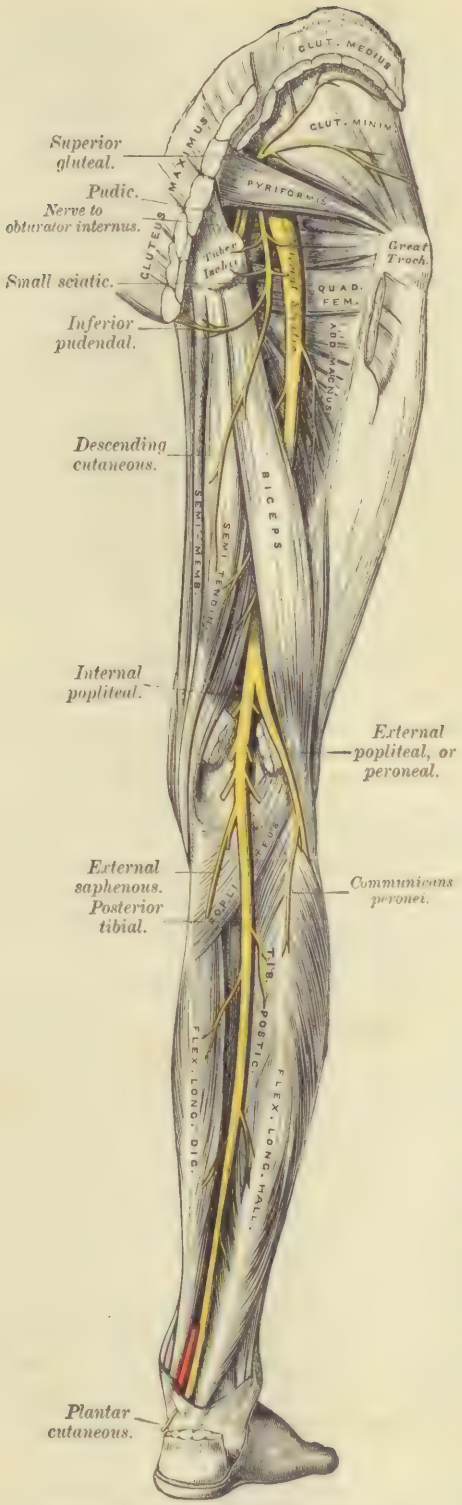

FIG. 657.—Nerves of the lower extremity.[1] Posterior view.

[1] N. B.—In this diagram the external saphenous and communicans peronei are not in their normal position. They have been displaced by the removal of the superficial muscles.

The **Perineal Nerve** (*n. perinei*), the inferior and larger of the two terminal branches of the pudic, is situated below the pudic artery. It accompanies the superficial perineal artery in the perineum, dividing into **cutaneous** and **muscular branches.**

The **cutaneous branches** (superficial perineal) are two in number, **posterior** and **anterior.** The **posterior** or **external branch** pierces the base of the triangular ligament of the urethra, and passes forward along the outer side of the urethral triangle in company with the superficial perineal artery; it is distributed to the skin of the scrotum (*nn. scrotales posteriores*). It communicates with the inferior haemorrhoidal, the inferior pudendal, and the other superficial perineal nerve. The **anterior** or **internal branch** also pierces the base of the triangular ligament, and passes forward nearer to the middle line, to be distributed to the inner and back part of the scrotum. Both these nerves supply the labia majora in the female.

The **muscular branches** are distributed to the Transversus perinaei, Accelerator urinae, Erector penis, and Compressor urethrae. A distant branch is given off from the nerve to the Accelerator urinae, which pierces this muscle, and supplies the corpus spongiosum, ending in the mucous membrane of the urethra. This is the **nerve to the bulb.**

The **Dorsal Nerve of the Penis** (*n. dorsalis penis*) is the deepest division of the pudic nerve; it accompanies the pudic artery along the ramus of the ischium; it then runs forward along the inner margin of the ramus of the os pubis, between the superficial and deep layers of the triangular ligament. Piercing the superficial layer it gives a branch to the corpus cavernosum, and passes forward, in company with the dorsal artery of the penis, between the layers of the suspensory ligament, on to the dorsum of the penis, along which it is carried as far as the glans, to which it is distributed.

In the female the dorsal nerve is very small, and supplies the **clitoris** (*n. dorsalis clitoridis*).

The Great Sciatic Nerve (*n. ischiadicus*) (Figs. 655 and 657).—The great sciatic nerve supplies nearly the whole of the integument of the leg, the muscles of the back of the thigh, and those of the leg and foot. It is the largest nervous cord in the body, measuring three-quarters of an inch in breadth, and is the direct continuation of the upper division of the sacral plexus. It passes out of the pelvis through the great sacro-sciatic foramen, below the Pyriformis muscle. It descends between the trochanter major and tuberosity of the ischium, along the back part of the thigh, to about its lower third, where it divides into two large branches, the **internal** and **external popliteal nerves** (Fig. 657).

This division may take place at any point between the sacral plexus and the lower third of the thigh. When the division occurs at the plexus, the two nerves descend together side by side; or they may be separated, at their commencement, by the interposition of part or the whole of the Pyriformis muscle. As the nerve descends along the back of the thigh, it rests upon the posterior surface of the ischium, the nerve of the Quadratus femoris, and the External rotator muscles, in company with the small sciatic nerve and artery, being covered by the Gluteus maximus; lower down, it lies upon the Adductor magnus, and is covered by the long head of the Biceps. The great sciatic even when apparently a single nerve is really two nerves appearing as one.

Branches.—The branches of the nerve, before its division, are **articular** and **muscular.**

The **Articular Branches** (*rami articulares*) arise from the upper part of the nerve; they supply the hip-joint, perforating the posterior part of its fibrous capsule. These branches are sometimes derived from the sacral plexus.

The **Muscular Branches** (*rami musculares*) are distributed to the flexors of the leg—viz., the Biceps, Semitendinosus, and Semimembranosus, and a branch goes to the Adductor magnus. These branches are given off beneath the Biceps muscle.

The **Internal Popliteal** or **Tibial Nerve** (*n. tibialis*) (Figs. 655 and 657), in reality, arises from the fourth and fifth lumbar nerves and the first three sacral nerves, and becomes a part of the trunk of the great sciatic in the buttock, to emerge from it again at the bifurcation of the sciatic. It is the larger of the two terminal branches of the great sciatic, descends along the back part of the thigh, through the middle of the popliteal space, to the lower part of the Popliteus muscle, where it passes with the artery beneath the arch of the Soleus and becomes the **posterior tibial**. It is overlapped by the hamstring muscles above, and then becomes more superficial, and lies to the outer side of, and some distance from, the popliteal vessels; opposite the knee-joint it is in close relation with the vessels, and crosses to the inner side of the artery. Below, it is overlapped by the Gastrocnemius muscle.

The **branches** of this nerve are—**articular, muscular,** and a **cutaneous branch, the communicating tibial nerve.**

The **articular branches** (*rami articulares*), usually three in number, supply the knee-joint; two of these branches accompany the superior and inferior internal articular arteries, and a third, the azygos articular artery.

The **muscular branches** (*rami musculares*), four or five in number, arise from the nerve as it lies between the two heads of the Gastrocnemius muscle; they supply that muscle, and the Plantaris, Soleus, and Popliteus. The filaments which supply the Popliteus turn around its lower border and are distributed to its deep surface.

The **tibial communicating nerve** (*n. cutaneus surae medialis*) is the cutaneous branch. It descends between the two heads of the Gastrocnemius muscle, and about the middle of the back of the leg pierces the deep fascia, and joins the **peroneal** or **fibular communicating nerve** (*ramus anastomoticus peronaeus*) from the external popliteal nerve to form the **external** or **short saphenous** (*n. suralis*) (Fig. 657). The external saphenous nerve, formed by the communicating branches of the internal and external popliteal nerves, passes downward and outward near the outer margin of the tendo Achillis, lying close to the external saphenous vein, to the interval between the external malleolus and the os calcis. It divides in two branches, the posteror of which breaks up into **external calcaneal branches** (*rami calcanei laterales*). The **anterior branch** (*n. cutaneus dorsalis lateralis*) winds around the outer malleolus, and is distributed to the integument along the outer side of the foot and little toe, communicating on the dorsum of the foot with the musculo-cutaneous nerve. In the leg its branches communicate with those of the small sciatic. The cutaneous area supplied by the external saphenous nerve is indicated in Figs. 651, 652, and 659.

The **Posterior Tibial Nerve** (Fig. 657) is the terminal portion of the internal popliteal nerve. It commences at the lower border of the Popliteus muscle, and passes along the back part of the leg with the posterior tibial vessels to the interval between the inner malleolus and the heel, where it divides into the **external** and **internal plantar nerves**. It lies upon the deep muscles of the leg, and is covered in the upper part by the muscles of the calf, lower down by the skin and fascia. In the upper part of its course it lies to the inner side of the posterior tibial artery, but it soon crosses that vessel, and lies to its outer side as far as the ankle. In the lower third of the leg it is placed parallel with the inner margin of the tendo Achillis.

The **branches** of the posterior tibial nerve are **muscular, internal calcaneal** or **calcaneo-plantar,** and **articular.**

The **muscular branches** (*rami musculares*) arise either separately or by a common trunk from the upper part of the nerve. They supply the Soleus, Tibialis posticus, Flexor longus digitorum, and Flexor longus hallucis muscles; the branch to the latter muscle accompanying the peroneal artery. The branch to the Soleus enters its deep surface, while the branch which this muscle receives from the internal popliteal enters its superficial aspect.

The **internal calcaneal** or **calcaneo-plantar branches** (*rami calcanei mediales*) perforate the internal annular ligament, and supply the integument of the heel and inner side of the foot (Fig. 659).

The **articular branch** (*ramus articularis ad articulationem talocruralem*) is given off just above the bifurcation of the nerve and supplies the ankle-joint.

The **Internal Plantar Nerve** (*n. plantaris medialis*) (Fig. 658), the larger of the two terminal branches of the posterior tibial, accompanies the internal plantar artery along the inner side of the foot. From its origin at the inner ankle it passes beneath the Abductor hallucis, and divides into the **common plantar digital nerves** (*nn. digitales plantares communes*), which pass forward between the Abductor hallucis and the Flexor brevis digitorum, divides opposite the bases of the metatarsal bones into **four collateral plantar digital branches**, and communicates with the external plantar nerve.

In its course the internal plantar nerve gives off **cutaneous branches**, which pierce the plantar fascia and supply the integument of the sole of the foot (Fig. 659); **muscular branches**, which supply the Abductor hallucis and Flexor brevis digitorum; **articular branches**, to the articulations of the tarsus and metatarsus; and **four collateral plantar digital branches** (*nn. digitales plantares proprii*). The three outer branches pass between the divisions of the plantar fascia in the clefts between the toes; the first (innermost) branch becomes cutaneous farther back between the Adductor hallucis

Fig. 658.—The plantar nerves.

Fig. 659.—Areas of distribution of the cutaneous nerves of the sole. (W. Keiller, in Gerrish's Text-book of Anatomy.)

and Flexor brevis digitorum. They are distributed in the following manner: The **first** supplies the inner border of the great toe, and sends a filament to the Flexor brevis hallucis muscle; the **second** bifurcates, to supply the adjacent sides of the great and second toes, sending a filament to the First lumbrical muscle; the **third** supplies the adjacent sides of the second and third toes; the **fourth** supplies the corresponding sides of the third and fourth toes, and receives a communicating branch from the external plantar nerve (Fig. 659). Each digital nerve gives off cutaneous and articular filaments; and opposite the last phalanx sends a dorsal branch, which supplies the structures around the nail, the continuation of the nerve

being distributed to the ball of the toe. It will be observed that the distribution of these branches is precisely similar to that of the median nerve in the hand.

The **External Plantar Nerve** (*n. plantaris lateralis*) (Fig. 658), the smaller of the two, completes the nervous supply to the structures of the sole of the foot (Fig. 659), being distributed to the little toe, and one-half of the fourth, as well as to most of the deep muscles, its distribution being similar to that of the ulnar in the hand. It passes obliquely forward with the external plantar artery to the outer side of the foot, lying between the Flexor brevis digitorum and Flexor accessorius, and in the interval between the former muscle and Abductor minimi digiti divides into a **superficial** and a **deep branch.** Before its division it supplies the Flexor accessorius and Abductor minimi digiti.

The **superficial branch** (*ramus superficialis*) separates into two digital nerves. Before division they are called **common plantar digital nerves** (*nn. digitales plantares communes*), after division the **collateral plantar digital nerves** (*nn. digitales plantares proprii*): one, the **external branch,** the smaller of the two, supplies the outer side of the little toe, the Flexor brevis minimi digiti, and the two Interosseous muscles of the fourth metatarsal space; the *other* and larger digital branch supplies the adjoining sides of the fourth and fifth toes, and communicates with the internal plantar nerve.

The **deep** or **muscular branch** (*ramus profundus*) accompanies the external plantar artery into the deep part of the sole of the foot, beneath the tendons of the Flexor muscles and Adductor obliquus hallucis, and supplies all the Interossei (except those in the fourth metatarsal space), the three outer Lumbricales, the Adductor obliquus hallucis, and the Adductor transversus hallucis.

The **External Popliteal** or **Peroneal Nerve** (*n. peronaeus communis*) (Figs. 655 and 657) in reality arises from the fourth and fifth lumbar and the first and second sacral nerves. It is about one-half the size of the internal popliteal, descends obliquely along the outer sides of the popliteal space to the head of the fibula, close to the inner margin of the Biceps muscle. It is easily felt beneath the skin behind the head of the fibula at the inner side of the tendon of the Biceps. It passes between the tendon of the Biceps and outer head of the Gastrocnemius muscle, winds around the neck of the fibula, between the Peroneus longus and the bone, and divides beneath the muscle into the **anterior tibial** and **musculo-cutaneous nerves.**

The **branches** of the peroneal nerve, previous to its division, are **articular** and **cutaneous.**

The **articular branches** (*rami articulares*) are three in number: two of these accompany the superior and inferior external articular arteries to the outer side of the knee. The upper one occasionally arises from the great sciatic nerve before its bifurcation. The third (*recurrent*) articular nerve is given off at the point of division of the peroneal nerve; it ascends with the anterior recurrent tibial artery through the Tibialis anticus muscle to the front of the knee, which it supplies.

The Sural or Lateral Cutaneous Branch (*n. cutaneus surae lateralis*).—There may be two or three of these branches. They supply the integument along the back part and outer side of the leg (Fig. 652). The largest **cutaneous** branch of the peroneal is the **peroneal communicating** (*ramus anastomoticus peronaeus* or *communicans fibularis*), arises near the head of the fibula, crosses the external head of the Gastrocnemius to the middle of the leg, and joins with the communicans tibialis to form the external saphenous. This nerve occasionally exists as a separate branch, which is continued as far down as the heel.

The **Anterior Tibial Nerve** (*n. peronaeus profundus*) (Fig. 650) commences at the bifurcation of the peroneal nerve, between the fibula and upper part of the Peroneus longus muscle, passes obliquely forward beneath the Extensor longus digitorum muscle to the forepart of the interosseous membrane, and gets into relation with the anterior tibial artery above the middle of the leg; it then descends with

the artery to the front of the ankle-joint, where it divides into an **external** and an **internal branch**. This nerve lies at first on the outer side of the anterior tibial artery, then in front of it, and again at its outer side at the ankle-joint.

The **branches** of the anterior tibial nerve in its course through the leg are the **muscular branches** (*rami musculares*) to the Tibialis anticus, Extensor longus digitorum, Peronaeus tertius, and Extensor proprius hallucis muscles, and an **articular branch** to the ankle-joint.

The **external** or **tarsal branch** of the anterior tibial passes outward across the tarsus, beneath the Extensor brevis digitorum, and, having become enlarged, like the posterior interosseous nerve at the wrist, supplies the Extensor brevis digitorum muscle. From the enlargement three minute **interosseous branches** are given off which supply the tarsal joints and the metatarso-phalangeal joints of the second, third, and fourth toes. The first of these sends a filament to the second dorsal interosseous muscle.

The **internal branch**, the continuation of the nerve, accompanies the dorsalis pedis artery along the inner side of the dorsum of the foot, and at the first interosseous space divides into two **dorsal digital branches** (*nn. digitales dorsales hallucis lateralis et digiti secundi medialis*), which supply the adjacent sides of the great and second toes (Fig. 651), communicating with the internal branch of the musculo-cutaneous nerve. Before it divides it gives off an **interosseous branch** to the first space, which supplies the metatarso-phalangeal joint of the great toe and sends a filament to the First dorsal interosseous muscle.

The **Musculo-cutaneous Nerve** (*n. peronaeus superficialis*) (Fig. 650) supplies the muscles on the fibular side of the leg and the integument of the dorsum of the foot (Fig. 651). It passes forward between the Peronei muscles and the Extensor longus digitorum, pierces the deep fascia at the lower third of the leg on its front and outer side, and divides into two branches. This nerve in its course between the muscles gives off **muscular branches** (*rami musculares*) to the Peroneus longus and brevis, and **cutaneous filaments** to the integument of the lower part of the leg (Fig. 651).

The **internal branch** (*n. cutaneus dorsalis medialis*) of the musculo-cutaneous nerve passes in front of the ankle-joint, and divides into two **dorsal digital branches** (*nn. digitales dorsales pedis*), one of which supplies the inner side of the great toe, the other the adjacent sides of the second and third toes. It also supplies the integument of the inner ankle and inner side of the foot, communicating with the internal saphenous nerve, and joining with the anterior tibial nerve, between the great and second toes.

The **external branch** (*n. cutaneus dorsalis intermedius*), the smaller, passes along the outer side of the dorsum of the foot, and divides into two **dorsal digital branches**, the inner being distributed to the contiguous sides of the third and fourth toes, the outer to the opposed sides of the fourth and fifth toes. It also supplies the integument of the outer ankle and outer side of the foot, communicating with the short saphenous nerve.

The branches of the musculo-cutaneous nerve supply all the toes excepting the outer side of the little toe, which is supplied by the external saphenous nerve. The adjoining sides of the great toe or second toe are also supplied by the internal branch of the anterior tibial. It frequently happens that some of the outer branches of the musculo-cutaneous are absent, their place being then taken by branches of the external saphenous nerve.

Surgical Anatomy.—The lumbar plexus passes through the Psoas muscle, and, therefore, in *psoas abscess* any or all of its branches may be irritated, causing severe pain in the parts to which the irritated nerves are distributed. The *genito-crural nerve* is the one which is most frequently implicated. This nerve is also of importance, as it is concerned in one of the *reflexes* employed in the investigation of diseases of the spine. If the skin over the inner side of the thigh just below Poupart's ligament, the part supplied by the crural branch of the genito-crural nerve, be gently tickled in a male child, the testicle will be noticed to be drawn

upward through the action of the Cremaster muscle, which is supplied by the genital branch of the same nerve. The same result may sometimes be noticed in adults, and can almost always be produced by severe stimulation. This reflex, when present, shows that the portion of the cord from which the first and second lumbar nerves are derived is in a normal condition.

The *anterior crural nerve* is in danger of being injured in *fractures of the true pelvis*, since the fracture most commonly takes place through the ascending ramus of the os pubis, at or near the point where this nerve crosses the bone. It is also liable to be injured in *fractures* and *dislocations of the femur*, and is likely to be pressed upon, and its functions impaired, in some *tumors* growing in the pelvis. Moreover, on account of its superficial position, it is exposed to injury in *wounds and stabs in the groin*. When this nerve is *paralyzed*, the patient is unable to flex his hip completely, on account of the loss of motion in the Iliacus; or to extend the knee on the thigh, on account of paralysis of the Quadriceps extensor cruris; there are complete paralysis of the Sartorius and partial paralysis of the Pectineus. There is loss of sensation down the front and inner side of the thigh, except in that part supplied by the crural branch of the genito-crural nerve, and by the ilio-inguinal nerve. There is also loss of sensation down the inner side of the leg and foot as far as the ball of the great toe.

The *obturator nerve* is of special surgical interest. It is rarely *paralyzed* alone, but occasionally is paralyzed in association with the anterior crural. The principal interest attached to it is in connection with its supply to the knee; pain in the knee being symptomatic of many diseases in which the trunk of this nerve, or one of its branches, is irritated. Thus it is well known that in the earlier stages of *hip-joint disease* the patient does not complain of pain in that articulation, but on the inner side of the knee, or in the knee-joint itself, both these articulations being supplied by the obturator nerve, the final distribution of the nerve being to the knee-joint. Again, the same thing occurs in *sacro-iliac disease:* pain is complained of in the knee-joint or on its inner side. The obturator nerve is in close relationship with the sacro-iliac articulation, passing over it, and, according to some anatomists, distributing filaments to it. Again, in *cancer of the sigmoid flexure*, and even in cases where masses of hardened faeces are impacted in this portion of the gut, pain is complained of in the knee. The left obturator nerve lies beneath the sigmoid flexure, and is readily pressed upon and irritated when disease exists in this part of the intestine. Finally, pain in the knee forms an important diagnostic sign in *obturator hernia*. The hernial protrusion as it passes out through the opening in the obturator membrane presses upon the nerve and causes pain in the parts supplied by its peripheral filaments. When the obturator nerve is *paralyzed*, the patient is unable to press his knees together or to cross one leg over the other, on account of paralysis of the Adductor muscles. Rotation outward of the thigh is impaired from paralysis of the Obturator externus. Sometimes there is loss of sensation in the upper half of the inner side of the thigh.

The *great sciatic nerve* is liable to be pressed upon by various *pelvic tumors*, giving rise to pain along its trunk, to which the term *sciatica* is applied. Tumors growing from the pelvic viscera, or bones, *aneurisms* of some of the branches of the internal iliac artery, *calculus in the bladder* when of large size, accumulation of faeces in the rectum, may all cause pressure on the nerve inside the pelvis, and give rise to sciatica. Outside the pelvis exposure to cold, violent movements of the hip-joint, *exostoses* or other tumors growing from the margin of the sacro-sciatic foramen, may also give rise to the same condition. When paralyzed there is loss of motion in all the muscles below the knee, and loss of sensation in the same situation, except the upper half of the back of the leg, supplied by the small sciatic and the upper half of the inner side of the leg, when the communicating branch of the obturator is large.

The sciatic nerve has been frequently cut down upon and *stretched*, or has been acupunctured for the relief of sciatica. The nerve has also been stretched in cases of locomotor ataxia, the anæsthesia of leprosy, etc. In order to define it on the surface, a point is taken at the junction of the middle and lower third of a line stretching from the posterior superior spine of the ilium to the outer part of the tuber ischii, and a line is drawn from this point to the middle of the upper part of the popliteal space. The line must be slightly curved with its convexity outward, and as it passes downward to the lower border of the Gluteus maximus is slightly nearer the tuberosity of the ischium than to the great trochanter, as it crosses a line drawn between these two points. The operation of stretching the sciatic nerve is performed by making an incision over the course of the nerve about the centre of the thigh. The skin, superficial structures, and deep fascia having been divided, the interval between the inner and outer hamstrings is to be defined, and these muscles respectively pulled inward and outward with retractors. The nerve will be found a little to the inner side of the Biceps. It is to be separated from the surrounding structures, hooked up with the finger, and stretched by steady and continuous traction for two or three minutes. The sciatic nerve may also be stretched by what is known as the "dry" plan. The patient is laid on his back, the foot is extended, the leg flexed on the thigh, and the thigh strongly flexed on the abdomen. While the thigh is maintained in this position the leg is forcibly extended to its full extent, and the foot as fully flexed on the leg. This last-named method is uncertain.

The position of the external popliteal nerve, close behind the tendon of the Biceps on the outer side of the ham, should be remembered in *subcutaneous division of the tendon*. After it is divided,

a cord often rises up close beside it, which might be mistaken for a small undivided portion of the tendon, and the surgeon might be tempted to reintroduce his knife and divide it. This must never be done, as the cord is the external popliteal nerve, which becomes prominent as soon as the tendon is divided.

THE CEREBRAL OR CRANIAL NERVES (NERVI CEREBRALES).

The cranial nerves arise from some part of the cerebro-spinal centre, and are transmitted through foramina in the base of the cranium. They have been named numerically, according to the order in which they pass through the dura mater lining the base of the skull. Other names are also given to them, derived from the parts to which they are distributed or from their functions. Taken in their order, from before backward, they are as follows:

1st. Olfactory.
2d. Optic.
3d. Motor oculi.
4th. Trochlear (Pathetic).
5th. Trifacial (Trigeminus).
6th. Abducent.
7th. Facial (Portio dura).
8th. Auditory (Portio mollis).
9th. Glosso-pharyngeal.
10th. Pneumogastric (or Vagus).
11th. Spinal accessory.
12th. Hypoglossal.

All the cranial nerves are connected to some part of the surface of the brain. This is termed their **superficial** or **apparent origin.** But their fibres may, in all cases, be traced deeply into the substance of the brain and to some special centre of gray matter, termed a **nucleus.** This is called their **deep** or **real origin.** The nerves, after emerging from the brain at their apparent origin, pass through foramina or tubular prolongations in the dura mater, leave the skull through foramina in its base, and pass to their final distribution.

THE FIRST OR OLFACTORY NERVE (N. OLFACTORIUS) (Fig. 660).

The olfactory nerves are the special nerves of the sense of smell, and are about twenty in number on each side. These filaments constitute the first or olfactory nerves. They are given off from the under surface of the **olfactory bulb,** an oval mass of a grayish color, which rests on the cribriform plate of the ethmoid bone, and forms the anterior expanded extremity or a slender process of brain-substance, named the **olfactory tract.** The olfactory tract and bulb have already been described (p. 880). The **olfactory tubercle** (*trigonum olfactorium*) is a small triangular mass of gray matter between the diverging roots of the optic tract (p. 881).

Each nerve is surrounded by tubular prolongations from the dura mater and pia mater, the former being lost on the periosteum lining the nose, the latter in the neurilemma of the nerve. The nerves, as they enter the nares, are divisible into two groups: an **inner group,** larger than those on the outer wall, spread out over the upper third of the septum; and an **outer set,** which is distributed over the superior turbinated bone, and the surface of the ethmoid in front of it. As the filaments descend, they unite in a plexiform network, and are believed by most observers to terminate by becoming continuous with the deep extremities of the olfactory cells.

The olfactory nerves differ in structure from other nerves in being composed exclusively of non-medullated fibres. They are deficient in the white substance of Schwann, and consist of axis-cylinders, with a distinct nucleated sheath, in which there are, however, fewer nuclei than in ordinary non-medullated fibres.

The Olfactory Path (Figs. 660 and 661).—Impressions from the *upper portion* of the Schneiderian mucous membrane pass along the olfactory nerves, reach the olfactory bulb, and traverse the olfactory tract to the cerebral hemisphere of the same side. The cortical area of the sense of smell is in the uncus hip-

(Ramon y Cajal.)

pocampi. Impressions which are conveyed by the internal root pass to Broca's area which is in front of the inner root of the olfactory tract, to the anterior extremity of the gyrus fornicatus, the cingulum, and the uncinate fasciculus to the cortical centre (Santee). Impressions travelling by the middle root reach

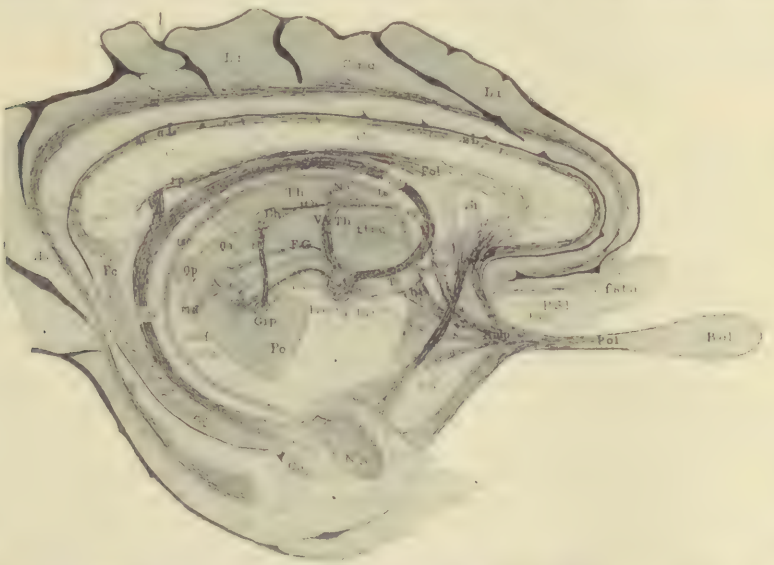

FIG. 661.—The olfactory system and tracts. Bol, olfactory bulb; Pol, olfactory tract; Rolp, deep olfactory fibres; Roli, internal olfactory fibres; Role, external olfactory fibres. The deep fibres pass to the thalamus (Th) and its nuclei; Tc, tuber cinereum; Tm, tuber mamillare; and to tsc, taenia semicircularis, and tth, taenia thalami; also into the anterior commissure, coa. The internal olfactory fibres pass into the striae of Lancisi, sL, and thus to the fasciola cinerea, Fc. The external olfactory fibres pass directly to the uncinate gyrus, U. Tg, fornix from the corpus mamillare (Tm) to Ammon's horn (Cg); NA, nucleus amygdalae; Cing, cingulum; Cc, corpus callosum; Fc, fasc. cinerea; FG, Gudden's fasciculus; FM, fasc. retroflexus of Meynert; Na, ant. nuc. of thalamus; Gip, interpeduncular ganglion; Gh, ganglion; habenula; Qa, Qp, corp. quadrigemina; Po, pons; VA, fascic. Vicq, d'Azyr. (Dejerine.)

the trigone and then pass to the cortical centre, as do those by way of the internal root, or they reach it by way of the anterior commissure (Santee). The outer root conducts impulses directly to the cortical area. Fig. 661 shows the olfactory path according to Dejerine.

Surgical Anatomy.—Destruction of the olfactory tract of one side causes loss of smell (*anosmia*) on the side of the injury, because the olfactory tract is uncrossed. In severe injuries to the head the olfactory bulb may become separated from the olfactory nerves, thus producing loss of the sense of smell, and with this a considerable loss in the sense of taste, as much of the perfection of the sense of taste is due to the sapid substances being also odorous and simultaneously exciting the sense of smell. When the sense of smell is lost, an individual cannot distinguish the *flavor* of food, but he can distinguish that a substance is salt, or sweet, or bitter, or acid. The most usual cause of injury to the olfactory nerve is fracture of the base of the skull, the line of fracture passing through the cribriform plate of the ethmoid bone, but a blow upon the face, forehead, or back of the head, which does not produce fracture may injure the nerve.

THE SECOND OR OPTIC NERVE (N. OPTICUS) (Fig. 662).

The second or optic nerve, the special nerve of the sense of sight, is distributed exclusively to the eyeball. It joins the eyeball about one-eighth of an inch to the inner side of the axis of the globe, penetrates the fibrous coat and the vascular tunic, and at the optic disk is expanded and forms part of the retina. The nerves of opposite sides are connected together at the commissure, and from the back of the commissure they may be traced to the brain, under the name of the **optic tracts.**

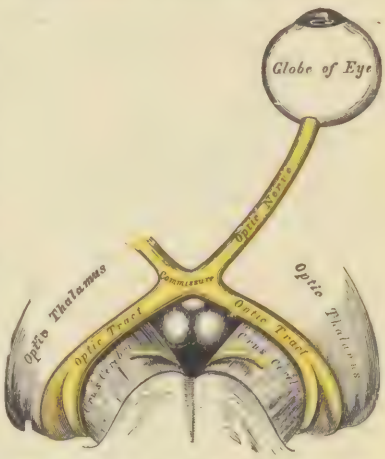

FIG. 662. The left optic nerve and optic tracts.

The Optic Tract.—The optic tract, at its connection with the brain, is divided into two bands, external and internal. The **external band** is the larger; it arises from the external geniculate body and from the under part of the pulvinar of the optic thalamus, and is partly continuous with the brachium of the anterior or upper quadrigeminal body. The **internal band** curves around the crusta, and passes beneath the internal geniculate body, with which it is connected, and then appears to lose itself in the brachium of the posterior or inferior quadrigeminal body. The fibres by which it is connected to the internal geniculate body are merely commissural, forming part of **Gudden's commissure.** From this origin the tract winds obliquely across the under surface of the crus cerebri, in the form of a flattened band, and is attached to the crus by its anterior margin. It then assumes a cylindrical form, and, as it passes forward, is connected with the tuber cinereum and lamina cinerea. It finally joins with the tract of the opposite side to form the **optic commissure.**

The Optic Commissure (*chiasma opticum*) (Figs. 662 and 663, and p. 882) is somewhat quadrilateral in form, rests upon the olivary eminence and on the anterior part of the diaphragma sellae, being bounded, above, by the lamina cinerea; behind by the tuber cinereum; on either side by the anterior perforated space. Within the commissure, the optic nerves of the two sides undergo a partial decussation (Figs. 663 and 664). The fibres which form the inner margin of each tract and posterior part of the commissure have no connection with the optic nerves. They simply pass across the commissure from one hemisphere of the brain to the other, and connect the internal geniculate bodies of the two sides. They are known as the **inter-cerebral fibres of the optic commissure** or the **commissure of Gudden.** The remainder and principal part of the optic com-

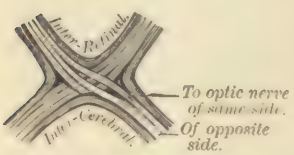

FIG. 663.—Course of the fibres in the optic commissure.

missure consists of two sets of fibres, crossed and uncrossed. The **crossed fibres**, which are the more numerous, occupy the central part of the chiasma, and pass from the optic tract of one side to the optic nerve of the other, decussating in the commissure with similar fibres of the opposite tract. The **uncrossed fibres** occupy the outer part of the chiasma, and pass from the tract of one side to the nerve of the same side.[1]

The great majority of the fibres of the optic nerve consist of the afferent axones of nerve-cells in the retina. Some few, however, are efferent fibres, and grow out from the brain. The afferent fibres end in arborizations around the cells in the external geniculate body, pulvinar, nucleus of the motor oculi nerve, and the upper quadrigeminal body. The external geniculate body and pulvinar are sometimes termed the **lower visual centres**. From these nuclei other fibres are prolonged to the **cortical half-visual centre**, which, according to most observers, is situated in the cuneus, and probably also, to a small extent, in the curved portion of the occipital lobe (Fig. 664).

It should be stated that some fibres are detached from the optic tract, and pass through the crus cerebri to the **nucleus of the third nerve.** These fibres are small, and may be regarded as afferent branches for the sphincter pupillae and ciliary muscles. Other fibres pass to the cerebellum through its superior peduncles, while others, again, are lost in the pons.

The optic nerves *arise* from the forepart of the commissure, and, diverging from one another, become rounded in form and firm in texture, and are enclosed in a sheath derived from the pia mater and arachnoid. As each nerve passes through the corresponding optic foramen it receives a sheath from the dura mater; and as it enters the orbit this sheath subdivides into two layers, one of which becomes continuous with the periosteum of the orbit; the other forms the proper sheath of the nerve and surrounds it as far as the sclerotic. The nerve passes forward and outward through the cavity of the orbit, pierces the sclerotic and choroid coats at the back part of the eyeball, about one-eighth of an inch to the nasal side of its centre, and expands into the retina. A small artery, the *arteria centralis retinae*, perforates the optic nerve a little behind the globe, and runs along its interior in a tubular canal of fibrous tissue. It supplies the inner surface of the retina, and is accompanied by corresponding veins.

The Optic Path (Fig. 664).—Impulses of sight originate in the retina. From the right half of each retina impulses pass by way of the optic nerves to the right optic tract. From the left half of each retina impulses pass by way of the optic nerves to the left optic tract. Impulses from the nasal half of each retina pass by decussated fibres to the opposite optic tract. Impulses from the temporal half of the retina pass by undecussated fibres to the optic tract of the same side, although a few fibres may cross farther back through the quadrigeminal bodies. From the optic tract impulses pass to the external geniculate body, pulvinar, upper quadrigeminal body, and nucleus of the motor oculi nerve. From the external geniculate body and pulvinar impulses pass by way of the optic radiatus through the posterior segment of the internal capsule to the half-vision centre in the cuneus and the convexity of the occipital lobe. The superior quadrigeminal body and the nucleus of the third nerve produce ocular reflexes and the pupillary reflex.

Surgical Anatomy.—The optic nerve is peculiarly liable to become the seat of *neuritis* or undergo *atrophy* in affections of the central nervous system, and, as a rule, the pathological relationship between the two affections is exceedingly difficult to trace. There are, however, certain points in connection with the anatomy of this nerve which tend to throw light upon the frequent association of these affections with intracranial disease: (1) From its mode of develop-

[1] A specimen of congenital absence of the optic commissure is to be found in the Museum of the Westminster Hospital. See also Henle, Nervenlehre, p. 393, ed 2.—Ed. of 15th English edition.

ment and from its structure the optic nerve must be regarded as a prolongation of the brain-substance, rather than as an ordinary cerebro-spinal nerve. (2) As it passes from the brain it receives sheaths from the three cerebral membranes—a perineural sheath from the pia mater, an intermediate sheath from the arachnoid, and an outer sheath from the dura mater, which is also connected with the periosteum as it passes through the optic foramen. These sheaths are separated from each other by spaces which communicate with the subdural and subarachnoid spaces respectively. The innermost or perineural sheath sends a process around the arteria centralis retinae into the interior of the nerve, and enters intimately into its structure. Thus inflammatory affections of the meninges or of the brain may readily extend themselves along these spaces or along the interstitial connective tissue in the nerve.

The course of the fibres in the optic commissure has an important pathological bearing, and has been the subject of much controversy. Microscopic examination, experiments, and pathology all seem to point to the fact that there is a partial decussation of the fibres, each tract supplying

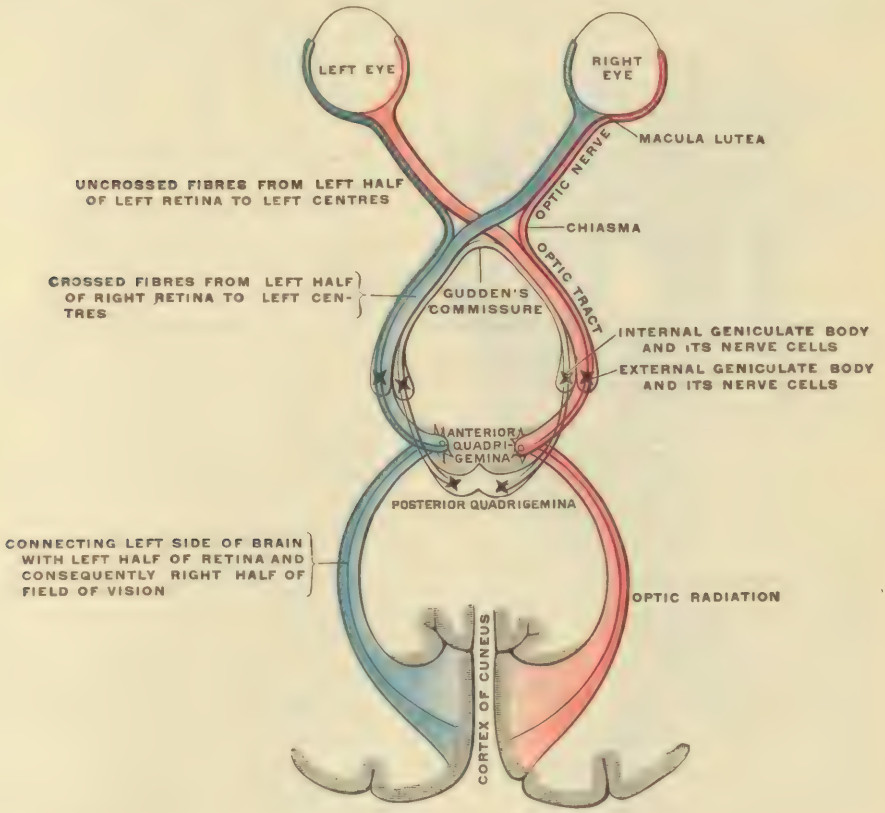

FIG. 664.—Diagram of the course of the optic fibres. (W. Keiller in Gerrish's Anatomy.)

the corresponding half of each eye, so that the right tract supplies the right half of each eye, and the left tract the left half of each eye. At the same time, Charcot believes—and his view has met with general acceptation—that the fibres which do not decussate at the optic commissure have already decussated in the corpora quadrigemina, so that lesion of the cerebral centre of one side causes complete blindness of the opposite eye because both sets of decussating fibres are destroyed. Whereas should one tract—say the right—be destroyed by disease, there will be blindness of the right half of both retinae.

An antero-posterior section through the commissure would divide the decussating fibres, and would therefore produce blindness of the inner half of each eye; while a section at the margin of the side of the optic commissure would produce blindness of the external half of the retina of the same side.

The optic nerve may also be affected in injuries or diseases involving the orbit, in fractures of the anterior fossa of the base of the skull, in tumors of the orbit itself, or those invading this cavity from neighboring parts.

THE THIRD OR MOTOR OCULI NERVE (N. OCULOMOTORIUS) (Figs. 665, 666, 669).

The third or motor oculi nerve supplies all the muscles of the orbit except the Superior oblique and External rectus; it also supplies, through its connection with the ciliary ganglion, the Sphincter muscle of the iris and the Ciliary muscle. It is rather a large nerve, of rounded form and firm texture.

Its *apparent origin* is from the inner surface of the crus cerebri, immediately in front of the pons Varolii. The *deep origin* may be traced through the substantia nigra and tegmentum of the crus to a nucleus situated on either side of the median line beneath the floor of the aqueduct of Sylvius (Fig. 613). The nucleus of the third nerve also receives fibres from the sixth nerve of the opposite side. These will be referred to again in the description of the latter nerve. The nucleus of the third nerve, considered from a physiological standpoint, can be subdivided into several smaller groups of cells, each group controlling a particular muscle. The nerves to the different muscles appear to take their origin from before backward, as follows: Inferior oblique, Inferior rectus, Superior rectus and Levator palpebrae, Internal rectus; while from the anterior end of the nucleus the fibres for accommodation and for the Sphincter pupillae take their origin.

FIG. 665.—Nerves of the orbit, seen from above.

On emerging from the brain, the nerve is invested with a sheath of pia mater, and enclosed in a prolongation from the arachnoid. It passes between the superior cerebellar and posterior cerebral arteries, and then pierces the dura mater in front of and external to the posterior clinoid process, passing between the two processes from the free and attached borders of the tentorium, which are prolonged forward to be connected with the anterior and posterior clinoid processes of the sphenoid bone. It passes along the outer wall of the cavernous sinus (Figs. 454 and 455); above the other orbital nerves, receiving in its course one or two filaments from the cavernous plexus of the sympathetic, and a communicating branch from the first division of the fifth. It then divides into two branches, which enter the orbit through the sphenoidal fissure, between the two heads of the External rectus muscle (Fig. 665). On passing through the fissure, the nerve is placed below the fourth and the frontal and lachrymal branches of the ophthalmic nerve, and has passing between its two divisions the nasal nerve (Fig. 675).

The Superior Division (*ramus superior*) (Fig. 666).—The superior division, the smaller, passes inward over the optic nerve, and supplies the Superior rectus and Levator palpebrae.

The Inferior Division (*ramus inferior*) (Fig. 666).—The inferior division, the larger, divides into three branches. One passes beneath the optic nerve to the Internal rectus; another, to the Inferior rectus; and the third, the longest of the three, passes forward between the Inferior and External recti to the Inferior oblique. From this latter a short, thick branch, **radix brevis ganglii ciliaris**, is given off to the lower part of the lenticular ganglion and forms its *short* or *motor* root

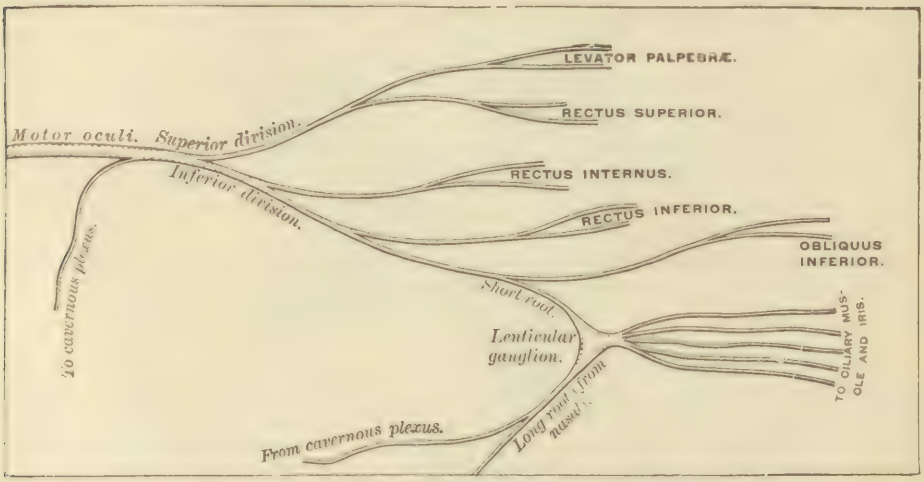

FIG. 666.—Plan of the motor oculi nerve. (The lenticular ganglion is not shown in normal position. If it were the short root would enter the inferior angle.) (After Flower.)

(Figs. 666, 669, and 670). It also gives off one or two filaments to the Inferior rectus. All these branches enter the muscles on their ocular surface, except that to the Inferior oblique, which enters its posterior border.

Surgical Anatomy. *Paralysis* of the third nerve may be the result of many causes: as cerebral disease; conditions causing pressure on the cavernous sinus; periostitis of the bones entering into the formation of the sphenoidal fissure; fracture of the orbit. It results, when complete, in (1) ptosis, or drooping of the upper eyelid, in consequence of the Levator palpebrae being paralyzed; (2) external strabismus, on account of the unopposed action of the External rectus muscle, which is not supplied by the third nerve, and is not therefore paralyzed; (3) dilatation of the pupil, because the sphincter fibres of the iris are paralyzed; (4) loss of power of accommodation, as the sphincter pupillae, the ciliary muscle, and the Internal rectus are paralyzed; (5) slight prominence of the eyeball, owing to most of its muscles being relaxed. Occasionally paralysis may affect only a part of the nerve; that is to say, there may be, for example, a dilated and fixed pupil, with ptosis, but no other signs. *Irritation* of the nerve causes spasm of one or other of the muscles supplied by it; thus, there may be internal strabismus from spasm of the Internal rectus; accommodation for near objects only from spasm of the Ciliary muscle, or contraction of the pupil (myosis), from irritation of the sphincter of the pupil.

THE FOURTH OR TROCHLEAR NERVE (N. TROCHLEARIS) (Figs. 665 and 669).

The fourth or trochlear nerve or **Patheticus**, the smallest of the cranial nerves, supplies the Superior oblique muscle.

The *apparent origin*, at the base of the brain, is on the outer side of the crus cerebri, just in front of the pons Varolii, but the fibres can be traced backward behind the corpora quadrigemina to the valve of Vieussens, on the upper surface of which the two nerves decussate, **decussatio nervorum trochlearium**. Its *deep origin* may be traced to a nucleus in the floor of the aqueduct of Sylvius immediately below that of the third nerve, with which it is continuous (Fig. 613).

Emerging from the upper end of the valve of Vieussens, the nerve is directed outward across the superior peduncle of the cerebellum, and then winds forward

around the outer side of the crus cerebri, immediately above the pons Varolii, pierces the dura mater in the free border of the tentorium cerebelli, just behind, and external to, the posterior clinoid process, and passes forward in the outer wall of the cavernous sinus, between the third nerve and the ophthalmic division of the fifth (Figs. 454 and 455). It crosses the third nerve and enters the orbit through the sphenoidal fissure (Fig. 675). It now becomes the highest of all the nerves, lying at the inner extremity of the fissure internal to the frontal nerve. In the orbit it passes inward, above the origin of the Levator palpebrae, and finally enters the orbital surface of the Superior oblique muscle. In the outer wall of the cavernous sinus this nerve is not infrequently blended with the ophthalmic division of the fifth.

Branches of Communication.—In the outer wall of the cavernous sinus it receives some filaments from the cavernous plexus of the sympathetic. In the sphenoidal fissure it occasionally gives off a branch to assist in the formation of the lachrymal nerve.

Branches of Distribution.—It gives off a recurrent branch, which passes backward between the layers of the tentorium, dividing into two or three filaments which may be traced as far back as the wall of the lateral sinus.

Surgical Anatomy.—The fourth nerve when *paralyzed* causes loss of function in the Superior oblique, so that the patient is unable to turn his eye downward and outward. Should the patient attempt to do this, the eye on the affected side is twisted inward, producing *diplopia* or double vision. Accordingly, it is said that the first symptom of this disease which presents itself is giddiness when going down hill or in descending stairs, owing to the double vision induced by the patient looking at his steps while descending.

THE FIFTH, TRIGEMINAL OR TRIFACIAL NERVE (N. TRIGEMINUS)

(Figs. 665, 667, 668, 669, 670, 671, 672, 673, 674).

The fifth, trigeminal or trifacial nerve is the largest cranial nerve. It resembles a spinal nerve (1) in arising by two roots; (2) in having a ganglion developed on its posterior root; and (3) in its function, since it is a compound nerve. It is the great sensory nerve of the head and face and the motor nerve of the muscles of mastication. Its upper two divisions, **portio major,** are entirely sensory, the third division, **portio minor,** is partly sensory and partly motor. It *arises* by two roots: of these the anterior is the smaller, and is the **motor root** (Fig. 613); the posterior, the larger and **sensory root.** Its *superficial origin* is from the side of the pons Varolii, nearer to the upper than the lower border (Fig. 613). The smaller root consists of three or four bundles; the larger root consists of numerous bundles of fibres, varying in number from seventy to a hundred. The two roots are separated from one another by a few of the transverse fibres of the pons. The *deep origin* of the larger or sensory root is chiefly from a long tract in the medulla, the **lower sensory nucleus,** which is continuous below with the substantia gelatinosa of Rolando (Fig. 607). The fibres from this nucleus form the so-called **ascending root of the fifth nerve** (Fig. 607); they pass upward through the pons and join with fibres from the locus caeruleus or **upper sensory nucleus** (Fig. 613), which is situated to the outer side of the nucleus, from which the lower part of the motor root takes origin. The *deep origin* of the smaller or motor root is derived partly from a nucleus embedded in the gray matter of the upper part of the floor of the fourth ventricle and partly from a collection of nerve-cells situated at the side of the aqueduct of Sylvius, from which the fibres pass downward under the name of the **descending root of the fifth nerve** (Fig. 613).

The two roots of the nerve pass forward below the tentorium cerebelli as it bridges over the notch on the inner part of the superior border of the petrous portion of the temporal bone (Fig. 668); they then run between the bone and the dura

mater to the apex of the petrous portion of the temporal bone, where the fibres of the sensory root form the **large semilunar** or **Gasserian ganglion** (Figs. 667 and 668), while the motor root passes beneath the ganglion without having any connection with it, and joins outside the cranium with one of the trunks derived from it (Figs. 667 and 668).

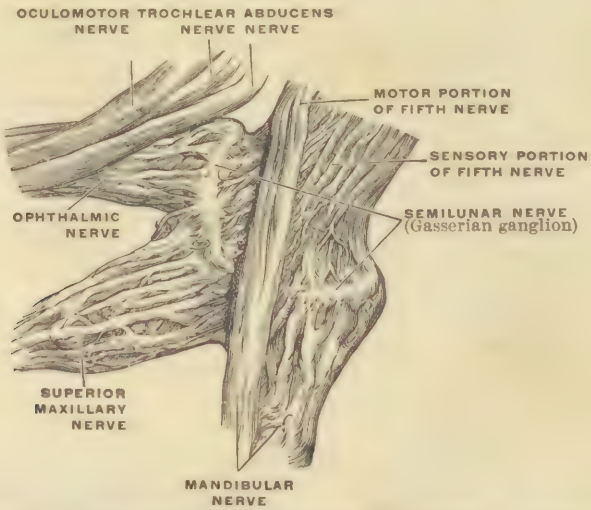

FIG. 667.—The right semilunar or Gasserian ganglion, viewed from the medial side. (Spalteholz.)

The Gasserian or Semilunar Ganglion[1] (*ganglion semilunare*) (Figs. 667, 668, 669, 670, 671, 672, and 673).—The Gasserian or semilunar ganglion is lodged in an osteo-fibrous space, the **cavum Meckelii** (Figs. 545 and 668), near the apex of the petrous portion of the temporal bone. The ganglion is of somewhat crescentic form, with its convexity turned forward. Its upper surface is intimately adherent to the dura mater. Besides the small or motor root, the **large superficial petrosal nerve** lies underneath the ganglion.

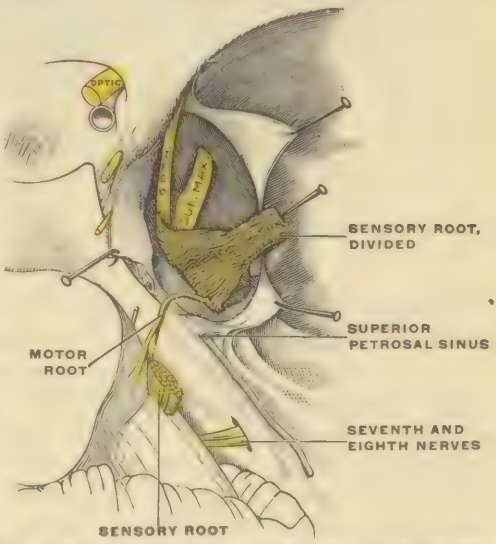

FIG. 668.—The course of the motor root of the fifth nerve. (Poirier and Charpy.)

Branches of Communication.—This ganglion receives on its **inner side** filaments from the carotid plexus of the sympathetic.

Branches of Distribution.—It gives off minute branches to the tentorium cerebelli and the dura mater in the middle fossa of the cranium. From its *anterior border*, which is directed forward and outward, three large branches proceed—the **ophthalmic, superior maxillary**, and **inferior maxillary**. The ophthalmic and superior maxillary consist exclusively of fibres derived from the larger root and ganglion, and are solely nerves of common sensation. The third division, or inferior

[1] A Viennese anatomist, Raimund Balthasar Hirsch (1765), was the first who recognized the ganglionic nature of the swelling on the sensory root of the fifth nerve, and called it, in honor of his otherwise unknown teacher, Jon. Laur. Gasser, the "Ganglion Gasseri." Julius Casserius, whose name is given to the musculo-cutaneous nerve of the arm, was professor at Padua, 1545–1605. (See Hyrtl, Lehrbuch der Anatomie, p. 895 and p. 55.) ED. of 15th English edition.

maxillary, is joined outside the cranium by the motor root. This, therefore, strictly speaking, is the only portion of the fifth nerve which can be said to resemble a spinal nerve.

Ophthalmic Nerve (*n.ophthalmicus*) (Figs. 665, 667, 668, 669, 670, 671, 672, and 673).—The ophthalmic, or **first division** of the fifth, is a sensory nerve. It supplies the eyeball, the lachrymal gland, the mucous lining of the eye and nasal fossae, and the integument of the eyebrow, forehead, and nose (Fig. 674). It is the smallest of the three divisions of the fifth, arising from the upper part of the Gasserian ganglion. It is a short, flattened band, about an inch in length, which passes forward along the outer wall of the cavernous sinus (Figs. 454 and 455), below the other nerves (Fig. 667), and just before entering the orbit, through the sphenoidal fissure, divides into three branches—**lachrymal, frontal,** and **nasal** (Figs. 665, 669, 670, 671).

Branches of Communication.—The ophthalmic nerve gives off in the cavernous sinus a branch to the dura mater (*n. tentorii*), is joined by filaments from the cavernous plexus of the sympathetic, and gives off minute branches to communicate with the third and sixth nerves, and not infrequently with the fourth.

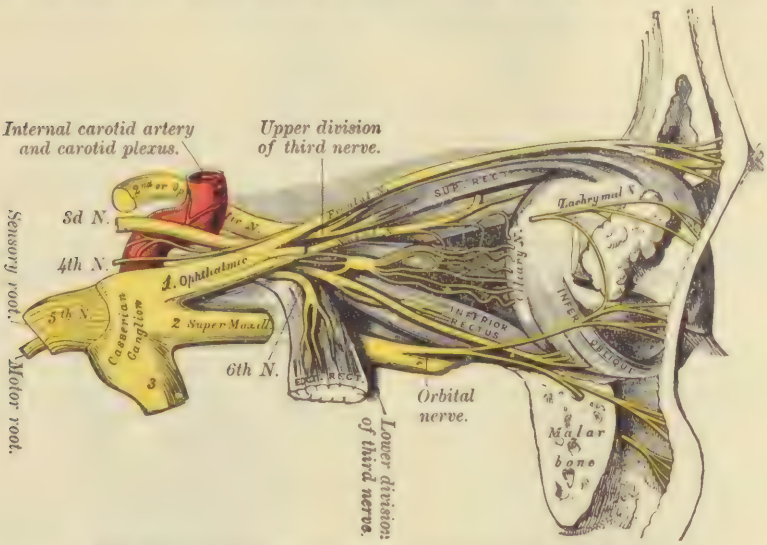

FIG. 669.—Nerves of the orbit and ophthalmic ganglion, side view.

Branches of Distribution.—It gives off recurrent filaments which pass between the layers of the tentorium, and then divide into—

Lachrymal. Frontal. Nasal.

The Lachrymal Nerve (*n. lacrimalis*) (Figs. 665, 669, 670, and 671).—The lachrymal is the smallest of the three branches of the ophthalmic. It sometimes receives a filament from the fourth nerve, but this is possibly derived from the branch of communication which passes from the ophthalmic to the fourth. It passes forward in a separate tube of dura mater, and enters the orbit through the narrowest part of the sphenoidal fissure (Fig. 675). In the orbit it runs along the upper border of the External rectus muscle, with the lachrymal artery, and communicates with the temporo-malar branch of the superior maxillary nerve. It enters the lachrymal gland and gives off several filaments, which supply the gland and the conjunctiva. Finally, it pierces the superior palpebral ligament, and terminates in the integument of the upper eyelid, joining with filaments of the facial nerve. The lachrymal nerve is occasionally absent, when its place is taken by the temporal branch of the superior maxillary. Sometimes the latter branch is absent, and a continuation of the lachrymal is substituted for it.

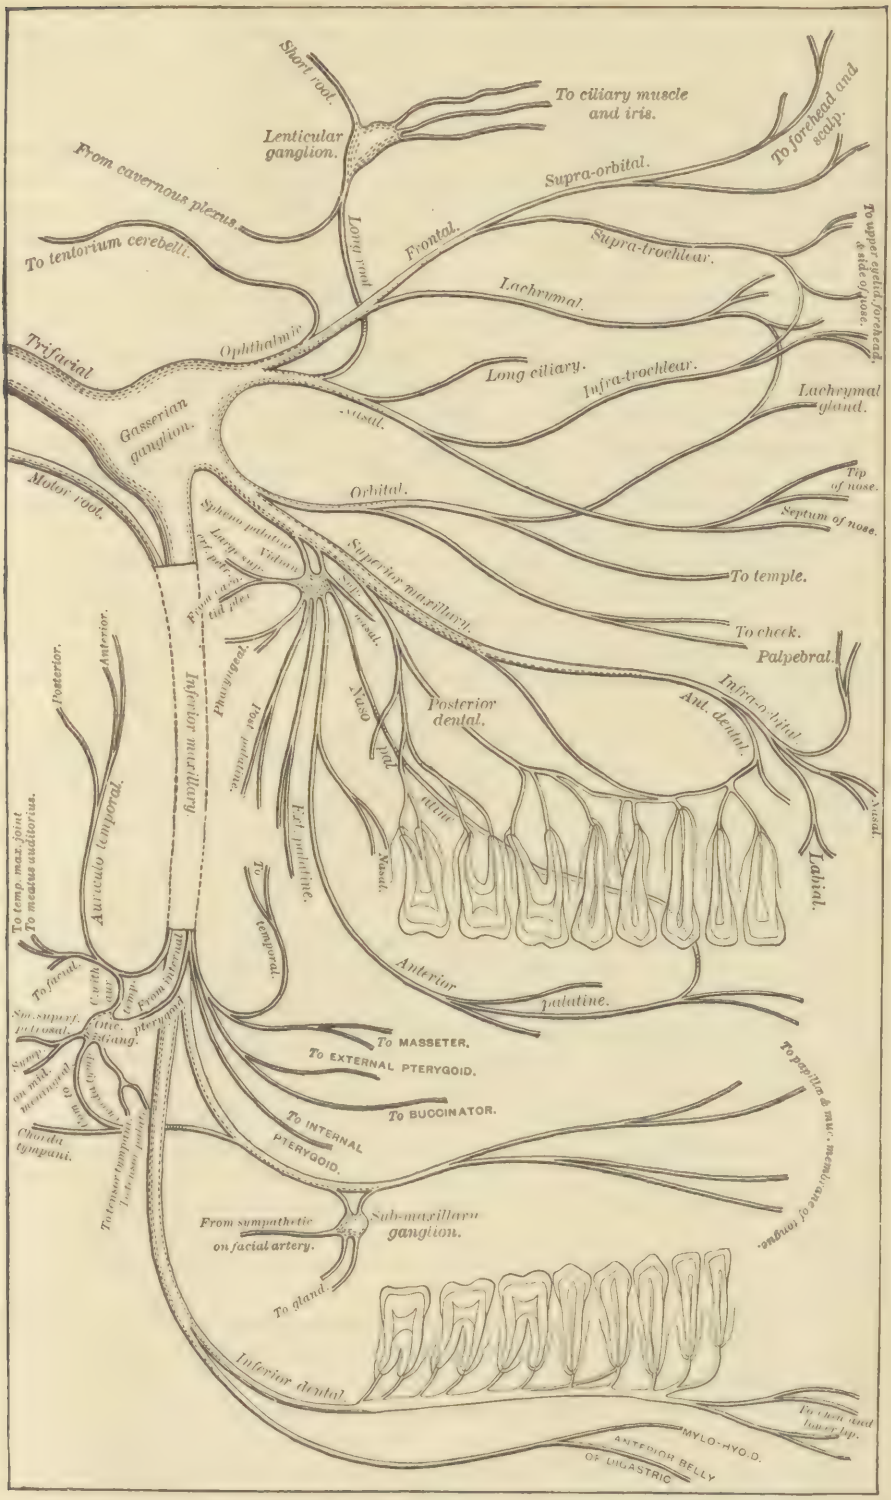

FIG. 670.—Plan of the fifth cranial nerve. (The lenticular ganglion is displaced from its normal position. The portion where the short root enters is really the inferior angle; in the diagram it is the superior angle.) (After Flower.)

The Frontal Nerve (*n. frontalis*) (Figs. 665, 669, and 670).—The frontal is the largest division of the ophthalmic, and may be regarded, both from its size and direction, as the continuation of the nerve. It enters the orbit above the muscles, through the sphenoidal fissure (Fig. 675), and runs forward along the middle line, between the Levator palpebrae and the periosteum. Midway between the apex and the base of the orbit it divides into two branches, **supratrochlear** and **supra-orbital.**

The **Supratrochlear Branch** (*n. supratrochlearis*) (Figs. 665 and 670), the smaller of the two, passes inward, above the pulley of the superior oblique muscle, and gives off a descending filament, which joins with the infratrochlear branch of the nasal nerve. It then escapes from the orbit between the pulley of the Superior oblique and the supraorbital foramen, curves up on to the forehead close to the bone, ascends beneath the Corrugator supercilii and Occipito-frontalis muscles, and, dividing into branches which pierce these muscles, it supplies the integument of the lower part of the forehead on either side of the middle line and sends filaments to the conjunctiva and skin of the upper lid.

The **Supraorbital Branch** (*n. supraorbitalis*) (Figs. 675 and 670) passes forward through the supraorbital foramen, and gives off, in this situation, **palpebral filaments** to the upper eyelid. It then ascends upon the forehead, and terminates in **cutaneous** and **pericranial branches.**

The **cutaneous branches,** two in number, an inner and an outer, supply the integument of the cranium as far back as the vertex. They are at first situated beneath the Occipito-frontalis, the inner branch perforating the frontal portion of the muscle, the outer branch its tendinous aponeurosis.

The **pericranial branches** are distributed to the pericranium over the frontal and parietal bones.

The Nasal Nerve (*n. nasociliaris*) (Figs. 665, 669, and 670).—The nasal nerve is intermediate in size between the frontal and lachrymal, and more deeply placed than the other branches of the ophthalmic. It enters the orbit by way of the sphenoidal fissure (Fig. 675) between the two heads of the External rectus, and passes obliquely inward across the optic nerve, beneath the Superior rectus and Superior oblique muscles, to the inner wall of the orbit, where it passes through the anterior ethmoidal foramen, and, entering the cavity of the cranium, traverses a shallow groove on the front of the cribriform plate of the ethmoid bone, and passes down, through the slit by the side of the crista galli, into the nose (Fig. 672), where it divides into two branches, an **internal** and an **external branch.** The **internal branch** (*rami nasales mediales*) supplies the mucous membrane near the forepart of the septum of the nose. The **external branch** (*rami nasales laterales*) descends in a groove on the inner surface of the nasal bone, and supplies a few filaments to the mucous membrane covering the forepart of the outer wall of the nares as far as the inferior spongy bone; it then leaves the cavity of the nose, between the lower border of the nasal bone and the upper lateral cartilage of the nose, and, passing down beneath the Compressor nasi, supplies the integument of the ala and the tip of the nose, joining with the facial nerve.

Branches.—The branches of the nasal nerve are the **ganglionic, ciliary,** and **infratrochlear.**

The **Ganglionic Branch,** or the **long root of the ciliary ganglion** (*radix longa ganglii ciliaris*) (Figs. 666, 669, and 670), is a slender branch, about half an inch in length, which usually arises from the nasal nerve, between the two heads of the External rectus muscle. It passes forward on the outer side of the optic nerve, and enters the postero-superior angle of the ciliary ganglion, forming its long root. It is sometimes joined by a filament from the cavernous plexus of the sympathetic or from the superior division of the third nerve.

The **Long Ciliary Nerves** (*nn. ciliares longi*) (Fig. 670), two or three in number, are given off from the nasal as it crosses the optic nerve. They join the *short*

ciliary nerves (Figs. 666, 669, and 670) from the ciliary ganglion, pierce the posterior part of the sclerotic, and, running forward between it and the choroid, are distributed to the ciliary muscle, iris, and cornea.

The **Infratrochlear Branch** (*n. infratrochlearis*) (Figs. 665 and 670) is given off just before the nasal nerve passes through the anterior ethmoidal foramen. It runs forward along the upper border of the Internal rectus muscle, and is joined, beneath the pulley of the Superior oblique, by a filament from the supratrochlear nerve. It then passes to the inner angle of the eye, and supplies the integument of the eyelids and side of the nose, the conjunctiva, the lachrymal sac, and the caruncula lacrimalis.

Connected with the three divisions of the fifth nerve are four small ganglia. With the first division is connected the **ophthalmic ganglion**; with the second division, the **spheno-palatine** or **Meckel's ganglion**; and with the third, the **otic** and **submaxillary ganglia.** All the four receive sensory filaments from the fifth nerve, and motor and sympathetic filaments from various sources; these filaments are called the *roots of the ganglia.*

The **Ophthalmic, Lenticular** or **Ciliary Ganglion** (*ganglion ciliare*) (Figs. 666, 669, and 670) is a small, quadrangular, flattened ganglion, of a reddish-gray color, and about the size of a pin's head, situated at the back part of the orbit between the optic nerve and the External rectus muscle, lying generally on the outer side of the ophthalmic artery. It is enclosed in a quantity of loose fat, which makes its exposure by dissection somewhat difficult.

Its **branches of communication** or **roots** are three, all of which enter its posterior border. One, the **long** or **sensory root** (*radix longa ganglii ciliaris*), is derived from the nasal branch of the ophthalmic and joins the superior angle of the ganglion. The second, the **short** or **motor root** (*radix brevis ganglii ciliaris*), is a short, thick nerve, occasionally divided into two parts, which is derived from the branch of the **third nerve** to the Inferior oblique muscle, and is connected with the inferior angle of the ganglion. The third, the **sympathetic root** (*radix sympathetica ganglii ciliaris*), is a slender filament from the *cavernous plexus* of the sympathetic. This is frequently blended with the long root, though it sometimes passes to the ganglion separately. According to Tiedemann, this ganglion receives a filament of communication from the **spheno-palatine ganglion.**

Its **branches of distribution** are the **short ciliary nerves** (*nn. ciliares breves*) (Figs. 666, 669, and 670). These are delicate filaments, from six to ten in number, which arise from the forepart of the ganglion in two bundles, connected with its superior and inferior angles; the lower bundle is the larger. They run forward with the ciliary arteries in a wavy course, one set above and the other below the optic nerve, and are accompanied by the long ciliary nerves from the nasal nerve. They pierce the sclerotic at the back part of the globe, pass forward in delicate grooves on its inner surface, and are distributed to the Ciliary muscle, iris, and cornea. Tiedemann has described one small branch as penetrating the optic nerve with the arteria centralis retinae.

The **circular fibres** of the iris are innervated by the third nerve; the **radiating fibres** are innervated by the sympathetic.

The Superior Maxillary Nerve (*n. maxillaris*) (Figs. 667, 668, 669, 670, 671, and 672).—The superior maxillary or **second division of the fifth** is a sensory nerve. It is intermediate, both in position and size, between the ophthalmic and inferior maxillary. It commences at the middle of the Gasserian ganglion as a flattened plexiform band (Fig. 667), and, passing horizontally forward, it leaves the skull through the foramen rotundum (Fig. 668), where it becomes more cylindrical in form and firmer in texture. It then crosses the spheno-maxillary fossa (Fig. 67), enters the orbit through the spheno-maxillary fissure, traverses the infraorbital canal in the floor of the orbit, and appears upon the face of the infraorbital fora-

men. After it enters the infraorbital canal the nerve is usually called the **infraorbital** (*n. infraorbitalis*), and the infraorbital nerve is the terminal branch of the superior maxillary nerve (Fig. 671). At its termination the nerve lies beneath the Levator labii superioris muscle, and divides into a leash of branches, which spread out upon the side of the nose, the lower eyelid, and upper lip, joining with filaments of the facial nerve.

Branches of Distribution.—The branches of this nerve may be divided into four groups: 1. Those given off in the **cranium**. 2. Those given off in the **spheno-maxillary fossa**. 3. Those in the **infraorbital canal**. 4. Those on the **face**.

In the cranium . . .	Meningeal.
Spheno-maxillary fossa .	Orbital or temporo-malar. Spheno-palatine. Posterior superior dental.
Infraorbital canal . . .	Middle superior dental. Anterior superior dental.
On the face	Palpebral. Nasal. Labial.

The Meningeal Branch (*n. meningeus medius*).—The meningeal branch is given off by the superior maxillary nerve directly after its origin from the Gasserian ganglion; it accompanies the middle meningeal artery and supplies the dura mater of the middle fossa of the base of the skull.

The Orbital or Temporo-malar Branch (*n. zygomaticus*) (Figs. 669, 670, and 671).—The orbital or temporo-malar branch arises in the spheno-maxillary fossa, enters the orbit by the spheno-maxillary fissure, and divides at the back of that cavity into two branches, **temporal** and **malar**.

The **Temporal Branch** (*ramus zygomaticotemporalis*) runs in a groove along the outer wall of the orbit (in the malar bone), receives a branch of communication from the lachrymal, and, passing through a foramen in the malar bone, enters the temporal fossa. It ascends between the bone and the substance of the Temporal muscle, pierces this muscle and the temporal fascia about an inch above the zygoma, and is distributed to the integument covering the temple and side of the forehead, communicating with the facial and the auriculo-temporal branch of the inferior maxillary nerve. As it pierces the temporal fascia it gives off a slender twig, which runs between the two layers of the fascia to the outer angle of the orbit.

The **Malar Branch** (*ramus zygomaticofacialis*) passes along the external inferior angle of the orbit, emerges upon the face through a foramen in the malar bone, and, perforating the Orbicularis palpebrarum muscle, supplies the skin on the prominence of the cheek, where it is named the **subcutaneous malae**. It joins with the facial and the palpebral branches of the superior maxillary.

The Spheno-palatine Branches (*nn. sphenopalatini*) (Figs. 670 and 671).—The spheno-palatine branches, two in number, *descend* to the spheno-palatine ganglion, of which ganglion they are the sensory or short roots.

The Posterior Superior Dental Branches (*rami alveolares superiores posteriores*) (Figs. 670 and 671).—The posterior superior dental branches arise from the trunk of the nerve just as it is about to enter the infraorbital canal; they are generally two in number, but sometimes arise by a single trunk, and immediately divide and pass downward on the tuberosity of the superior maxillary bone. They give off several twigs to the gums and neighboring parts of the mucous membrane of the cheek, **superior gingival branches** (*rami gingivales superiores*). They then enter the posterior dental canals on the zygomatic surface of the superior maxillary bone, and, passing from behind forward in the substance of the bone,

communicate with the middle dental nerve by a plexus formation, and give off branches to the lining membrane of the antrum and three twigs to each of the molar teeth. These twigs enter the foramina at the apices of the fangs and supply the pulp.

The Middle Superior Dental Branch (*ramus alveolaris superior medius*) (Fig. 670).—The middle superior dental branch is given off from the superior maxillary nerve in the back part of the infraorbital canal, and runs downward and forward in a special canal in the outer wall of the antrum to supply the two bicuspid teeth. It communicates with the posterior and anterior dental branches by a plexus formation. At its point of communication with the posterior branch, above the root of the second bicuspid tooth, is a slight thickening which has received the name of the **ganglion of Valentin**; and at its point of communication with the anterior branch is a second enlargement, which is called the **ganglion of Bochdalek.** Neither of these is probably a true ganglion.

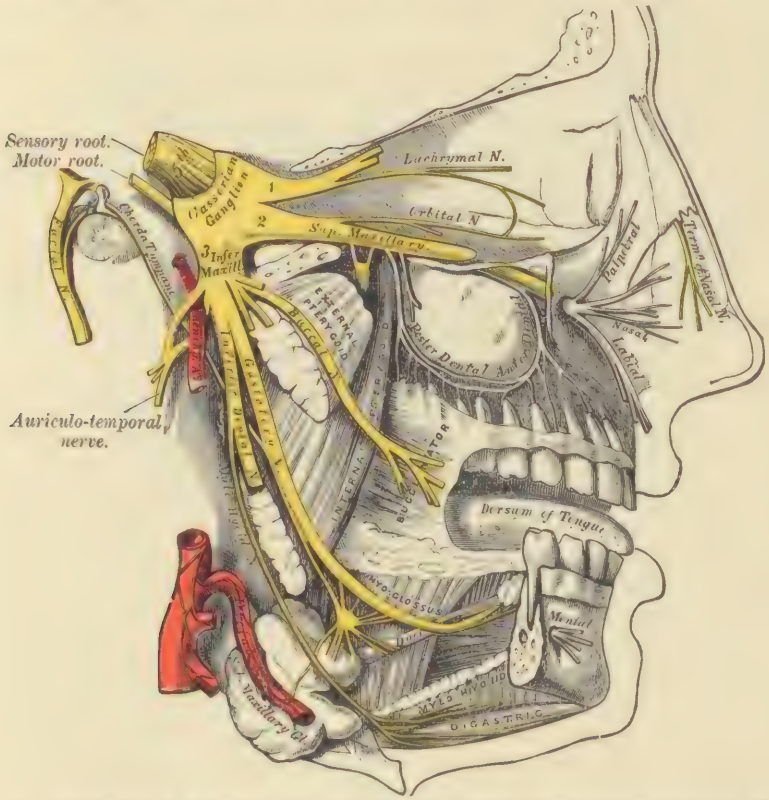

FIG. 671.—Distribution of the second and third divisions of the fifth nerve and submaxillary ganglion.

The Anterior Superior Dental Branch (*ramus alveolaris superior anteriores*) (Fig. 670).—The anterior superior dental branch, of large size, is given off from the superior maxillary nerve just before its exit from the infraorbital foramen; it enters a special canal in the anterior wall of the antrum, and divides into a series of branches which supply the incisor and canine teeth. It communicates with the middle dental nerve by a plexus, and gives off a **nasal branch,** which passes through a minute canal into the nasal fossa, and supplies the mucous membrane of the forepart of the inferior meatus and the floor of the cavity, communicating with the nasal branches from Meckel's ganglion.

The **superior dental plexus** (*plexus dentalis superior*) is formed by twigs of the three superior dental nerves. From the plexus come the nerves which supply the

teeth of the upper jaw (*rami dentales superiores*) and the gums (*rami gingivales superiores*).

The branches upon the face are known as the *rami n. infraorbitalis* (Fig. 671). There are three sets of them.

The Palpebral Branches (*rami palpebrales inferiores*).—The palpebral branches pass upward beneath the Orbicularis palpebrarum muscle. They supply the integument and conjunctiva of the lower eyelid, with sensation, joining at the outer angle of the orbit with the facial nerve and the malar branch of the orbital.

The Nasal Branches (*rami nasales interni*).—The nasal branches pass inward; they supply the integument of the side of the nose and join with the nasal branch of the ophthalmic.

The Labial Branches (*rami labiales superiores*).—The labial branches, the largest and most numerous, descend beneath the Levator labii superioris muscle, and are distributed to the integument of the upper lip, the mucous membrane of the mouth, and the labial glands.

All these branches are joined, immediately beneath the orbit, by filaments from the facial nerve, forming an intricate plexus, the **infraorbital plexus.**

The Spheno-palatine or **Meckel's Ganglion** (*ganglion sphenopalatinum*) (Figs. 670 and 672).—The spheno-palatine ganglion, the largest of the cranial ganglia, is deeply placed in the spheno-maxillary fossa, close to the spheno-palatine foramen. It is triangular or heart-shaped, of a reddish-gray color, and is situated just below the superior maxillary nerve as it crosses the fossa.

Branches of Communication.—Like the other ganglia of the fifth nerve, it possesses a motor, a sensory, and a sympathetic root. Its **sensory root** is derived from the superior maxillary nerve through its two spheno-palatine branches (p. 1032). These branches of the nerve are given off in the spheno-maxillary fossa and descend to the ganglion. Their fibres, for the most part, pass in front of the ganglion, as they proceed to their destination, in the palate and nasal fossa, and are not incorporated in the ganglionic mass; some few of the fibres, however, enter the ganglion, constituting its sensory root. Its **motor root** is derived from the facial nerve through the large superficial petrosal nerve, and its **sympathetic root** from the carotid plexus, through the large deep petrosal nerve. These two nerves join together before their entrance into the ganglion to form a single nerve, the **Vidian.**

The **Large** or **Great Superficial Petrosal Branch** (*n. petrosus superficialis major*) (Fig. 676) is given off from the **geniculate ganglion** of the facial nerve in the aquaeductus Fallopii; it passes through the hiatus Fallopii; enters the cranial cavity, and runs forward, being contained in a groove on the anterior surface of the petrous portion of the temporal bone and lying beneath the dura mater. It then enters the cartilaginous substance which fills in the foramen lacerum medium basis cranii, and, joining with the large deep petrosal branch, forms the Vidian nerve.

The **Large** or **Great Deep Petrosal Branch** (*n. petrosus profundus*) (Fig. 677) is given off from the carotid plexus of the sympathetic upon the internal carotid artery, and runs through the carotid canal on the outer side of the internal carotid artery. It then enters the cartilaginous substance which fills in the foramen lacerum medium basis cranii, and joins with the large superficial petrosal nerve to form the Vidian.

The **Vidian Nerve** (*n. canalis pterygoidei*) (Figs. 670 and 672), formed in the cartilaginous substance which fills in the middle lacerated foramen by the junction of the two preceding nerves, passes forward, through the Vidian canal, with the artery of the same name, and is joined by a small ascending nervous branch, the **sphenoidal branch,** from the **otic ganglion.** Finally, it enters the spheno-maxillary fossa, and joins the posterior angle of Meckel's ganglion.

Branches of Distribution of the Spheno-palatine Ganglion.—Its branches of distribution are divisible into four groups: **ascending**, which pass to the orbit; **descending**, to the palate: **internal**, to the nose; and **posterior branches**, to the pharynx and nasal fossae.

The **Ascending Branches** (*rami orbitales*) are two or three delicate filaments, which enter the orbit by the spheno-maxillary fissure, and supply the periosteum. According to Luschka, some filaments pass through foramina in the suture between the os planum of the ethmoid and frontal bones to supply the mucous membrane of the posterior ethmoidal and sphenoidal sinuses.

The **Descending** or **Palatine Branches** (*nn. palatini*) (Figs. 670 and 672) are distributed to the roof of the mouth, the soft palate, tonsil, and lining membrane of the nose. They are almost a direct continuation of the spheno-palatine branches of the superior maxillary nerve, and are three in number—**anterior, middle,** and **posterior.**

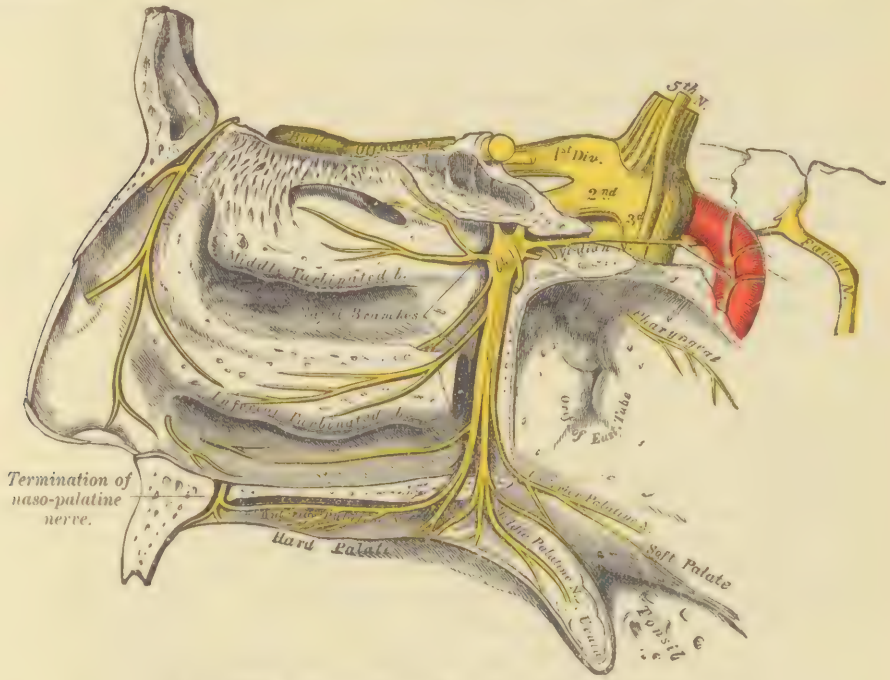

FIG. 672.—The spheno-palatine or Meckel's ganglion and its branches.

The **anterior** or **large palatine nerve** (*n. palatinus anterior*) descends through the **large posterior palatine canal,** emerges upon the hard palate at the posterior palatine foramen, and passes forward through a groove in the hard palate nearly as far as the incisor teeth. It supplies the gums, the mucous membrane and glands of the hard palate, and communicates in front with the termination of the **naso-palatine nerve** (p. 1036). While in the posterior palatine canal it gives off **inferior nasal branches** (*rami nasales posteriores inferiores*), which enter the nose through openings in the palate bone, and ramify over the inferior turbinated bone, the middle and the inferior meatus; and at its exit from the canal a palatine branch is distributed to both surfaces of the soft palate.

The **middle** or **external palatine nerve** (*n. palatinus medius*) descends through one of the **accessory palatine canals,** distributing branches to the uvula, tonsil, and soft palate. It is occasionally wanting.

The **posterior** or **small palatine nerve** (*n. palatinus posterior*) descends with a minute artery through the **small posterior palatine canal,** emerging by a separate

opening behind the posterior palatine foramen. It supplies the Levator palati and Azygos uvulae muscles,[1] the soft palate, tonsil, and uvula. The middle and posterior palatine join with the tonsillar branches of the glosso-pharyngeal to form the plexus around the tonsil, the **circulus tonsillaris.**

The **Internal Branches** are distributed to the septum and outer wall of the nasal fossae. They are the **posterior superior nasal** and the **naso-palatine.**

The **posterior superior nasal branches** (*rami nasales posteriores superiores*), three in number, enter the back part of the nasal fossa by the spheno-palatine foramen. They supply the mucous membrane covering the superior and middle spongy bones, and that lining the posterior ethmoidal cells, a few being prolonged to the upper and back part of the septum.

The **naso-palatine nerve** (*n. nasopalatinus*) has been called the **nerve of Scarpa** and also the **nerve of Cotunnius.** It enters the nasal fossa through the spheno-palatine foramen, and passes inward across the roof of the nose, below the orifice of the sphenoidal sinus, to reach the septum; it then runs obliquely downward and forward along the lower part of the septum, to the anterior palatine foramen, lying between the periosteum and mucous membrane. It descends to the roof of the mouth through the **anterior palatine canal** (Fig. 672). The two nerves are here contained in separate and distinct canals, situated in the intermaxillary suture, and termed the **foramina of Scarpa,** the left nerve being usually anterior to the right one. In the mouth they become united, supply the mucous membrane behind the incisor teeth, and join with the anterior palatine nerve. The naso-palatine nerve furnishes a few small filaments to the mucous membrane of the septum.

The **Posterior Branches** are the **pharyngeal** or **pterygo-palatine** and the **upper posterior nasal branches.**

The **pharyngeal** or **pterygo-palatine nerve** (Figs. 670 and 672) is a small branch arising from the back part of the **spheno-palatine ganglion,** being generally blended with the Vidian nerve. It passes through the **pterygo-palatine canal** with the pterygo-palatine artery, and is distributed to the mucous membrane of the upper part of the pharynx, behind the Eustachian tube.

The **upper posterior nasal branches** are a few twigs given off from the posterior part of the **spheno-palatine ganglion,** which run backward in the sheath of the Vidian nerve to the mucous membrane at the back part of the roof, septum, and superior meatus of the nose and that covering the end of the Eustachian tube.

The Mandibular or Inferior Maxillary Nerve (*n. mandibularis*) (Figs. 667, 669, 670, and 671).—The **inferior maxillary** or **third division of the fifth nerve** distributes branches to the teeth and gums of the lower jaw, the integument of the temple and external ear, the lower part of the face and lower lip, and the muscles of mastication; it also supplies the tongue with a large branch. It is the largest of the three divisions of the fifth, and is made up of two roots: a **large** or **sensory root,** proceeding from the inferior angle of the Gasserian ganglion; and a **small** or **motor root,** which passes beneath the ganglion and unites with the sensory root just after its exit from the skull through the **foramen ovale** (Figs. 667, 668, 670, and 671). Immediately beneath the base of the skull this nerve divides into two trunks, **anterior** and **posterior.** Previous to its division the primary trunk gives off from its inner side a recurrent branch and the nerve to the Internal pterygoid muscle.

The Recurrent or Meningeal Branch (*n. spinosus*).—The recurrent or meningeal branch is given off directly after the exit of the mandibular nerve from the foramen ovale. It passes backward into the skull through the foramen spinosum with the middle meningeal artery. It divides into two branches, **anterior** and **posterior,** which accompany the main divisions of the artery and supply the dura mater. The pos-

[1] It is probable that this is not the true motor supply to these muscles, but that they are supplied by the spinal accessory through the pharyngeal plexus.—Ed. of 15th English edition.

terior branch also supplies the mucous lining of the mastoid cells. The anterior branch communicates with the meningeal branch of the superior maxillary nerve.

The Internal Pterygoid Nerve (*n. pterygoideus internus*) (Fig. 670).—The internal pterygoid nerve, given off from the inferior maxillary previous to its division, is intimately connected at its origin with the otic ganglion. It is a long and slender branch, which passes inward to enter the deep surface of the Internal pterygoid muscle.

The **anterior** and smaller division of the inferior maxillary nerve, which receives nearly the whole of the motor root of the fifth nerve, divides into branches which supply the muscles of mastication. They are the **masseteric, deep temporal, buccal,** and **external pterygoid branches** (Figs. 670 and 671).

The **Masseteric Branch** (*n. massetericus*) passes outward, above the External pterygoid muscle, in front of the temporo-mandibular articulation and behind the tendon of the temporal muscle; it crosses the sigmoid notch with the masseteric artery, to the deep surface of the Masseter muscle, in which it ramifies nearly as far as its anterior border. It occasionally gives a branch to the Temporal muscle, and a filament to the articulation of the jaw.

The **Deep Temporal Branches** (*nn. temporales profundi*), two in number, anterior and posterior, supply the deep surface of the Temporal muscle. The **posterior branch** (*n. temporalis profundus posterior*), of small size, is placed at the back of the temporal fossa. It is sometimes joined with the masseteric branch. The **anterior branch** (*n. temporalis profundus anterior*) is frequently given off from the buccal nerve; it is reflected upward, at the pterygoid ridge of the sphenoid, to the front of the temporal fossa. Sometimes there are three deep temporal branches, and if this maintains the third branch, the **middle deep temporal,** passes outward above the External pterygoid muscle, and runs upward on the bone to enter the deep surface of the Temporal muscle.

The **Buccal** or **Buccinator Branch** (*n. buccinatorius*) passes forward between the two heads of the External pterygoid, and downward beneath the inner surface of the coronoid processes of the lower jaw, or through the fibres of the Temporal muscle, to reach the surface of the Buccinator muscle, upon which it divides into a superior and an inferior branch. It gives a branch to the External pterygoid during its passage through that muscle, and a few ascending filaments to the Temporal muscle, one of which occasionally joins with the anterior branch of the deep temporal nerve. The **superior** or **upper branch** supplies the integument and upper part of the Buccinator muscle, joining with the facial nerve around the facial vein. The **inferior** or **lower branch** passes forward to the angle of the mouth; it supplies the integument and Buccinator muscle, as well as the mucous membrane lining the inner surface of that muscle, and joins the facial nerve.[1]

The **External Pterygoid Nerve** (*n. pterygoideus externus*) is most frequently derived from the buccal, but it may be given off separately from the anterior trunk of the mandibular nerve. It enters the muscle on its inner surface.

The **posterior** and **larger division** of the inferior maxillary nerve is for the most part sensory, but receives a few filaments from the motor root. It divides into three branches: **auriculo-temporal, lingual** (gustatory), and **inferior dental** (Figs. 670, 671).

The **Auriculo-temporal Nerve** (*n. auriculotemporalis*) (Fig. 673) generally arises by two roots, between which the middle meningeal artery passes. It runs backward beneath the External pterygoid muscle to the inner side of the neck of the lower jaw. It then turns upward with the temporal artery, between the external ear and the condyle of the jaw, under cover of the parotid gland, and, escaping from beneath this structure, ascends over the zygoma and divides into two **temporal branches.**

[1] There seems to be no reason to doubt that the branch supplying the Buccinator muscle is entirely a nerve of ordinary sensation, and that the true motor supply of this muscle is from the facial.—Ed. of 15th English edition.

The **branches of communication** are with the **facial** and with the **otic ganglion.** The branches of communication with the facial (*rami anastomotici cum n. faciali*), usually two in number, pass forward from behind the neck of the condyle of the jaw, to join this nerve at the posterior border of the Masseter muscle. They form one of the principal branches of communication between the facial and the fifth nerve. The filaments of communication with the otic ganglion are derived from the commencement of the auriculo-temporal nerve.

The **branches of distribution** are—

Anterior auricular.
Branches to the meatus auditorius.
Articular.
Parotid.
Superficial temporal.

The **anterior auricular branches** (*nn. auriculares anteriores*) are usually two in number. They supply the front of the upper part of the pinna, being distributed principally to the skin covering the front of the helix and tragus.

Branch to the external auditory meatus (*n. meatus auditorii externi*) divides into two. The two nerves enter the canal between the bony and cartilaginous portion of the meatus. They supply the skin lining the meatus; the upper one sending a filament to the membrana tympani (*ramus membranae tympani*).

A branch to the temporo-mandibular articulation, the **articular branch,** is usually derived from the auriculo-temporal nerve.

The **parotid branches** (*rami parotidei*) supply the parotid gland.

The **superficial temporal branches** (*rami temporales superficiales*) accompany the temporal artery to the vertex of the skull, and supplies the integument of the temporal region, communicating with the facial nerve, and with the temporal branch of the temporo-malar, from the superior maxillary.

The Lingual Nerve or Gustatory Nerve (*n. lingualis*) (Figs. 670 and 671).—The lingual or gustatory nerve supplies the papillae and mucous membrane of the **anterior two-thirds of the tongue.** It is deeply placed throughout the whole of its course. It lies at first beneath the External pterygoid muscle, together with the inferior dental nerve, being placed to the inner side of this nerve, and is occasionally joined to it by a branch which may cross the internal maxillary artery. The **chorda tympani nerve** also joins it at an acute angle in this situation. The nerve then passes between the Internal pterygoid muscle and the inner side of the ramus of the jaw, and crosses obliquely to the side of the tongue over the Superior constrictor of the pharynx and the Stylo-glossus muscles, and then between the Hyo-glossus muscle and the deep part of the submaxillary gland; the nerve finally runs across **Wharton's duct,** and along the side of the tongue to its apex, lying immediately beneath the mucous membrane.

The **branches of communication** are with the facial through the chorda tympani, with the inferior dental and hypoglossal nerves, and the submaxillary ganglion. The chorda tympani branch of the facial joins the lingual nerve under the external pterygoid muscle and is distributed with the lingual to the tongue. The hypoglossal nerve and the lingual nerve lie near together, over the Hyo-glossus muscle, and the two nerves are joined by loops (*rami anastomotici cum n. hypoglosso*). The branches to the submaxillary ganglion are two or three in number; those connected with the hypoglossal nerve form a plexus at the anterior margin of the Hyo-glossus muscle.

The **branches of distribution** supply the mucous membrane of the mouth, the gums, the sublingual gland, the filiform and fungiform papillae and mucous membrane of the tongue; the terminal filaments communicate, at the tip of the tongue, with the hypoglossal nerve. The lingual fibres are fibres of common sensation. The chorda tympani fibres which join the lingual nerve are probably taste-fibres.

The Inferior Dental Nerve (*n. alveolaris inferior*) (Figs. 670 and 671).—The inferior dental is the largest of the branches of the inferior maxillary nerve. It passes downward with the inferior dental artery, at first beneath the External pterygoid muscle, and then between the internal lateral ligament and the ramus of the jaw to the **dental foramen.** It then passes forward in the **dental canal** of the inferior maxillary bone, lying beneath the teeth, as far as the **mental foramen,** where it divides into two terminal branches, incisor and mental.

The **Branches** of the inferior dental are: the **mylo-hyoid, dental, incisor,** and **mental.**

The **Mylo-hyoid** (*n. mylohyoideus*) is derived from the inferior dental just as that nerve is about to enter the **dental foramen.** It descends in a groove on the inner surface of the ramus of the jaw, in which it is retained by a process of fibrous membrane. It reaches the under surface of the Mylo-hyoid muscle, and supplies it and the anterior belly of the Digastric.

The **Dental Branches** supply the molar and bicuspid teeth. They correspond in number to the fangs of those teeth: each nerve entering the orifice at the point of the fang and supplying the pulp of the tooth.

The **Incisor Branch** is continued onward within the bone to the middle line, and supplies the canine and incisor teeth.

The dental branches and the incisor branch form a plexus (*plexus dentalis inferior*), and from this plexus come the branches to the teeth (*rami dentales inferiores*) and to the gums (*rami gingivales inferiores*).

The **Mental Branch** (*n. mentalis*) emerges from the bone at the **mental foramen,** and divides beneath the Depressor anguli oris muscle into two or three branches; one descends to supply the skin of the chin, and another (sometimes two) ascends to supply the skin and mucous membrane of the lower lip. These branches communicate freely with the facial nerve.

Two small ganglia are connected with the inferior maxillary nerve—the **otic** with the trunk of the nerve, and the **submaxillary** with its lingual branch.

Otic or Arnold's Ganglion (*ganglion oticum*) (Figs. 670 and 673).—The otic or Arnold's ganglion is a small, oval-shaped, flattened ganglion of a reddish-gray color, situated immediately below the foramen ovale, on the inner surface of the inferior maxillary nerve, and round the origin of the internal pterygoid nerve. It is in relation, *externally*, with the trunk of the inferior maxillary nerve, at the point where the motor root joins the sensory portion; *internally*, with the cartilaginous part of the Eustachian tube, and the origin of the Tensor palati muscle; *behind*, it lies in the middle meningeal artery.

Branches of Communication.—This ganglion is connected with the internal pterygoid branch of the inferior maxillary nerve by two or three short delicate filaments. From this nerve the ganglion may obtain a motor root, and possibly also a sensory root, as these filaments from the nerve to the Internal pterygoid perhaps contain sensory fibres. The otic ganglion communicates with the glossopharyngeal and facial nerves through the **small superficial petrosal nerve** (Figs. 673 and 676) continued from the tympanic plexus, and through this communication it probably receives its sensory root from the **glosso-pharyngeal** and its motor root from the **facial**; its communication with the sympathetic is effected by a filament from the plexus surrounding the middle meningeal artery. The ganglion also communicates with the auriculo-temporal nerve (*ramus anastomoticus cum n. auriculotemporali*). This communicating filament is probably a branch from the glosso-pharyngeal which passes to the ganglion, and through it and the auriculo-temporal nerve to the parotid gland. A slender filament, the **sphenoidal,** ascends from it to the Vidian nerve.

Branches of Distribution.—Its branches of distribution are a filament to the Tensor tympani (*n. tensoris tympani*) and one to the Tensor palati (*n. tensoris veli*

palatini). The former passes backward on the outer side of the Eustachian tube; the latter arises from the ganglion, near the origin of the internal pterygoid nerve, and passes forward. The fibres of these nerves are, however, mainly derived from the nerve to the Internal pterygoid muscle. It also gives off a small communicating branch to the chorda tympani (*ramus anastomoticus cum n. chorda tympani*).

The Submaxillary Ganglion (*ganglion submaxillare*) (Figs. 670 and 671).—The submaxillary ganglion is of small size, fusiform in shape, and situated above the deep portion of the submaxillary gland, near the posterior border of the Mylo-hyoid muscle, being connected by filaments with the lower border of the lingual or gustatory nerve.

Branches of Communication.—This ganglion is connected with the lingual nerve by a few filaments (*rami communicantes cum n. linguali*), which join it separately at its fore and back part. It also receives a branch from the chorda tympani, by which it communicates with the facial, and communicates with the sympathetic by filaments from the sympathetic plexus around the facial artery.

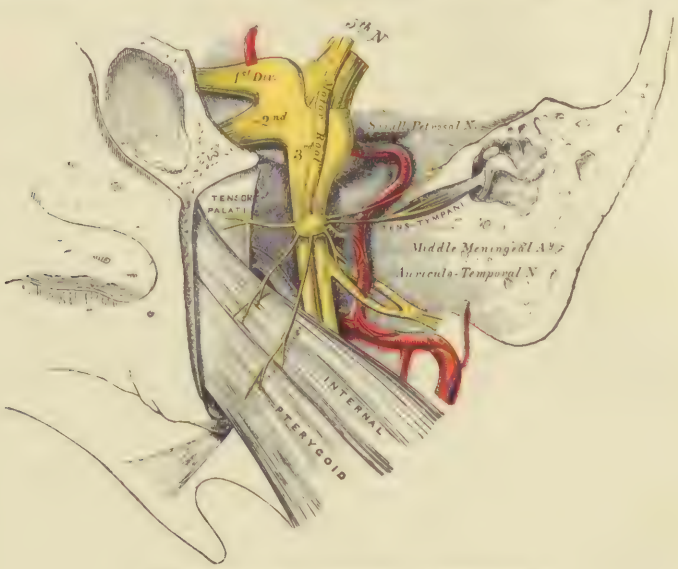

FIG. 673.—The otic ganglion and its branches.

Branches of Distribution.—These are five or six in number; they arise from the lower part of the ganglion, and supply the mucous membrane of the mouth and Wharton's duct, some being lost in the submaxillary gland (*rami submaxillares*). The branch of communication from the lingual nerve to the forepart of the ganglion is by some regarded as a branch of distribution, by which filaments of the chorda tympani pass from the ganglion to the lingual nerve, and by it are conveyed to the sublingual gland and the tongue.

Summary of the Distribution and Connections of the Fifth Nerve.—It is the chief sensory nerve of the face, the anterior half of the scalp, the mouth, nasal cavity, lips, teeth, anterior two-thirds of the tongue, orbit, and eyeball. The clearly defined cutaneous distributions of the branches are shown in Fig. 674. The motor portion of the nerve supplies the muscles of mastication, the mylo-hyoid, and the anterior belly of the digastric. By way of branches from the otic ganglion it supplies the Tensor tympani and Tensor palati muscles, and by way of branches from the spheno-palatine ganglion perhaps supplies the Levator palati and Azygos uvulae muscles, although it is more probable that these muscles

receive their motor influence by the spinal accessory through the pharyngeal plexus. The ganglia associated with the nerve create communications with the sympathetic, the motor oculi, the facial, and the glosso-pharyngeal, and through these ganglia, as Prof. Cunningham says, "important organs, areas, and muscles" are innervated. The trigeminal communicates many times with the facial, and thus gives sensory fibres to the "muscles of expression supplied by the facial nerve."[1]

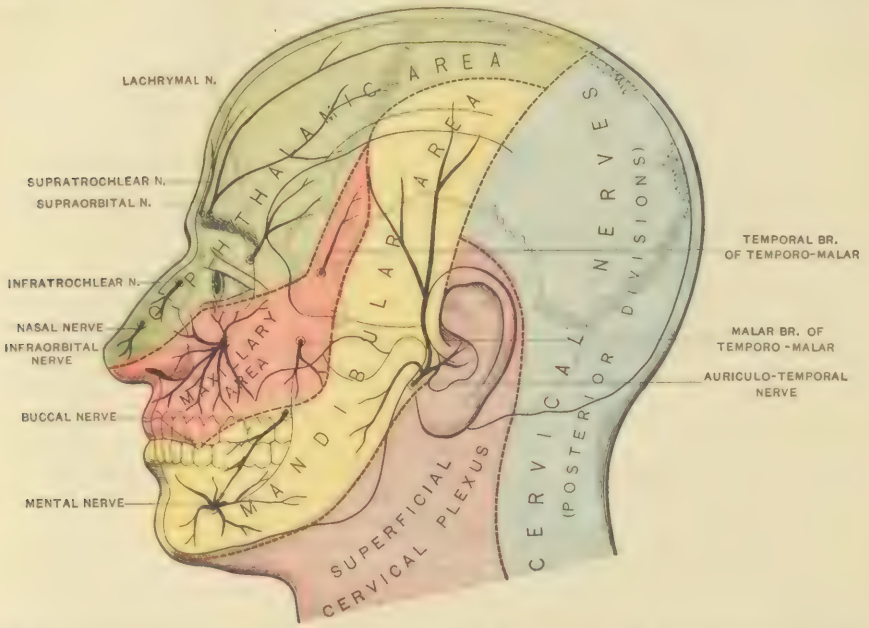

FIG. 674.—Sensory areas of the head, showing the general distribution of the three divisions of the fifth nerve. Gerrish's Anatomy. (Modified from Testut.)

Surface Marking. It will be seen from the above description that the three terminal branches of the three divisions of the fifth nerve emerge from foramina in the bones of the skull and pass on to the face: the terminal branch of the first division emerging through the supraorbital foramen; that of the second through the infraorbital foramen; and the third through the mental foramen. The supraorbital foramen is situated at the junction of the internal and middle third of the supraorbital arch. If a straight line is drawn from this point to the lower border of the inferior maxillary bone, so that it passes between the two bicuspid teeth of the lower jaw, it will pass over the infraorbital and mental foramina, the former being situated about one centimetre (two-fifths of an inch) below the margin of the orbit, and the latter varying in position according to the age of the individual. In the adult it is midway between the upper and lower borders of the inferior maxillary bone; in the child it is nearer the lower border; and in the edentulous jaw of old age it is close to the upper margin.

Surgical Anatomy. In *fracture of the base of the skull*, the fifth nerve or one of its branches may be injured. It seems certain that occasionally, though seldom, the fifth nerve may be actually divided by such an injury. The fifth nerve may be affected in its entirety, or its sensory or motor root may be affected, or one of its primary main divisions. In injury to the sensory root there is anæsthesia of the half of the face on the side of the lesion, with the exception of the skin over the parotid gland; insensibility of the conjunctiva, followed, if the eye is not temporarily protected with a watch-glass, by destructive inflammation of the cornea, partly, it is held, from loss of trophic influence, and partly, it is certain, from the irritation produced by the presence of foreign bodies on it, which are not perceived by the patient, and therefore not expelled by the act of winking; dryness of the nose, loss to a considerable extent of the sense of taste, and diminished secretion of the lachrymal and salivary glands. In injury to the motor root there is impaired action of the lower jaw from paralysis of the muscles of mastication on the affected side.

The fifth nerve is often the seat of *neuralgia*, and each of the three divisions has been divided or a portion of the nerve excised for this affection. The **supraorbital nerve** may be exposed

[1] Cunningham's Text-book of Anatomy.

by making an incision an inch and a half in length along the supraorbital margin below the eyebrow, which is to be drawn upward, the centre of the incision corresponding to the supraorbital notch. The skin and Orbicularis palpebrarum having been divided, the nerve can be easily found emerging from the notch and lying in some loose cellular tissue. It should be drawn up by a blunt hook and divided, or, what is better, a portion of it should be removed. The *infraorbital nerve* has been divided at its exit by an incision on the cheek; or the floor of the orbit has been exposed, the infraorbital canal opened up, and the anterior part of the nerve resected; or the whole nerve, together with Meckel's ganglion as far back as the foramen rotundum, has been removed. This latter operation, though undoubtedly a severe proceeding, appears to have been followed by better results than has nerve resection. The operation is performed as follows: The superior maxillary bone is first exposed by a T-shaped incision, one limb of the incision passing along the lower margin of the orbit, the other from the centre of the first cut vertically down the cheek toward the angle of the mouth. The nerve is then found, is divided, and a piece of silk is tied to it as a guide. A small trephine (one-half inch) is then applied to the bone below, but including the infraorbital foramen, and the antrum opened. The trephine is now applied to the posterior wall of the antrum, and the spheno-maxillary fossa exposed. The infraorbital canal is now opened up from below by fine cutting-pliers or a chisel, and the nerve drawn down into the trephine hole, it being held on the stretch by means of the piece of silk; it is severed with fine curved scissors as near the foramen rotundum as possible, any branches coming off from the ganglion being also divided.[1] The *mental branch of the inferior dental nerve* may be divided at its exit from the foramen through an incision made through the mucous membrane where it is reflected from the alveolar process on to the lower lip; or a portion of the trunk of the *inferior dental nerve* may be resected through an incision on the cheek through the Masseter muscle, exposing the outer surface of the ramus of the jaw. A trephine is then applied over the position of the inferior dental foramen and the outer table removed, so as to expose the inferior dental canal. The nerve is dissected out of the portion of the canal exposed, and, having been divided after its exit from the mental foramen, it is by traction on the end exposed in the trephine-hole, drawn out entire, and cut off as high up as possible.[2] The inferior dental nerve has also been divided through an incision within the mouth, the bony point guarding the inferior dental foramen forming the guide to the nerve. The *buccal nerve* may be divided by an incision through the mucous membrane of the mouth and the Buccinator muscle just in front of the anterior border of the ramus of the lower jaw (Stimson).

In inveterate neuralgia of one or two of the branches of the fifth nerve a peripheral operation may cure the case, but seldom does. It often gives relief, perhaps for months. In neuralgia of the second division *or* third division, or of the second division *and* third division, Abbe, of New York, opens the skull and divides the nerve or nerves by an intracranial operation, removes a piece of nerve so as the foramen of exit is empty, and covers the foramen with rubber tissue, to hinder regrowth of the nerve. Other operators, after removing a piece from each nerve, have plugged the foramina of the exit with dentists' cement or silver-foil.

Rose's method of neurectomy is very valuable for neuralgia of the second division. It is a modification of the Braun-Lossen method. The infraorbital nerve is exposed, a ligature is tied about it, the roof of the infraorbital canal is chiselled open, and the nerve is freed as far back as possible. An incision is made from below the external angular process outward along the zygoma to in front of the lobule of the ear, downward to just above the angle of the jaw, and forward for two inches. The flap is raised and the zygoma is exposed. The root of the zygoma is drilled at two points, and the zygomatic process of the temporal bone is drilled at two points. The bone is sawed in two places between the drill-holes. The freed arch is lifted down and back, the tendon of the temporal muscle is drawn backward, and the pterygo-maxillary fossa is thus exposed. The internal maxillary artery is divided between two ligatures. The External pterygoid muscle is separated from the greater wing of the sphenoid and from the root of the external pterygoid process. The superior maxillary nerve is grasped and twisted off as near the ganglion as possible. The entire nerve is then drawn back from the infraorbital foramen and removed. The wound is then closed. If the third division is also haunted by neuralgia, it too should be removed a few weeks after the performance of Rose's operation.

If a peripheral operation fails, or if all the branches of the fifth are involved, the Gasserian ganglion must be removed or the sensory root of the fifth must be divided, as suggested by Frazier and Spiller.

Removal of the Gasserian ganglion was suggested by J. Ewing Mears in 1884, and was first carried out by Rose in 1890.

The method chiefly in vogue was devised by Hartley, and was first performed by him in 1891. An osteoplastic flap is made in front of the ear, the dura is exposed and lifted. Following Krause's advice, the third division is exposed and clamped. The second division is exposed and clamped. The nerves are loosened from their beds and then are rolled about the clamps. This twisting

[1] Carnochan, American Journal of the Medical Sciences, 1858, p. 136.
[2] Mears, Transactions of the American Surgical Association, vol. ii. p. 469.

pulls out the ganglion intact along with the motor root, and also the sensory root from the pons.

A difficulty in the Hartley operation is the danger of division of the meningeal artery. If this happens, the surgeon may be able to arrest bleeding and proceed with the operation. If the vessel is torn off at the foramen spinosum, it will be necessary to pack the wound and postpone any further operative manipulation for forty-eight hours.

Dr. Harvey Cushing has modified Hartley's operation by trephining the wall of the temporal fossa very low down. He opens the skull *below* the arch of the meningeal vessels, and thus avoids the meningeal at the foramen spinosum, and also the sulcus arteriosus of the parietal bone.

After the removal of the ganglion, Professor Keen, in order to prevent undue inflammation of the eye, sews the eyelids of the affected side together, leaving a space open at each angle, and covers the eye with a watch-crystal. Boracic acid solution is flushed into the opening at the external angle at frequent intervals. The stitches are removed from the lid in from eight to ten days.

The *lingual* (gustatory) nerve is occasionally divided with the view of relieving the pain in cancerous disease of the tongue. This may be done in that part of its course where it lies below and behind the last molar tooth. If a line is drawn from the middle of the crown of the last molar tooth to the angle of the jaw, it will cross the nerve, which lies about half an inch behind the tooth, parallel to the bulging alveolar ridge on the inner side of the body of the bone. If the knife is entered three-quarters of an inch behind and below the last molar tooth and carried down to the bone, the nerve will be divided. Hilton divided it opposite the second molar tooth, where it is covered only by the mucous membrane, and Lucas pulls the tongue forward and over to the opposite side, when the nerve can be seen standing out as a firm cord under the mucous membrane by the side of the tongue and can be easily seized with a sharp hook and divided or a portion excised. This is a simple enough operation on the cadaver, but when the disease is extensive and has extended to the floor of the mouth, as is generally the case when division of the nerve is thought of, the operation is not practicable.

THE SIXTH OR ABDUCENT NERVE (N. ABDUCENS) (Fig. 669).

The sixth or abducent nerve supplies the External rectus muscle. Its *superficial origin* is by several filaments from the constricted part of the pyramid, close to the pons, or from the lower border of the pons itself, in the groove between this body and the medulla. Its *deep origin* is from the upper part of the floor of the fourth ventricle, close to the median line, beneath the eminentia teres (Fig. 613.)

From the nucleus of the sixth nerve fibres pass through the posterior longitudinal bundle to the oculo-motor nucleus of the opposite side and into the third nerve, along which they are carried to the Internal rectus muscle. The External rectus of one eye and the Internal rectus of the other may therefore be said to receive their nerves from the same nucleus—a factor of great importance in connection with the conjugate movements of the eyeball, and one that may explain certain paralytic phenomena of the Recti muscles, which are often associated with lesions in the pons.

The nerve pierces the dura mater on the basilar surface of the sphenoid bone, runs through a notch immediately below the posterior clinoid process, and enters the cavernous sinus. It passes forward through the sinus, lying on the outer side of the internal carotid artery (Fig. 454). It enters the orbit through the sphenoid fissure, and lies above the ophthalmic vein, from which it is separated by a lamina of dura mater (Fig. 675). It then passes between the two heads of the External rectus muscle, and is distributed to that muscle on its ocular surface.

Branches of Communication.—It is joined by several filaments from the carotid and cavernous plexuses, and by one from the ophthalmic nerve.

Relations to Each Other of the Third, Fourth, Ophthalmic Division of the Fifth and Sixth Nerves as They Pass to the Orbit.—The third, the fourth, the ophthalmic division of the fifth, and the sixth nerves, as they pass to the orbit, bear a certain relation to each other in the cavernous sinus, at the sphenoidal fissure, and in the cavity of the orbit, which will now be described.

In the **Cavernous Sinus** (Figs. 454 and 455) the third, fourth, and ophthalmic division of the fifth are placed on the outer wall of the sinus, in their numerical

order, both from above downward and from within outward. The sixth nerve lies at the outer side of the internal carotid artery. As these nerves pass forward to the sphenoidal fissure, the third and fifth nerves become divided into branches, and the sixth nerve approaches the rest, so that their relative position becomes considerably changed.

In the **Sphenoidal Fissure** (Fig. 675) the fourth nerve and the frontal and lachrymal branches of the ophthalmic division of the fifth lie upon the same plane, the former being most internal, the latter external, and they enter the cavity of the orbit above the muscles. The remaining nerves enter the orbit between the two heads of the External rectus muscle. The superior division of the third nerve is the highest of these; beneath this lies the nasal branch of the ophthalmic nerve; then the inferior division of the third nerve; and the sixth nerve lowest of all.

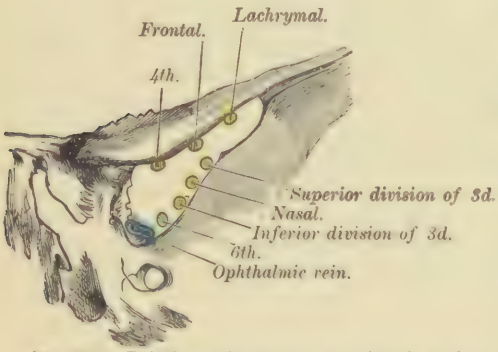

FIG. 675.—Relations of structures passing through the sphenoidal fissure.

In the **Orbit** (Figs. 665 and 669) the fourth nerve and the frontal and lachrymal divisions of the ophthalmic nerve lie on the same plane immediately beneath the periosteum, the fourth nerve being internal and resting on the Superior oblique muscle, the frontal nerve resting on the Levator palpebræ muscle, and the lachrymal nerve on the External rectus muscle. Next in order comes the superior division of the third nerve, lying immediately beneath the Superior rectus muscle, and then the nasal branch of the ophthalmic nerve, crossing the optic nerve from the outer to the inner side of the orbit. Beneath these is found the optic nerve, surrounded in front by the ciliary nerves, and having the lenticular ganglion on its outer side, between it and the External rectus muscle. Below the optic nerve is the inferior division of the third nerve and the sixth nerve, which lies on the outer side of the orbit.

Surgical Anatomy.—It is often stated that the sixth nerve is more frequently involved in *fractures of the base of the skull* than any other of the cranial nerves. As a matter of fact, however, it is injured in only about 2 per cent. of cases of fracture of the skull (Putscher). Cases have been reported in which the nerve was actually ruptured. The nerve may be injured by traction, pressure of a blood clot, of a tumor, or of an arterio-venous aneurism. The result of paralysis of this nerve is internal or *convergent squint*. When injured so that its function is destroyed, there is, in addition to the paralysis of the External rectus muscle, often a certain amount of contraction of the pupil, because some of the sympathetic fibres to the radiating muscle of the iris pass along with this nerve.

THE SEVENTH OR FACIAL NERVE (N. FACIALIS) (Figs. 676, 677, 678).

The seventh or facial nerve or **Portio Dura** is the motor nerve of all the muscles of expression in the face, and of the Platysma and Buccinator; the muscles of the External ear; the posterior belly of the Digastric, and the Stylo-hyoid. Its chorda tympani branch is the nerve of taste for the anterior two-thirds of the tongue and the vaso-dilator nerve of the submaxillary and sublingual glands; its tympanic branch supplies the Stapedius.

Its *superficial origin* is from the upper end of the medulla oblongata, in the groove between the olivary and restiform bodies. Its *deep origin* is from a nucleus situated in the floor of the fourth ventricle, beneath the superior fovea (Fig. 613).

The facial nucleus is deeply placed in the reticular formation of the lower part of the pons, a little external and ventral to the nucleus of the sixth nerve. From this origin the fibres pursue a curved course in the substance of the pons. They first pass backward and inward, and then turn upward and forward, forming the **fasciculus teres,** which produces an eminence, the **eminentia teres,** on the floor of the fourth ventricle, and finally bend sharply downward and outward around the upper end of the nucleus of origin of the sixth nerve, to reach their superficial origin between the olivary and restiform bodies. From the nucleus of the third nerve some fibres arise which descend in the posterior longitudinal bundle and join the facial just before it leaves the pons; these fibres are said to supply the anterior belly of the Occipito-frontalis, the Orbicularis palpebrarum, and the Corrugator supercilii, as these muscles have been observed to escape paralysis in lesions of the nucleus of the facial nerve.

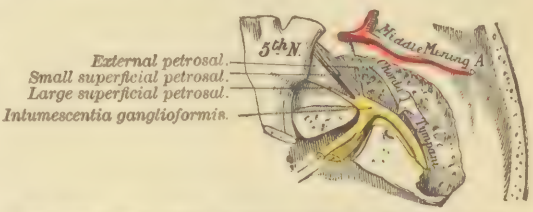

FIG. 676.—The course and connection of the facial nerve in the temporal bone.

The **auditory nerve** (*portio mollis*) lies to the outer side of the facial nerve; and between the two is a small fasciculus, the **pars intermedia of Wrisberg** (*n. intermedius*), which *arises* from the medulla and joins the facial nerve in the internal auditory meatus. The deep origin of the pars intermedia is from the upper end of the nucleus of the glosso-pharyngeal nerve, and at its emergence it is frequently connected with both nerves.

The pars intermedia may be regarded as the **sensory root of the facial nerve,** analogous to the sensory root of the fifth, and its real nucleus of origin would then consist of the geniculate ganglion.

The facial nerve, firmer, rounder, and smaller than the auditory, passes forward and outward upon the middle peduncle of the cerebellum, and enters the **internal auditory meatus** with the auditory nerve. Within the meatus the facial nerve lies in a groove along the upper and anterior part of the auditory nerve and the pars intermedia is placed between the two, and joins the inner angle of the geniculate ganglion. Occasionally a few of its fibres pass into the auditory nerve. Beyond the ganglion its fibres are generally regarded as forming the chorda tympani.

At the bottom of the meatus the facial nerve enters the **aquaeductus Fallopii,** and follows the course of that canal through the petrous portion of the temporal bone, from its commencement at the internal meatus to its termination at the **stylo-mastoid foramen** (Figs. 49 and 676). It is at first directed outward between the cochlea and vestibule toward the inner wall of the tympanum; it then bends suddenly backward and arches downward behind the tympanum to the stylo-mastoid foramen. At the point in the aqueduct of Fallopius where the nerve changes its direction (*geniculum n. facialis*), it presents a reddish gangliform swelling, the **geniculate ganglion** (*ganglion geniculi*), which is also called the **intumescentia ganglioformis** (Fig. 676). The geniculate ganglion receives a branch from the vestibular division of the auditory nerve, which probably carries fibres of the pars intermedia. On emerging from the stylo-mastoid foramen the facial nerve runs forward in the substance of the parotid gland, crosses the external carotid artery, and divides behind the ramus of the lower jaw into two primary branches, **temporo-facial** and **cervico-facial,** from which numerous offsets are distributed over the side of the head, face, and upper part of the neck, supplying the superficial muscles in these regions. As the primary branches and their offsets diverge from each other, they present somewhat the appearance of a bird's claw; hence the name of **pes anserinus** is given to the divisions of the facial nerve in and near the parotid gland.

Branches of Communication (Fig. 677).—The communications of the facial nerve may be thus arranged:

In the internal auditory meatus	With the auditory nerve. The pars intermedia, which is between the facial and auditory, gives branches to both. The branch given to the auditory accompanies it for a certain distance, and then departs from it to join the geniculate ganglion.
From the geniculate ganglion	With the auditory as explained above. With Meckel's ganglion by the large superficial petrosal nerve. With the otic ganglion by the small superficial petrosal nerve. With the sympathetic on the middle meningeal artery by the external superficial petrosal nerve.
In the Fallopian aqueduct	With the auricular branch of the pneumogastric.
At its exit from the stylo-mastoid foramen	With the glosso-pharyngeal. With the pneumogastric. With the auricularis magnus. With the auriculo-temporal.
Behind the ear	With the small occipital.
On the face	With the three divisions of the fifth.
In the neck	With the superficial cervical.

In the internal auditory meatus some minute filaments pass between the facial and auditory nerves.

Opposite the hiatus Fallopii, the gangliform enlargement on the facial nerve communicates with Meckel's ganglion by means of the large superficial petrosal nerve, which forms its motor root; with the otic ganglion, by the small superficial petrosal nerve; and with the sympathetic filaments accompanying the middle meningeal artery, by the external petrosal nerve (Bidder). From the gangliform enlargement, according to Arnold, a twig is sent back to the auditory nerve. Just before the facial nerve emerges from the stylo-mastoid foramen it generally receives a twig of communication from the auricular branch of the pneumogastric.

After its exit from the stylo-mastoid foramen, it sends a twig to the glosso-pharyngeal, another to the pneumogastric nerve, and communicates with the great auricular branch of the cervical plexus, with the auriculo-temporal branch of the inferior maxillary nerve in the parotid gland, with the small occipital nerve behind the ear, on the face with the terminal branches of the three divisions of the fifth, and in the neck with the transverse cervical.

Branches of Distribution (Fig. 677).—The branches of distribution of the facial nerves may be thus arranged:

Within the aquaeductus Fallopii	Tympanic, to the Stapedius muscle. Chorda tympani.	
At its exit from the stylo-mastoid foramen	Posterior Auricular. Digastric. Stylo-hyoid.	
On the face	Temporo-facial	Temporal. Malar. Infraorbital.
	Cervico-facial	Buccal. Supramaxillary. Inframaxillary.

The branches of the two terminal divisions form the **parotid plexus** (*plexus parotideus*).

The Tympanic Branch (*n. stapedius*) (Fig. 677).—The tympanic branch *arises* from the nerve opposite the pyramid; it passes through a small canal in the pyramid and supplies the Stapedius muscle.

The Chorda Tympani (Figs. 671, 676, and 677).—The chorda tympani is given off from the facial as it passes vertically downward at the back of the tympanum, about a quarter of an inch before its exit from the stylo-mastoid foramen. It passes from below upward and forward in a distinct canal, and enters the cavity of the tympanum through an aperture (*iter chordae posterius*) on its posterior wall between the opening of the mastoid cells and the attachment of the membrana tympani, and becomes invested with mucous membrane. It passes forward through the cavity of the tympanum, between the fibrous and mucous layers of the membrana tympani, and over the handle of the malleus, emerging from that cavity

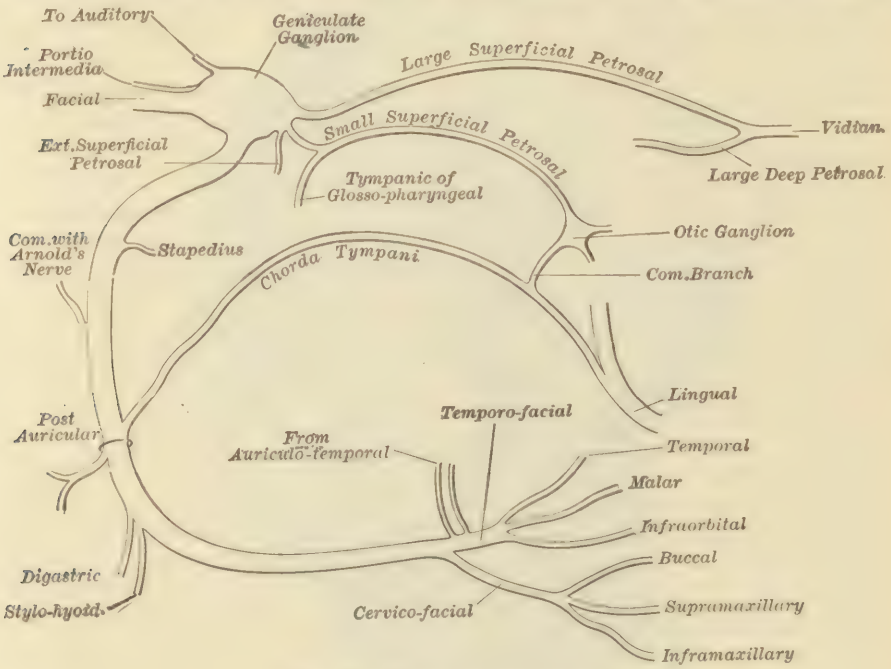

FIG. 677.—Plan of the facial nerve.

through a foramen at the inner end of the Glaserian fissure, which is called the **canal of Huguier** (*iter chordae anterius*). It then descends between the two Pterygoid muscles, meets the lingual nerve at an acute angle, and accompanies it to the submaxillary gland; part of it then joins the submaxillary ganglion; the rest is continued onward through the muscular substance of the tongue to the mucous membrane covering its anterior two-thirds. A few of its fibres probably pass through the submaxillary ganglion to the sublingual gland. Before joining the lingual nerve it receives a small communicating branch from the otic ganglion. As already stated, the chorda tympani nerve is by many regarded as the continuation of the pars intermedia of Wrisberg.

The Posterior Auricular Nerve (*n. auricularis posterior*) (Figs. 634, 677, and 678).—The posterior auricular nerve arises close to the stylo-mastoid foramen, and passes upward in front of the mastoid process and between the mastoid process and the external ear, where it is joined by a filament from the auricular branch of the pneumogastric (Fig. 684), and communicates with the mastoid branch of the great

auricular and with the small occipital. As it ascends between the external auditory meatus and the mastoid process it divides into two branches, the **auricular** and the **occipital branches.**

The **Auricular Branch** supplies the Retrahens auriculam and the small muscles on the cranial surface of the pinna.

The **Occipital Branch** (*ramus occipitalis*), the larger, passes backward along the superior curved line of the occipital bone, and supplies the occipital portion of the Occipito-frontalis.

The Digastric Branch of the Facial Nerve (*ramus digastricus*).—The digastric branch usually arises by a common trunk with the Stylo-hyoid branch; it divides into several filaments, which supply the posterior belly of the Digastric; one of these perforates that muscle to join the glosso-pharyngeal nerve (*ramus anastomoticus cum n. glossopharyngeo*).

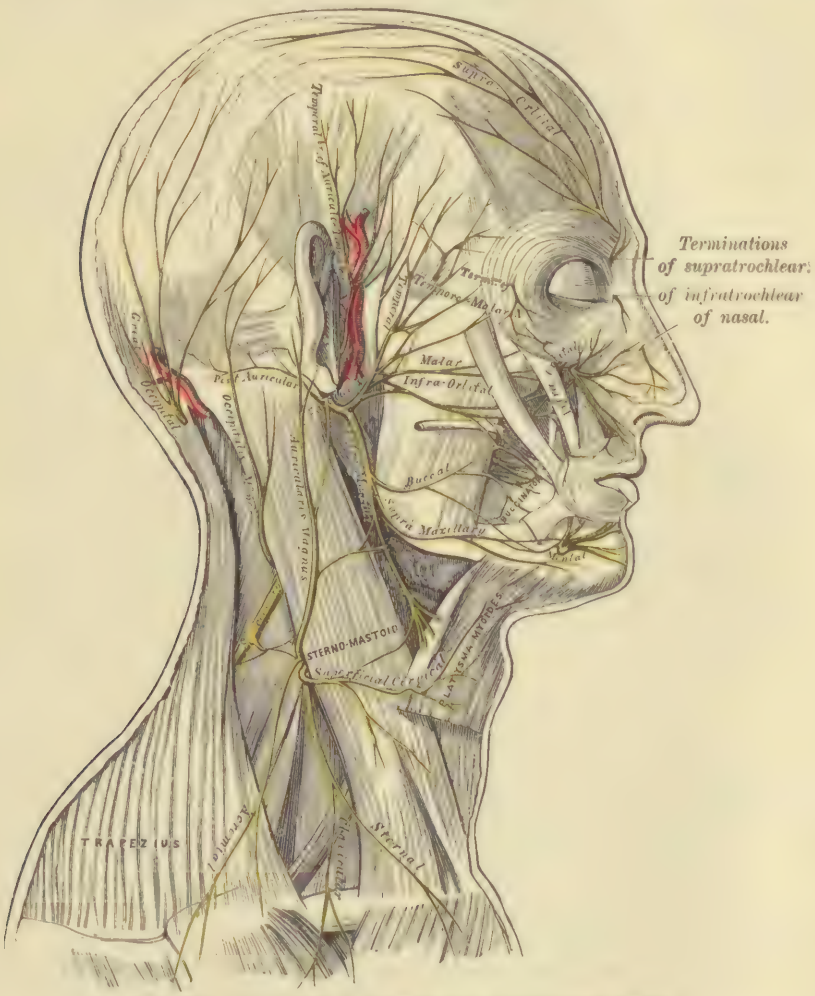

FIG. 678.—The nerves of the scalp, face, and side of the neck.

The Stylo-hyoid Branch (*ramus stylohyoideus*).—The stylo-hyoid branch is a long, slender branch, which passes inward, entering the Stylo-hyoid muscle about its middle.

The Temporo-facial Division (Figs. 677 and 678).—The temporo-facial, the larger of the two terminal branches of the facial, passes upward and forward through

the parotid gland, crosses the external carotid artery and temporo-maxillary vein, and passes over the neck of the condyle of the jaw, being connected in this situation with the auriculo-temporal branch of the inferior maxillary nerve, and divides into branches which are distributed over the temple and upper part of the face; these are divided into three sets—**temporal, malar,** and **infraorbital.**

The **Temporal Branches** (*rami temporales*) cross the zygoma to the temporal region, supplying the Attrahens and Attollens auriculam muscles, and join with the temporal branch of the temporo-malar division of the superior maxillary, and with the auriculo-temporal branch of the inferior maxillary. The more anterior branches supply the frontal portion of the Occipito-frontalis, the Orbicularis palpebrarum, and Corrugator supercilii muscles, joining with the supraorbital and lachrymal branches of the ophthalmic.

The **Malar Branches** (*rami zygomatici*) pass across the malar bone to the outer angle of the orbit. Where they supply the Orbicularis palpebrarum muscle, joining with filaments from the lachrymal nerve; others supply the lower eyelid, joining with filaments of the malar branch (*subcutaneous malae*) of the superior maxillary nerve.

The **Infraorbital Branches** (*rami buccales*), of larger size than the rest of the malar branches, pass horizontally forward to be distributed between the lower margin of the orbit and the mouth. The **superficial branches** run beneath the skin and above the superficial muscles of the face, which they supply; some branches are distributed to the Pyramidalis nasi, joining at the inner angle of the orbit with the infratrochlear and nasal branches of the ophthalmic. The **deep branches** pass beneath the Zygomatici and the Levator labii superioris, supplying the Levator anguli oris, the Levator labii superioris alaeque nasi and the small muscles of the nose, and form a plexus, **infraorbital plexus,** by joining with the branches of the infraorbital branch of the superior maxillary nerve and the buccal branches of the cervico-facial.

The Cervico-facial Division.—The cervico-facial division of the facial nerve passes obliquely downward and forward through the parotid gland, crossing the external carotid artery. In this situation it is joined by branches from the great auricular nerve. Opposite the angle of the lower jaw it divides into branches which are distributed on the lower half of the face and upper part of the neck. These may be divided into three sets—**buccal, supramaxillary,** and **inframaxillary.**

The **Buccal Branches** (*rami buccales*) cross the Masseter muscle. They supply the Buccinator and Orbicularis oris, and join with the infraorbital branches of the temporo-facial division of the nerve, and with filaments of the buccal branch of the inferior maxillary nerve.

The **Supramaxillary** or **Supramandibular Branch** (*ramus marginalis mandibulae*) passes forward beneath the Platysma and Depressor anguli oris, supplying the muscles of the lower lip and chin, and communicating with the mental branch of the inferior dental nerve.

The **Inframaxillary, Inframandibular** or **Cervical Branch** (*ramus colli*) runs forward beneath the Platysma, and forms a series of arches across the side of the neck over the suprahyoid region. A branch descends vertically to join with the superficial cervical nerve from the cervical plexus; others supply the Platysma.

Surgical Anatomy.—The facial nerve is more frequently paralyzed than any of the other of the cranial nerves. The paralysis may depend either upon (1) central causes—*i. e.*, blood-clots or intracranial tumors pressing on the nerve before its entrance into the internal auditory meatus. It is also one of the nerves involved in *bulbar paralysis*. Or (2) it may be paralyzed in its passage through the petrous bone by damage due to *middle-ear disease* or by *fractures of the base*. Or (3) it may be affected at or after its exit from the stylo-mastoid foramen. This is commonly known as *Bell's paralysis*. It may be due to exposure to cold or to injury of the nerve, either from accidental wounds of the face or during some surgical operation, as removal of parotid tumors, opening of abscesses, or operations on the lower jaw.

When the cause is central, the sixth nerve is usually paralyzed as well, and there is also hemiplegia on the opposite side. In these cases the electric reactions are the same as in health; whereas, when the paralysis is due to a lesion in the course of the nerve, the reactions of degeneration develop. When the nerve is paralyzed in the petrous bone, in addition to the paralysis of the muscles of expression, there is loss of taste in the anterior part of the tongue, and the patient is unable to recognize the difference between bitters and sweets, acids and salines, from involvement of the chorda tympani. The mouth is dry, because the salivary glands are not secreting; the sense of hearing is affected from paralysis of the Stapedius, but there is not hemiplegia. When the cause of the paralysis is from fracture of the base of the skull, the auditory nerve and the petrosal nerves, which are connected with the intumescentia ganglioformis, are also involved. When the injury to the nerve is after its exit from the stylo-mastoid foramen, all the muscles of expression, except the Levator palpebrae, together with the posterior belly of the Digastric and Stylo-hyoid, are paralyzed. There is smoothness of the forehead, and the patient is unable to frown; the eyelids cannot be closed, and the lower lid droops, so that the punctum is no longer in contact with the globe, and the tears run down the cheek; there is smoothness of the cheek and loss of the naso-labial furrow; the nostril of the paralyzed side cannot be dilated; the mouth is drawn to the sound side, and there is inability to whistle; food collects between the cheek and gum from paralysis of the Buccinator.

The facial nerve is at fault in cases of so-called *histrionic spasm*, which consists in an almost constant and uncontrollable twitching of the muscles of the face. This twitching is sometimes so severe as to cause great discomfort and annoyance to the patient and to interfere with sleep, and for its relief the facial nerve has been *stretched*. The operation is performed by making an incision behind the ear from the root of the mastoid process to the angle of the jaw. The parotid is turned forward, and the dissection carried along the anterior border of the Sterno-mastoid muscle and mastoid process until the upper border of the posterior belly of the Digastric is found. The nerve is parallel to this on about a level with the middle of the mastoid process. When found, the nerve may be stretched by passing a blunt hook beneath it and pulling it forward and outward. Too great force must not be used, for fear of permanent injury to the nerve. In facial palsy of extracerebral origin it may be advisable to expose the nerve, cut it across, and anastomose the distal end of the paralyzed nerve to the spinal accessory, or, better, to the hypoglossal nerve (facio-accessory anastomosis or facio-hypoglossal anastomosis). The idea was first proposed by Ballance, and has been put in practice by Ballance and Stewart, Keen, Cushing, Faure, Kennedy and others.

THE EIGHTH OR AUDITORY NERVE (N. ACUSTICUS) (Fig. 679).

The eighth or auditory nerve or **Portio Mollis** is the special nerve of the sense of hearing, being distributed exclusively to the internal ear. It is soft in texture; hence the name, *portio mollis*, and is destitute of neurilemma.

The Origin of the Eighth Nerve.—The eighth nerve consists of two sets of fibres, which, although differing in their central connections, are both concerned in the transmission of afferent impulses from the internal ear to the medulla and pons, and from there, by means of new fibres which arise from collections of gray matter in these structures, to the cerebrum and cerebellum. One set of fibres forms the vestibular root, another set forms the cochlear root of the nerve. At its connection with the brain the eighth nerve occupies the groove between the pons and medulla, where it is situated between the restiform body, which is behind, and the seventh nerve, which is in front.

Vestibular, Nexal or Ventral Root (*radix vestibularis*) (Fig. 613).—The fibres of this root enter the medulla to the inner side of those of the cochlear root, and pass between the restiform body, which is to their outer side, and the inferior root of the fifth, which lies to their inner side. They then divide into an ascending and a descending set. The fibres of the latter end by arborizing around the cells of the internal nucleus, which is situated in the trigonum acustici in the floor of the fourth ventricle. The ascending fibres either end in the same manner or in the external nucleus, which is situated to the outer side of the trigonum acustici and farther from the ventricular floor. It is described as consisting of two parts, an inner, the **nucleus of Deiters**, and an outer, the **nucleus of Bechterew**. Some of the axones of the cells of the external nucleus, and possibly also of the internal nucleus, are continued upward through the restiform body to the roof nuclei of the opposite

side of the cerebellum, to which also are prolonged other fibres of the vestibular root without undergoing a relay in the nuclei of the medulla. A second set of fibres from the internal and external nuclei end partly in the tegmentum, while the remainder ascend in the posterior longitudinal bundle to arborize around the nuclei of the oculo-motor nerve.

Cochlear, Dorsal or Lateral Root (*radix cochlearis*) (Fig. 613).—This part of the nerve is placed externally to the vestibular root. Its fibres end in two nuclei, one of which, the **accessory nucleus,** lies immediately in front of the restiform body; the other, the **tuberculum acusticum,** somewhat to its outer side.

The striae acusticae or medullary striae are the axones of the cells of the tuberculum acusticum. They pass backward and inward over the restiform body, and across the floor of the fourth ventricle toward the middle line. Here they dip into the substance of the pons, to end around the cells of the superior olive of the same or opposite side. There are, however, other fibres, and these are both direct and crossed, which do not arborize around the tegmental nuclei, but pass into the lat-

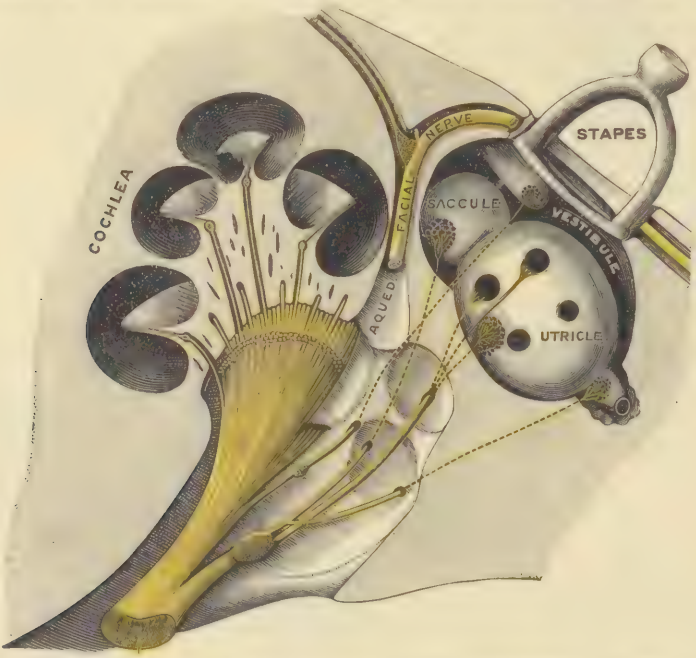

FIG. 679.—Distribution of the auditory nerve. (Semidiagrammatic.) (Testut.)

eral fillet. The cells of the accessory nucleus give origin to fibres which pass transversely in the pons and constitute the trapezium. The description given as to the mode of ending of the striae acusticae is applicable to that of the trapezoid fibres—viz., around the cells of the superior olive or of the trapezoid nucleus (which lies ventral to the olive) of the same or opposite side, while others, crossed or uncrossed, pass directly into the lateral fillet.

If the further connections of the cochlear nerve of one side, say the left, are considered, it is found that they lie to the outer side of the main sensory tract, the fillet, and are therefore termed the **lateral fillet.** The fibres comprising the left lateral fillet arise in the superior olive or trapezoid nucleus of the same or opposite side, while others are the uninterrupted fibres already alluded to, and these are either crossed or uncrossed, the former being the axones of the cells of the right accessory nucleus or of the cells of the right tuberculum acusticum, while the latter are derived from the same cells of the left side. In the upper part of the fillet there is a collection of nerve-cells, the **nucleus of the fillet** (*fila anastomotica*), around

the cells of which some of the fibres arborize, and from the cells of which axones originate to continue upward the tract of the lateral fillet. The ultimate ending of the left lateral fillet is partly in the quadrigeminal bodies of the same or opposite

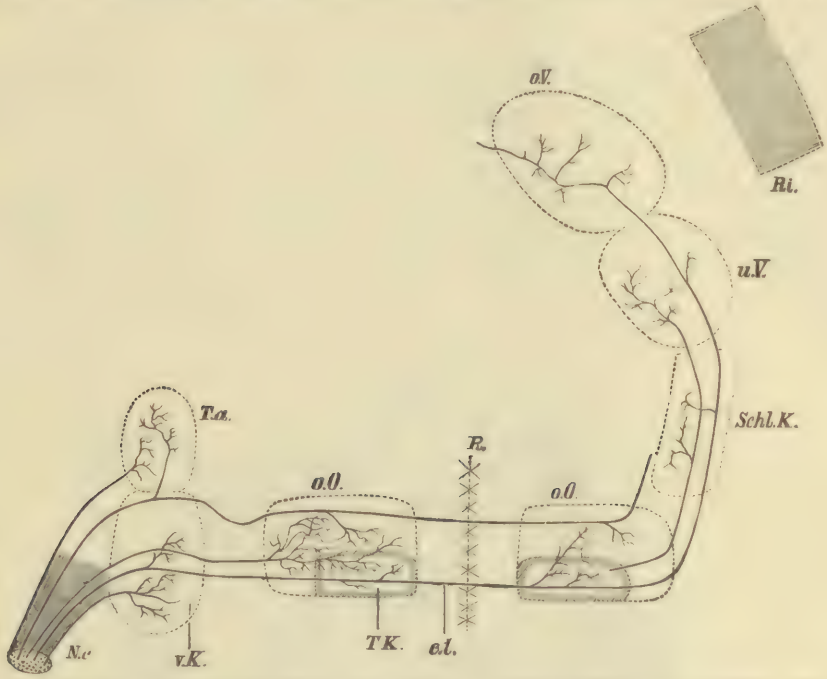

FIG. 680.—Diagram of the central auditory tract (direct or root-fibre system): *N.c.*, cochlear nerve; *F.a.*, acoustic tubercle; *v.K.*, ventral nucleus; *c.t.*, trapezoid body; *o.O.*, *o.O.*, superior olives; *R.*, raphé; *Schl.K.*, nucleus of the lemniscus; *o.V.*, pregeminum; *Ri.*, cortex. (Rauber, after Held.)

side, while the remainder of the fibres ascend in the posterior limb of the internal capsule to reach the first and perhaps the second left temporal convolution.

The auditory nerve contains a few afferent fibres which arise in the quadrigeminal bodies, the nucleus of the lateral fillet, trapezoid nucleus, and superior olive.

The auditory nerve after leaving the medulla passes forward across the posterior border of the middle peduncle of the cerebellum, in company with the facial nerve, from which it is partly separated by a small artery, the **auditory.** It then enters the internal auditory meatus with the facial nerve. In the meatus it divides into its two branches, the **inferior** or **cochlear trunk** (*n. cochleae*) and the **superior** or **vestibular trunk** (*n. vestibuli*). The cochlear trunk is a continuation of the cochlear root, gives branches to the macula acustica of the saccule, and to the ampulla of the posterior semicircular canal, and then passes through the lamina cribrosa to the labyrinth. The cochlear nerve is distributed to the modiolus and osseous spiral lamina, and is finally distributed to the organ of Corti. The vestibular

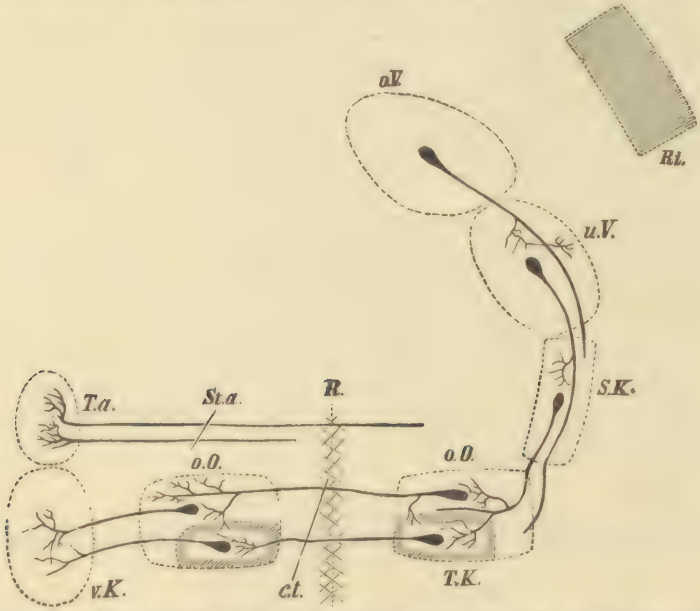

FIG. 682.—Diagram of the central auditory tract (recurrent system): *v.K.*, ventral nucleus; *c.t.*, trapezoid body; *R.*, raphé; *T.K.*, trapezoid nucleus; *o.O.*, superior olive; *Ta.*, acoustic tubercle; *Sta.*, acoustic striæ; *S.K.*, nucleus of the lemniscus; *o.V.*, pregeminum; *u.V.*, post-geminum; *Ri.*, cotex. (Rauber, after Held.)

trunk is a continuation of the vestibular root. In the internal meatus it receives fibres of the pars intermedia and gives a branch to the geniculate ganglion of the facial nerve (Cunningham). It divides into three branches, which pass through the lamina cribrosa and are distributed, one to the macula acustica of the utricle and the ampulla, one to the superior semicircular canal, and one to the external semicircular canal. There is a ganglion on the vestibular nerve called the **vestibular ganglion** (*ganglion vestibulare*), and a ganglion on the cochlear nerve, the **ganglion of Corti** (*ganglion spirale*). The fibres of the auditory nerve proper arise in these ganglia; the vestibular fibres in the ganglion vestibulare; the cochlear fibres in the ganglion spirale.

The Auditory Paths (Figs. 680, 681, and 682).—There are two auditory paths, the **cochlear** or **central auditory path** and the **vestibular path.**

The Cochlear Path.—The cochlear path conducts impulses of hearing. Such impulses pass from the organ of Corti to the **ganglion of Corti** (*ganglion spirale*) and then by the cochlear fibres to the cochlear nucleus in the medulla. The path from the nucleus to the cortical auditory centre is described as follows

by Santee.[1] Impulses from the cochlear nucleus "run either lateral and dorsal to the restiform body and cross to the opposite side through the acustic striae and trapezium, or they run medial to the restiform body and enter at once into the trapezium. By either course they reach the lateral fillet, and chiefly the opposite one. The lateral fillets conduct the impulses to the inferior quadrigeminal bodies; the inferior brachia to the internal geniculate bodies, and the acustic radiation to the third and fourth fifths of the superior temporal and to the transverse temporal gyri of the cerebrum."

The Vestibular Path.—The vestibular path conducts impulses of equilibrium. Impulses from the semicircular canals, utricle and saccule pass by way of the vestibular nerve to the vestibular nuclei in the floor of the fourth ventricle and a spinal nucleus of undetermined situation. From these nuclei impulses pass to the nuclei in the opposite side of the cerebellum by one of two routes. Either by the opposite medial fillet and fibres of the systems of Flechsig or through the acusticocerebellar tract and fibres of the vestibular nerve in the restiform body to the opposite cerebellum (nucleus fastigii, nucleus globosus, corpus dentatum, and cerebellar cortex).[2] From the cerebellum impulses pass along the superior peduncle to "the red nucleus and optic thalamus of both sides and thence to the cortex. They may excite in the cerebellum impulses of equilibration, which descend to the motor nuclei of spinal nerves in the anterior horns of gray matter by way of the antero-lateral descending cerebellar tracts" (Santee).

Surgical Anatomy. The auditory nerve is frequently injured, together with the facial nerve, in *fractures of the middle fossa of the base of the skull* implicating the internal auditory meatus. The nerve may be either torn across, producing permanent deafness, it may be bruised or it may be pressed upon by extravasated blood or inflammatory exudation, when the deafness will in all probability be temporary. The nerve may also be injured by violent blows on the head without fracture, and deafness may follow loud explosions of dynamite, etc., probably from some lesion of this nerve, which is more liable to be injured than the other cranial nerves on account of its structure. The test that the nerve is destroyed and that the deafness is not due to some lesion of the auditory apparatus is obtained by placing a vibrating tuning-fork on the head. The vibrations will be heard in cases where the auditory apparatus is at fault, but not in cases of destruction of the auditory nerve.

THE NINTH OR GLOSSO-PHARYNGEAL NERVE (N. GLOSSOPHARYNGEUS) (Figs. 683, 684, 685).

The ninth or glosso-pharyngeal nerve is distributed, as its name implies, to the tongue and pharynx, being the nerve of ordinary sensation to the mucous membrane of the pharynx, fauces, and tonsil; and the nerve of taste to all parts of the tongue to which it is distributed.

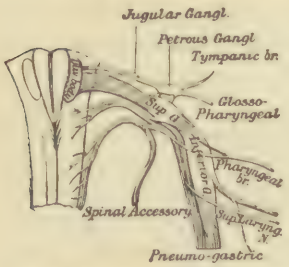

FIG. 683.—Origin, ganglia, and communication of the ninth, tenth, and eleventh cranial nerves.

Its *superficial origin* is by three or four filaments, closely connected together, from the upper part of the medulla oblongata, in the groove between the olivary and restiform body (Fig. 683). Its *deep origin* (Fig. 613) may be traced through the fasciculi of the lateral tract to three different sources: (1) some of the fibres may be traced to a nucleus of gray matter at the lower part of the floor of the fourth ventricle beneath the inferior fovea; (2) others may be traced downward into the **funiculus solitarius**, a rounded bundle of fibres in the lower part of the medulla, commencing immediately above the decussation of the pyramids (these fibres have not been distinctly traced to cells); (3) a third set of

[2] Santee, loc. cit.

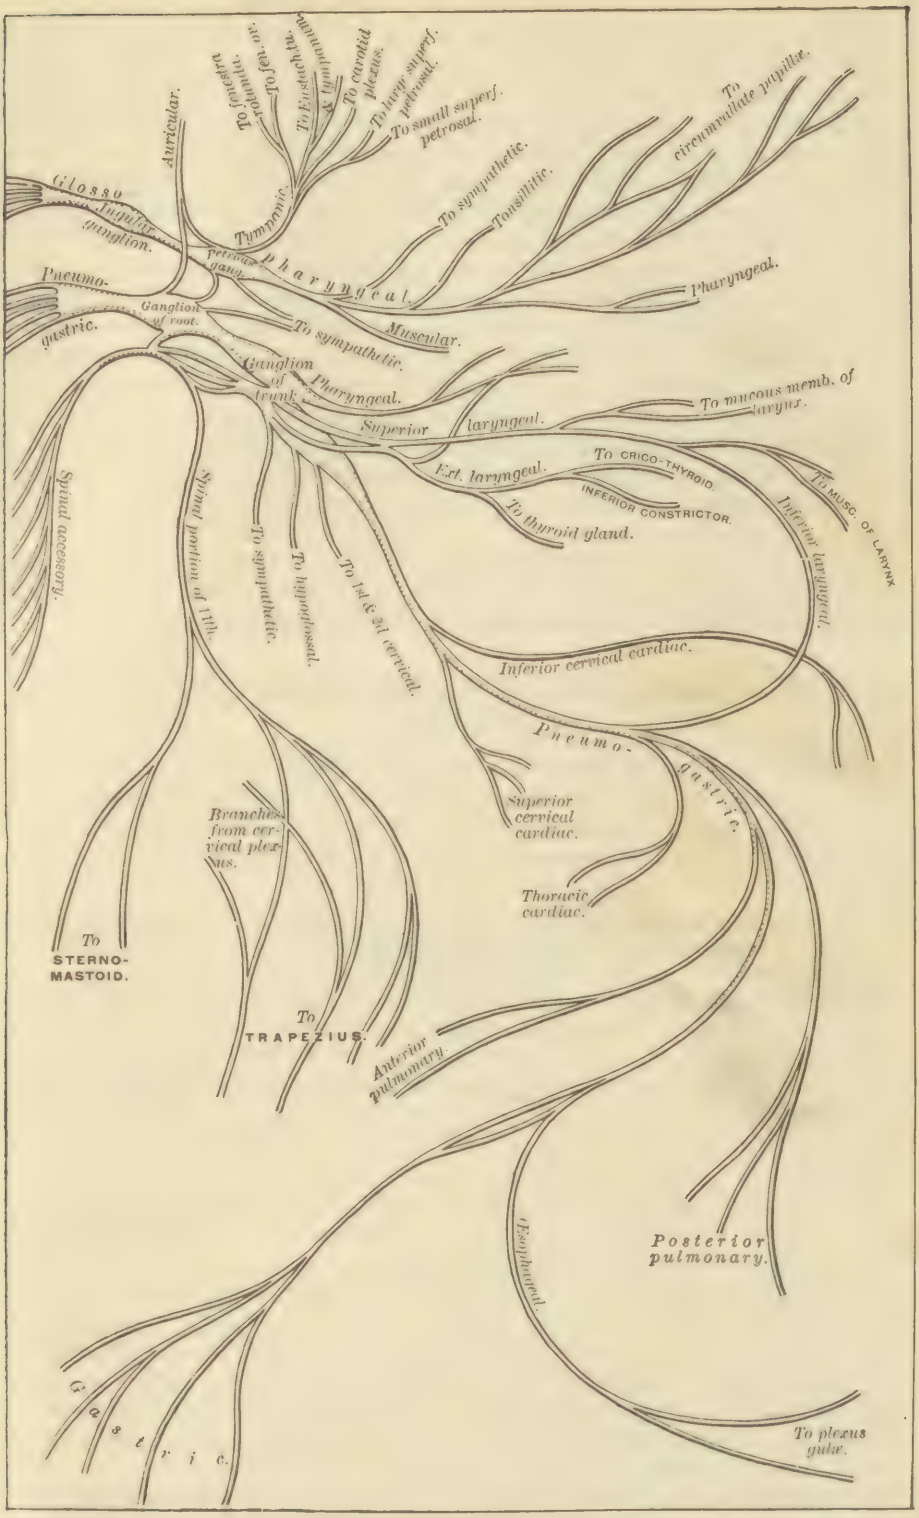

FIG 684.—Plan of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. (After Flower.)

fibres takes origin from the cells of the **nucleus ambiguus.** This nucleus is situated some distance from the floor of the fourth ventricle and lies slightly internal to the inferior fovea. It gives origin to the motor branches of the glosso-pharyngeal and vagus, and to the bulbar part of the spinal accessory. The real origin of the sensory fibres of the glosso-pharyngeal must be looked for in the jugular and petrosal ganglia which are developed from the neural crest.

From its superficial origin it passes outward across the flocculus, and leaves the skull at the central part of the jugular foramen, in a separate sheath of the dura mater, external to and in front of the pneumogastric and spinal accessory nerves (Fig. 685). In its passage through the jugular foramen it grooves the lower border of the petrous portion of the temporal bone, and at its exit from the skull passes forward between the jugular vein and internal carotid artery, and descends in front of the latter vessel, and beneath the styloid process of the temporal bone and the muscles connected with it, to the lower border of the Stylo-pharyngeus muscle. The nerve now curves inward, forming an arch on the side of the neck, and lying upon the Stylo-pharyngeus muscle and the Middle constrictor of the pharynx. It then passes beneath the Hyoglossus muscle, and is finally distributed to the mucous membrane of the fauces and base of the tongue, and the mucous glands of the mouth and tonsil.

In passing through the jugular foramen the nerve presents, in succession, two gangliform enlargements. The superior and smaller is called the **jugular ganglion**; the inferior and larger, the **petrous ganglion** or the **ganglion of Andersch.**

The Superior or Jugular Ganglion (Ganglion Superius n. Glossopharyngei) (Fig. 684).

The superior or jugular ganglion is situated in the upper part of the groove in which the nerve is lodged during its passage through the jugular foramen. It is of very small size, and involves only the lower part of the trunk of the nerve. It is usually regarded as a segmentation from the lower ganglion.

The Inferior or Petrous Ganglion (Ganglion Petrosum n. Glossopharyngei) (Figs. 683 and 684).

The inferior or petrous ganglion is situated in a depression in the lower border of the petrous portion of the temporal bone; it is larger than the superior ganglion and involves the whole of the fibres of the nerve. From this ganglion arise those filaments which connect the glosso-pharyngeal with the pneumogastric and sympathetic nerves.

Branches of Communication (Fig. 684).—The branches of communication are with the pneumogastric, sympathetic, and facial.

The branches to the pneumogastric are two filaments, arising from the petrous ganglion, one of which passes to the auricular branch of the pneumogastric, and one to the upper ganglion of the pneumogastric.

The branch to the sympathetic, also arising from the petrous ganglion, is connected with the superior cervical ganglion.

The branch of communication with the facial perforates the posterior belly of the Digastric muscle. It arises from the trunk of the nerve below the petrous ganglion, and joins the facial just after its exit from the stylo-mastoid foramen.

Branches of Distribution (Fig. 684). The branches of distribution are the **tympanic, carotid, pharyngeal, muscular, tonsillar,** and **lingual.**

The Tympanic Branch or Jacobson's Nerve (*n. tympanicus*). The tympanic branch or Jacobson's nerve *arises* from the petrous ganglion, and enters a small bony canal in the lower surface of the petrous portion of the temporal bone, the lower

opening of which is situated on the bony ridge which separates the carotid canal from the jugular fossa. It ascends to the tympanum, enters that cavity by an aperture in its floor close to the inner wall, and divides into branches which are contained in grooves upon the surface of the promontory. These branches form a **tympanic plexus** (*plexus tympanicus*). This plexus gives off (1) the greater part of the small superficial petrosal nerve (Fig. 677); (2) a branch to join the great superficial petrosal nerve; and (3) branches to the tympanic cavity, all of which will be described in connection with the anatomy of the ear.

The Carotid Branches (*n. caroticotympanicus superior* and *n. caroticotympanicus inferior*).—The carotid branches descend along the trunk of the internal carotid artery as far as its commencement, communicating with the pharyngeal branch of the pneumogastric and with branches of the sympathetic.

The Pharyngeal Branches (*rami pharyngei*) (Fig. 684).—The pharyngeal branches are three or four filaments which unite opposite the Middle constrictor of the pharynx with the pharyngeal branches of the pneumogastric and sympathetic nerves to form the **pharyngeal plexus,** branches from which perforate the muscular coat of the pharynx to supply the muscles and mucous membrane.

The Muscular Branch (*ramus stylopharyngeus*).—The muscular branch is distributed to the Stylo-pharyngeus muscle.

The Tonsillar Branches (*rami tonsillares*).—The tonsillar branches supply the tonsil, forming a plexus (*circulus tonsillaris*) around this body, from which branches are distributed to the soft palate and fauces, where they communicate with the palatine nerves.

The Lingual Branches (*rami linguales*).—The lingual branches are two in number: one supplies the circumvallate papillae and the mucous membrane covering the surface of the base of the tongue; the other perforates its substance, and supplies the mucous membrane and follicular glands of the posterior one-third of the tongue and communicates with the lingual nerve.

The Gustatory Path.—The impressions of taste reach the glosso-pharyngeal nucleus in the medulla in two ways. From the posterior one-third of the tongue and from the palate they reach the nucleus by the ninth nerve. From the anterior two-thirds of the tongue impulses of taste are conveyed by the chorda tympani and pars intermedia. From the glosso-pharyngeal nucleus gustatory impressions pass by way of the medial fillet to the optic thalamus of the opposite side, and from the optic thalamus through the inferior lamina of the internal capsule to the gyrus hippocampi, where the cortical gustatory centre is situated.

Surgical Anatomy.—Injury may produce hemorrhage about the roots of the nerve. Bergmann reported such a case. The patient died from œdema of the glottis after presenting evidences of disorder of speech and difficulty in swallowing.

THE TENTH OR PNEUMOGASTRIC NERVE (N. VAGUS) (Figs. 683, 684, 685).

The tenth or pneumogastric nerve has a more extensive distribution than any of the other crainal nerves, passing through the neck and thorax to the upper part of the abdomen. It is composed of both motor and sensory fibres. It supplies the organs of voice and respiration with motor and sensory fibres, and the pharynx, œsophagus, stomach, and heart with motor fibres. Its *superficial origin* (Fig. 683) is by eight or ten filaments from the groove between the olivary and the restiform body below the glosso-pharyngeal; its *deep origin* (Fig. 613) may be traced through the fasciculi of the medulla to a nucleus of gray matter, the **nucleus vagi,** at the lower part of the floor of the fourth ventricle beneath the ala cinerea below and continuous with the nucleus of origin of the glosso-pharyngeal. In addition to this a few fibres pass into the funiculus solitarius, and others into the nucleus ambiguus or

accessory vagal nucleus. The real origin of the sensory fibres of the vagus is to be found in the cells of the ganglia on the nerve—viz., the ganglion of the root and the ganglion of the trunk. The filaments become united and form a flat cord, which passes outward beneath the flocculus to the jugular foramen, through which it emerges from the cranium (Fig. 685). In passing through this opening the pneumogastric accompanies the spinal accessory, being contained in the same sheath of dura mater with it, a membranous septum separating them from the glossopharyngeal, which lies in front (Fig. 685). The nerve in this situation presents a well-marked ganglionic enlargement, which is called the **superior ganglion, jugular ganglion,** or the **ganglion of the pneumogastric;** to it the accessory part of the spinal accessory nerve is connected by one or two filaments. After the exit of the nerve from the jugular foramen the nerve is joined by the accessory portion of the spinal accessory, and enlarges into a second gangliform swelling, called the **inferior ganglion** or the **ganglion of the trunk of the nerve,** through which the fibres of the spinal accessory pass unchanged, being principally distributed to the pharyngeal and superior laryngeal branches of the vagus; but some of the filaments from it are continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent laryngeal nerve, and probably also with the cardiac nerves. The vagus nerve passes vertically down the neck within the sheath of the carotid vessels lying between the internal carotid artery and the internal jugular vein as far as the thyroid cartilage, and then between the same vein and the common carotid to the root of the neck (Fig. 685). From here the course of the nerve differs on the two sides of the body.

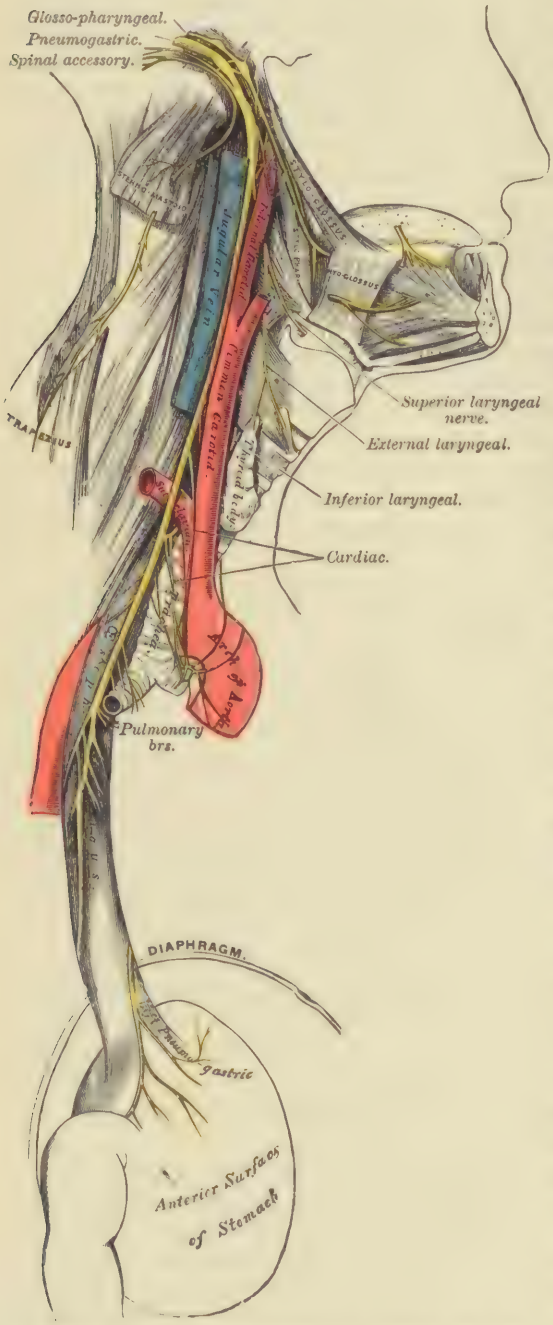

FIG. 685.—Course and distribution of the ninth, tenth, and eleventh nerves.

On the *right side* (Fig. 685) the nerve passes across the subclavian artery between

it and the right innominate vein, and descends by the side of the trachea to the back part of the root of the lung, where it spreads out in a plexiform network, the **posterior pulmonary plexus** (*plexus pulmonalis posterior*), from the lower part of which two cords descend upon the oesophagus, on which tube they divide, forming, with branches from the opposite nerve, the **oesophageal plexus** (*plexus gulae*); below, these branches are collected into a single cord, which runs along the back part of the oesophagus, enters the abdomen, and is distributed to the posterior surface of the stomach, joining the left side of the solar plexus, and sending filaments to the splenic plexus and a considerable branch to the cœliac plexus.

On the *left side* the pneumogastric nerve enters the chest between the left carotid and subclavian arteries, behind the left innominate vein. It crosses the arch of the aorta and descends behind the root of the left lung, forming the **anterior pulmonary plexus** (*plexus pulmonalis anterior*), and along the anterior surface of the oesophagus, where it unites with the nerve of the right side in forming the plexus gulae. It passes to the stomach, distributing branches over the anterior surface of that viscus, some extending over the great *cul-de-sac*, and others along the lesser curvature. Filaments from these branches enter the gastro-hepatic omentum and join the hepatic plexus.

The Ganglion of the Root of the Pneumogastric Nerve (Ganglion Jugulare) (Fig. 684).

The ganglion of the root or the jugular ganglion is of a grayish color, circular in form, about two lines in diameter, and resembles the ganglion on the large root of the fifth nerve.

Connecting Branches.—To this ganglion the accessory portion of the spinal accessory nerve is connected by several delicate filaments; it also has a communicating twig with the petrous ganglion of the glosso-pharyngeal, with the facial nerve by means of its (the ganglion's) auricular branch, and with the sympathetic by means of an ascending filament from the superior cervical ganglion.

The Ganglion of the Trunk of the Pneumogastric Nerve (Ganglion Nodosum) (Fig. 684).

The ganglion of the trunk or the inferior ganglion is a plexiform cord, cylindrical in form, of a reddish color, and about an inch in length; it involves the whole of the fibres of the nerve, and passing through it is the accessory portion of the spinal accessory nerve, which blends with the pneumogastric below the ganglion, and is then principally continued into its pharyngeal and superior laryngeal branches.

Connecting Branches (Fig. 684).—This ganglion is connected with the hypoglossal, the superior cervical ganglion of the sympathetic, and the loop between the first and second cervical nerves.

The *branches of the pneumogastric* are—

In the jugular fossa . .	Meningeal. Auricular.
In the neck	Pharyngeal. Superior laryngeal. Recurrent laryngeal. Cervical cardiac.
In the thorax	Thoracic cardiac. Anterior pulmonary. Posterior pulmonary. Oesophageal.
In the abdomen . . .	Gastric.

The Meningeal Branch (*ramus meningeus*).—The meningeal branch is a recurrent filament given off from the ganglion of the root in the jugular foramen. It passes

backward, and is distributed to the dura mater lining the posterior fossa of the base of the skull.

The Auricular Branch or Arnold's Nerve (*ramus auricularis*) (Fig. 684).—The auricular branch or Arnold's nerve *arises* from the ganglion of the root, and is joined soon after its origin by a filament from the petrous ganglion of the glosso-pharyngeal; it passes outward behind the jugular vein, and enters a small canal on the outer wall of the jugular fossa. Traversing the substance of the temporal bone, it crosses the aquaeductus Fallopii about two lines above its termination at the stylo-mastoid foramen; here it gives off an ascending branch, which joins the facial; the continuation of the nerve reaches the surface by passing through the auricular fissure between the mastoid process and the external auditory meatus, and divides into two branches, one of which communicates with the posterior auricular nerve, while the other supplies the integument at the back part of the pinna and the posterior part of the external auditory meatus.

The Pharyngeal Branch (*ramus pharyngeus*).—The pharyngeal branch, the principal motor nerve of the pharynx, arises from the upper part of the ganglion of the trunk of the pneumogastric. It consists principally of filaments from the accessory portion of the spinal accessory; it passes across the internal carotid artery to the upper border of the Middle constrictor of the pharynx, where it divides into numerous filaments which join with those from the glosso-pharyngeal, the superior laryngeal (its external branch), and sympathetic, to form the **pharyngeal plexus** (*plexus pharyngeus*), from which branches are distributed to the muscles and mucous membrane of the pharynx and the muscles of the soft palate. From the pharyngeal plexus a minute filament is given off, which descends and joins the hypoglossal nerve as it winds around the occipital artery.

The Superior Laryngeal Nerve (*n. laryngeus superior*) (Figs. 683, 684, and 685). – It is larger than the preceding, and arises from the middle of the ganglion of the trunk of the pneumogastric. It consists principally of filaments from the accessory portion of the spinal accessory. In its course it receives a branch from the superior cervical ganglion of the sympathetic. It descends by the side of the pharynx behind the internal carotid artery, where it divides into two branches, the **external** and **internal laryngeal**. This nerve is the nerve of sensation of the larynx, and also supplies the crico-thyroid muscle. Exner has pointed out that the superior laryngeal nerve innervates to some extent the muscles supplied by the inferior laryngeal, and this fact explains why division of the inferior laryngeal nerve is not of necessity followed by complete paralysis of the muscles it supplies.

The **External Laryngeal Branch of the Superior Laryngeal** (*ramus externus*) (Fig. 685), the smaller, descends by the side of the larynx, beneath the Sterno-thyroid, to supply the Crico-thyroid muscle. It gives branches to the pharyngeal plexus and the Inferior constrictor, and communicates with the superior cardiac nerve, behind the common carotid.

The **Internal Laryngeal Branch of the Superior Laryngeal** (*ramus internus*) descends to the opening in the thyro-hyoid membrane, through which it passes with the superior laryngeal artery, and is distributed to the mucous membrane of the larynx. A small branch communicates with the recurrent laryngeal nerve. The branches to the mucous membrane are distributed, some in front to the epiglottis, the base of the tongue, and the epiglottidean glands; while others pass backward, in the aryteno-epiglottidean fold, to supply the mucous membrane surrounding the superior orifice of the larynx, as well as the membrane which lines the cavity of the larynx as low down as the vocal cord. The filament which joins with the recurrent laryngeal descends beneath the mucous membrane on the inner surface of the thyroid cartilage, where the two nerves become united.

The Inferior or Recurrent Laryngeal Branch of the Pneumogastric (*n. laryngeus inferior*) (Figs. 684 and 685).—The inferior or recurrent laryngeal branch, so called from its reflected course, is the motor nerve of the larynx. It arises on

the right side, in front of the subclavian artery; winds from before backward around that vessel, and ascends obliquely to the side of the trachea, behind the common carotid artery and behind or in front of the inferior thyroid artery. On the left side it arises in front of the arch of the aorta, and winds from before backward around the aorta at the point where the remains of the ductus arteriosus are connected with it, and then ascends to the side of the trachea. The nerve on each side ascends in the groove between the trachea and oesophagus, and, passing under the lower border of the Inferior constrictor muscle, enters the larynx behind the articulation of the inferior cornu of the thyroid cartilage with the cricoid, being distributed to all the muscles of the larynx except the Crico-thyroid. It communicates with the superior laryngeal nerve and gives off a few filaments to the mucous membrane of the lower part of the larynx.

The recurrent laryngeal, as it winds around the subclavian artery and aorta, gives off several cardiac filaments, which unite with the cardiac branches from the pneumogastric and sympathetic. As it ascends in the neck it gives off oesophageal branches, more numerous on the left than on the right side, which supply the mucous membrane and muscular coat of the oesophagus; tracheal branches to the mucous membrane and muscular fibres of the trachea; and some pharyngeal filaments to the Inferior constrictor of the pharynx.

The Cervical Cardiac Branches (*rami cardiaci superiores*) (Fig. 684).—The cervical cardiac branches, two or three in number, arise from the pneumogastric, at the upper and lower part of the neck.

The **Superior Branches** are small, and communicate with the cardiac branches of the sympathetic. They can be traced to the great or deep cardiac plexus.

The **Inferior Branches**, one on each side, arise at the lower part of the neck, just above the first rib. On the right side this branch passes in front or by the side of the arteria innominata, and communicates with one of the cardiac nerves proceeding to the great or deep cardiac plexus. On the left side it passes in front of the arch of the aorta and joins the superficial cardiac plexus.

The Thoracic Cardiac Branches (*rami cardiaci inferiores*) (Fig. 684).—The thoracic cardiac branches, on the right side, arise from the trunk of the pneumogastric as it lies by the side of the trachea, and from its recurrent laryngeal branch, but on the left side from the recurrent nerve only; passing inward, they terminate in the deep cardiac plexus.

The Anterior Pulmonary Branches (Fig. 684).—The anterior pulmonary branches, two or three in number, and of small size, are distributed on the anterior aspect of the root of the lungs. They join with filaments from the sympathetic, and form the **anterior pulmonary plexus** (*plexus pulmonalis anterior*).

The Posterior Pulmonary Branches (Fig. 684).—The posterior pulmonary branches, more numerous and larger than the anterior, are distributed on the posterior aspect of the root of the lung; they are joined by filaments from the third and fourth (sometimes also from the first and second) thoracic ganglia of the sympathetic, and form the **posterior pulmonary plexus** (*plexus pulmonalis posterior*). Branches from both plexuses accompany the ramification of the air-tubes through the substance of the lungs (*rami bronchiales anteriores* and *rami bronchiales posteriores*).

The Oesophageal Branches (*rami oesophagei*).—The oesophageal branches are given off from the pneumogastric both above and below the pulmonary branches. The lower are more numerous and larger than the upper. They form, together with branches from the opposite nerve, the **oesophageal plexus** (*plexus gulae*). From this plexus branches are distributed to the back of the pericardium.

The Gastric Branches (*rami gastrici*) (Figs. 684 and 685.—The gastric branches are the terminal filaments of the pneumogastric nerve. The nerve on the right side is distributed to the posterior surface of the stomach. The right pneumogastric sends branches to the **coeliac plexus** (*rami coeliaci*), to the **splenic plexus** (*rami lienales*), and to the **renal plexus** (*rami renales*). The nerve on the left

side is distributed over the anterior surface of the stomach, some filaments (*rami hepatici*) passing across the great *cul-de-sac*, and others along the lesser curvature. They unite with branches of the right nerve and with the sympathetic, some filaments passing through the lesser omentum to the hepatic plexus.

Surgical Anatomy. -The *laryngeal nerves* are of considerable importance in considering some of the morbid conditions of the larynx. When the peripheral terminations of the superior laryngeal nerve are irritated by some foreign body passing over them, *reflex spasm of the glottis* is the result. When the trunk of the same nerve is pressed upon by, for instance, a goitre or an aneurism of the upper part of the carotid, we have a peculiar dry, brassy cough. When the nerve is paralyzed, we have anæsthesia of the mucous membrane of the larynx, so that foreign bodies can readily enter the cavity, and, in consequence of its supplying the crico-thyroid muscle, the vocal cords cannot be made tense, and the voice is deep and hoarse. Paralysis of the superior laryngeal nerves may be the result of bulbar paralysis, may be a sequel to diphtheria, when both nerves are usually involved, or it may, though less commonly, be caused by the pressure of tumors or aneurisms, when the paralysis is generally unilateral. Irritation of the inferior laryngeal nerves produces spasm of the muscles of the larynx. When both the recurrent nerves are paralyzed, the vocal cords are motionless in the so-called *cadaveric position* -that is to say, in the position in which they are found in ordinary tranquil respiration—neither closed as in phonation, nor open as in deep inspiratory effort. When one recurrent nerve is paralyzed, the cord of the same side is motionless, while the opposite cord crosses the middle line to accommodate itself to the affected one; hence phonation is present, but the voice is altered and weak in timbre. The recurrent laryngeal nerves may be paralyzed in bulbar paralysis or after diphtheria, when the paralysis usually affects both sides; or they may be affected by the pressure of aneurisms of the aorta, innominate or subclavian arteries; by mediastinal tumors; by bronchocele; or by cancer of the upper part of the oesophagus, when the paralysis is often unilateral. The nerve may be accidentally divided during the operation for goitre.

It is a well-recognized fact that disease or injury of the vagus may induce serious symptoms. Bruising may cause such symptoms; so may injury of the nerve by a stab, a bullet, or during surgical operations. Either accidental ligation or crushing with clamp forceps is particularly dangerous. Michaux accidentally ligated the vagus, and the patient became comatose and ceased to breathe, but was restored on removing the ligature. Tillmanns, while removing a cancer, accidentally caught and crushed a portion of the nerve in a clamp, and both pulse and respiration ceased. The clamp was removed, the patient was restored with difficulty, and the nerve was sutured. Recovery followed. It thus becomes evident that division of the vagus on one side is not, as was so long taught, a necessarily fatal accident; in fact, it is sometimes undertaken deliberately in removing tumors adherent to the nerve. Division of a nerve which has been long compressed is probably not so dangerous as division of a healthy nerve, as in the former case the opposite vagus has probably assumed some of its colleague's duties. A number of cases of deliberate division have been reported. Twenty-three cases are referred to in the system of surgery by von Bergmann and Mikulicz, and twelve of them died, but in none of the deaths was the removal of the vagus the apparent cause of the fatality. The editor of this American edition of "Gray" has seen three cases: One was operated upon by Dr. W. Joseph Hearn, one by Dr. Melvin Franklin, and one by the editor. All three recovered, and not one presented any serious disturbance, although each had hoarseness and weakness of voice.

One would assume that after division of the pneumogastric below the superior laryngeal nerve and above the recurrent laryngeal nerve (the region usually attacked) that there would be paralysis of all the muscles of one side of the larynx, except the crico-thyroid, and widespread aberration evinced by *disturbances* of the heart, stomach, and lungs. As a matter of fact, this has not been the case. It might be and probably would be the case, were a healthy nerve divided; but the surgeon who deliberately divides the nerve does so during the removal of a tumor which has long made pressure. In most cases there is no change in the pulse or respiration. In some cases dysphagia and pneumonia arise, but they may be due to other causes than pneumogastric injury (the formidable nature and the duration of the operation -the ligation of vessels of large size—the age of the subject).

Laryngeal symptoms, to a greater or less degree, are always noted. The difference in the degree of the palsy is explainable when we recall Exner's statement that the muscles supplied by the recurrent laryngeal also receive some innervation from the superior laryngeal. In fact, Mills points out that a portion of the recurrent laryngeal has been resected without completely paralyzing the muscles supposed to be supplied solely by the recurrent laryngeal. The laryngeal symptoms result from unilateral laryngeal paralysis, in which there is paralysis of the muscles which open the glottis. The voice may be lost or may be hoarse. Usually, after a time, this is, to a great extent, compensated for by the opposite vocal cord, although the voice may alway remain weak, and the patient will tire easily on talking. If both pneumogastrics were to be divided death would ensue.

THE ELEVENTH OR SPINAL ACCESSORY NERVE (N. ACCESSORIUS) (Figs. 683, 684, 685).

The eleventh or spinal accessory nerve consists of two parts: one the **accessory part to the vagus**, and the other the **spinal portion.**

The Bulbar or Accessory Part of the Spinal Accessory Nerve.

The bulbar or accessory part is the smaller of the two. It is accessory to the vagus. Its *superficial origin* (Fig. 683) is by four or five delicate filaments from the side of the medulla, below the roots of the vagus. Its *deep origin* (Fig. 613) may be traced to a nucleus of gray matter at the back of the medulla, dorso-lateral to the hypo-glossal nucleus, and extending as far down as the intermedio-lateral tract of the spinal cord. It passes outward to the jugular foramen, where it interchanges fibres with the spinal portion or becomes united to it for a short distance; it is also connected, in the foramen, with the upper ganglion of the vagus by one or two filaments. It then passes through the foramen (Fig. 685), and becoming again separated from the spinal portion it is continued over the surface of the ganglion of the trunk of the vagus, being adherent to its surface, and is distributed principally to the pharyngeal and superior laryngeal branches of the pneumogastric (Fig. 684). Through the pharyngeal branch it probably supplies the muscles of the soft palate. Some few filaments from it are continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent laryngeal nerve, and probably also with the cardiac nerves.

The Spinal Portion of the Spinal Accessory Nerve.

The spinal portion is firm in texture. Its *superficial origin* (Fig. 683) is by several filaments or rootlets from the lateral tract of the cord, as low down as the sixth cervical nerve. Its *deep origin* (Fig. 613) may be traced to the intermedio-lateral tract of the gray matter of the cord. The rootlets of origin join and form a trunk which ascends in the subdural space between the ligamentum denticulatum and the posterior roots of the spinal nerves, enters the skull through the foramen magnum, and is then directed outward to the jugular foramen, through which it passes, lying in the same sheath as the pneumogastric, but separated from it by a fold of the arachnoid. In the jugular foramen it receives one or two filaments from the accessory portion. At its exit from the jugular foramen it passes into the neck and becomes the **external branch** (*ramus externus*) (Figs. 634, 684, and 685). It passes backward, either in front of or behind the internal jugular vein, and descends obliquely behind the Digastric and Stylo-hyoid muscles to the upper part of the Sterno-mastoid muscle. It pierces that muscle, and passes obliquely across the posterior triangle, to terminate in the deep surface of the Trapezius muscle. This nerve gives several branches to the Sterno-mastoid muscle during its passage through it, and joins in its substance with branches from the second cervical, which supply the muscle. In the posterior triangle it joins with the second and third cervical nerves, while beneath the Trapezius it forms a sort of plexus with the third and fourth cervical nerves, and from this plexus fibres are distributed to the muscle.

Surgical Anatomy. Division of the external branch of the spinal accessory nerve causes paralysis of the Sterno-cleido-mastoid and Trapezius muscles; not absolute paralysis, for these muscles also receive nerves from the cervical plexus. In cases of *spasmodic torticollis* in which all palliative treatment has failed, division or excision of a portion of the external branch of the spinal accessory nerve has been suggested by Keen. This may be done either along the anterior or posterior border of the Sterno-mastoid muscle. The former operation is performed by making

an incision from the apex of the mastoid process, three inches in length, along the anterior border of the Sterno-mastoid muscle. The anterior border of the muscle is defined and pulled backward, so as to stretch the nerve, which is then to be sought for beneath the Digastric muscle, about two inches below the apex of the mastoid process. The other operation consists in making an incision along the posterior border of the muscle, so that the centre of the incision corresponds to the middle of this border of the muscle. The superficial structures having been divided and the border of the muscle defined, the nerve is to be sought for as it emerges from the muscle to cross the occipital triangle. When found, it is to be traced upward through the muscle, and a portion of it is excised above the point where it gives off its branches to the Sterno-mastoid. In this operation one of the descending branches of the superficial cervical plexus is liable to be mistaken for the nerve.

THE TWELFTH OR HYPOGLOSSAL NERVE (N. HYPOGLOSSUS) (Figs. 686, 687).

The twelfth or hypoglossal nerve is the motor nerve of the tongue. Its *superficial origin* is by several filaments, from ten to fifteen in number, from the groove

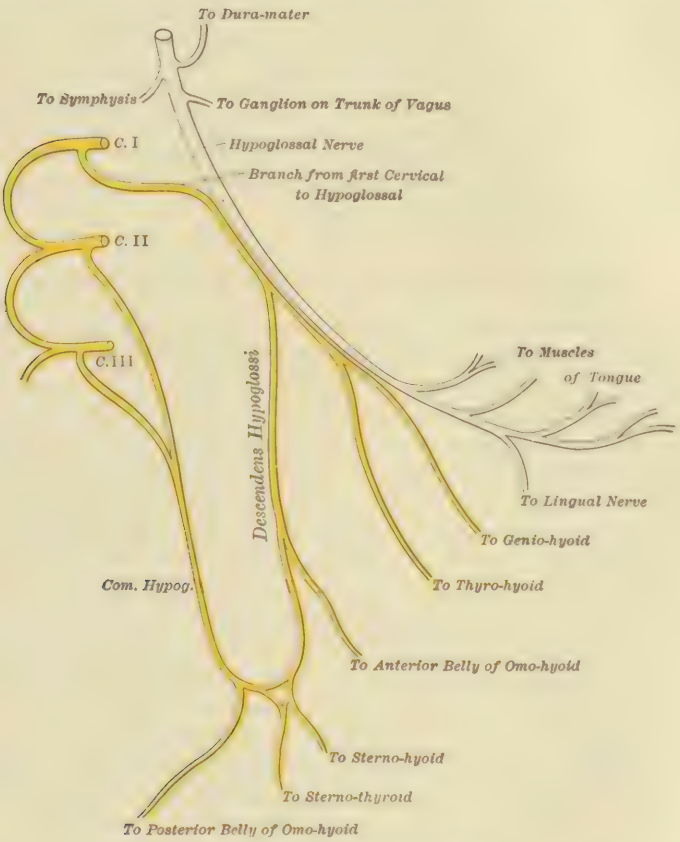

FIG. 686.—Plan of the hypoglossal nerve.

between the pyramidal and olivary bodies of the medulla, in a continuous line with the anterior roots of the spinal nerves. Its *deep origin* can be traced to a nucleus of gray matter (*trigonum hypoglossi*) on the floor of the fourth ventricle (Fig. 613).

The filaments of this nerve are collected into two bundles, which perforate the dura mater separately, opposite the anterior condyloid foramen, and unite together after their passage through it. In those cases in which the anterior condyloid

foramen in the occipital bone is double, these two portions of the nerve are separated by the small piece of bone which divides the foramen. The nerve descends almost vertically to a point corresponding with the angle of the jaw. It is at first deeply seated beneath the internal carotid artery and internal jugular vein, and is intimately connected with the pneumogastric nerve (Fig. 687); it then passes forward between the vein and artery, and lower down in the neck becomes superficial below the Digastric muscle. The nerve then loops around the occipital artery, and crosses the external carotid and its lingual branch below the tendon of the Digastric muscle. It passes beneath the tendon of the Digastric, the Stylo-hyoid, and the Mylo-hyoid muscles, lying between the last-named muscle and the Hyo-

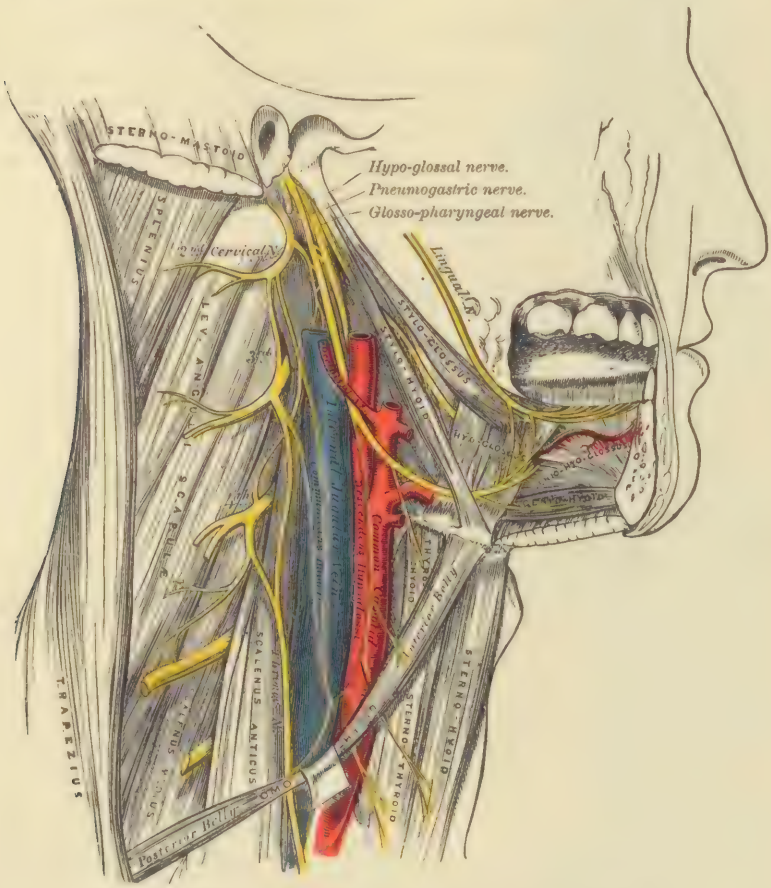

FIG. 687.—Hypoglossal nerve, cervical plexus, and their branches.

glossus (Fig. 687), and communicates at the anterior border of the Hyo-glossus with the lingual or gustatory nerve (Fig. 686); it is then continued forward in the fibres of the Genio-hyoglossus muscle as far as the tip of the tongue, distributing branches to its muscular substance.

Branches of Communication (Fig. 686).—The branches of communication are —with the

Pneumogastric.	First and Second Cervical Nerves.
Sympathetic.	Lingual (gustatory).

The first mentioned takes place close to the exit of the nerve from the skull, numerous filaments passing between the hypoglossal and the ganglion of the trunk

of the pneumogastric through the mass of connective tissue which here unites the two nerves. It also communicates with the pharyngeal plexus by a minute filament as it winds around the occipital artery.

The communication with the sympathetic takes place opposite the atlas vertebra by branches derived from the superior cervical ganglion, and in the same situation the nerve is joined by filaments derived from the loop connecting the first two cervical nerves.

The communication with the lingual (gustatory) takes place near the anterior border of the Hyo-glossus muscle by numerous filaments which ascend upon it.

Branches of Distribution (Fig. 686).—The branches of distribution are—the

Meningeal.	Thyro-hyoid.
Descendens hypoglossi.	Muscular.

Meningeal Branches (Fig. 686).—As the hypoglossal nerve passes through the anterior condyloid foramen it gives off, according to Luschka, several filaments to the dura mater in the posterior fossa of the base of the skull; these filaments are probably derived from a branch which passes from the first cervical nerve to the hypoglossal nerve.

The Descendens Hypoglossi (*ramus descendens*) (Figs. 686 and 687).—The descendens hypoglossi, long called the **descendens noni**, is a long slender branch, which quits the hypo-glossal where it turns around the occipital artery. It consists mainly of fibres which pass to the hypoglossal from the first and second cervical nerves in the above-mentioned communication. It descends in front of or within the sheath of the common carotid artery, giving off a branch to the anterior belly of the Omo-hyoid, and then joins the communicating branches from the second and third cervical nerves, just below the middle of the neck, to form a loop, the **ansa hypo-glossi**. From the convexity of this loop branches pass to supply the Sterno-hyoid, Sterno-thyroid, and the posterior belly of the Omo-hyoid. According to Arnold, another filament descends in front of the vessels into the chest, and joins the cardiac and phrenic nerves.

The Thyro-hyoid Branch (*ramus thyreohyoideus*) (Fig. 686).—The thyro-hyoid is a small branch arising from the hypoglossal near the posterior border of the Hyo-glossus; it passes obliquely across the great cornu of the hyoid bone and supplies the Thyro-hyoid muscle.

The Muscular Branches (Fig. 686).—The muscular branches are distributed to the Stylo-glossus, Hyo-glossus, Genio-hyoid, and Genio-hyo-glossus muscles. At the under surface of the tongue numerous slender branches (*rami linguales*) pass upward into the substance of the organ to supply its intrinsic muscles.

Surgical Anatomy.—A wound in the submaxillary region may injure the hypoglossal nerve and result in motor paralysis of the corresponding half of the tongue. The hypoglossal nerve is an important guide in the operation of ligation of the lingual artery (see page 604). It runs forward on the Hyo-glossus muscle just above the great cornu of the hyoid bone, and forms the upper boundary of the triangular space in which the artery is to be sought for by cutting through the fibres of the Hyo-glossus muscle.

THE SYMPATHETIC NERVE (SYMPATHICUS) (Fig. 688).

The sympathetic nervous system consists of (1) a series of **ganglia** (*ganglia trunci sympathici*) connected together by a **great ganglionic cord**, the **gangliated cord** (*truncus sympathicus*), extending from the base of the skull to the coccyx, one gangliated cord on each side of the middle line of the body, partly in front and partly on each side of the vertebral column; (2) of three **great gangliated plexuses** (*plexus sympathici*) or aggregations of nerves and ganglia, situated in front of

the spine in the thoracic, abdominal, and pelvic cavities respectively; (3) of **smaller** or **terminal ganglia**, situated in relation with the abdominal viscera; and (4) of numerous **nerve-fibres**. These latter are of two kinds: **communicating**, by which the ganglia communicate with each other and with the cerebro-spinal nerves; and **distributory**, supplying the internal viscera and the coats of the blood-vessels.

Each gangliated cord may be traced upward from the base of the skull into the cranial cavity by an ascending branch, which passes through the carotid canal, forms a plexus on the internal carotid artery and in the cavernous sinus (Fig. 692), and communicates with certain cranial nerves (p. 1073). According to some anatomists, the two cords are joined, at their cephalic extremities, by these ascending branches communicating in a small ganglion, the **ganglion of Ribes**, situated upon the anterior communicating artery. Upon the gangliated cord are ganglia distinguished as **cervical, dorsal, lumbar,** and **sacral**, and except in the neck they

FIG. 688.—The sympathetic nerve, reduced in size from Byron Robinson's life-size drawing of a dissection made by himself.

I.–VIII., cervical nerves; 2 *a*, 2 *b*, 1 *c*, 1 *d*, brachial plexus; 1, spinal accessory nerve (XI. nerve); 2, hypoglossal nerve (XII. nerve); 3, vagus nerve (X. nerve); 4, descendens nomi nerve; 5, laryngeal nerve; 6, superior cervical ganglion; 7, middle cervical ganglion; 8, 9, inferior cervical ganglion; 10, two superior cardiac nerves; 11, two middle cardiac nerves; 12, two ganglia on 10 and 11; 13, branch connecting the inferior cervical ganglion to phrenic nerve; 14, I. dorsal nerve; 15, left subclavian artery; 16, carotid artery; 17, right subclavian artery; 18, Wrisberg's ganglion; 19, *a*, sympathetic branches to the heart; 19, three inferior cardiac nerves. The phrenic nerve in this subject arose from the III., IV., and V. cervical nerves; 20 to 39, lateral chain of sympathetic ganglia; 40, left recurrent laryngeal nerve; 41, superior splanchnic nerve; 42, middle splanchnic nerve; 43, inferior splanchnic nerve; 44, 45, aortic branches from the lateral chain of ganglia; 45 to 56, intercostal nerve; 57, diaphragmatic ganglion; 58, right vagus nerve; 59, left vagus nerve; 60, nerve joining the vagi; 61, coeliac axis; 62, phrenic artery surrounded by the phrenic plexus, which is connected with the phrenic ganglion (57); 63, 64, abdominal brain (ganglion coeliacum); 65, renal ganglion, I. L., II. L., III. L., IV. L., V. L., lumbar nerves; 66, right superior splanchnic nerve; 67, seven nerves passing to the adrenal; 68, rich meshwork of nerves surrounding left renal artery; 69, right renal ganglion; 70, 71, ovarian ganglion; 72, aortic plexus; 73, inferior mesenteric ganglion; 74, hypogastric plexus; 75, 76, 77, pelvic brain (cervico-vaginal ganglion). At 75 branches from the pelvis brain are emitted to rectum, vagina, and bladder. At 76 the branches from the II., III., and IV. sacral nerves join the pelvic brain. At 77 the uterine nerves are emitted to supply the uterus; 78, oviducal nerves; 79, uterine nerves; 80, bladder; 81, vagina; 82, 83, rectum; I. S., II. S., III. S., IV. S., sacral nerves; 84, arteria uterina ovarica. The right lumbar lateral chain is not numbered; 85, nerves to levator ani; *Il.* and *Hy.*, ileo-hypogastric; *Ii.*, ileo-inguinal; *Ec.*, external cutaneous; *Ac.*, anterior crural; *Obt.*, Obturator; *G. C.*, genito-crural; *G. S.*, great sciatic.

correspond pretty nearly in number to the vertebrae against which they lie. They may be thus arranged:

Cervical	portion	.	.	.	.	3	pairs of	ganglia.
Dorsal	"	.	.	.	.	12	"	"
Lumbar	"	.	.	.	.	4	"	"
Sacral	"	.	.	.	4 or	5	"	"

In the neck they are situated in front of the transverse processes of the vertebrae; **in the dorsal region,** in front of the heads of the ribs; **in the lumbar region,** on the sides of the bodies of the vertebrae; and **in the sacral region,** in front of the sacrum. As the two cords pass into the pelvis they converge and unite together in a single ganglion, the **coccygeal ganglion** or **ganglion impar** (*ganglion coccygeum impar*) placed in front of the coccyx. Each ganglion may be regarded as a distinct centre, and, in addition to its branches of distribution, possesses also branches of communication which communicate with other ganglia and with the cerebro-spinal nerves.

The **branches of communication** between the ganglia (Figs. 689 and 690) are composed of gray nerve-fibres (*gray rami communicantes*) and white nerve-fibres (*white rami communicantes*), the latter being continuous with those fibres of the spinal nerves which pass to the ganglia.

The three great gangliated plexuses (*collateral ganglia*) are situated in front of the spine in the thoracic, abdominal, and pelvic regions, and are named, respectively, the **cardiac,** the **solar** or **epigastric,** and the **hypogastric plexus.** They consist of collections of nerves and ganglia, the nerves being derived from the gangliated cords and from the cerebro-spinal nerves. They distribute branches to the viscera.

Smaller or **Terminal ganglia** are also found lying amidst the nerves, some of them of microscopic size, in certain viscera—as, for instance, in the heart, the stomach, and the uterus. They serve as additional centres for the origin of nerve-fibres. There are numerous special ganglia connected with the cranial nerves.

These ganglia have been described in a previous section (see ophthalmic ganglion, otic ganglion, spheno-palatine ganglion, and submaxillary ganglion).

The **branches of distribution** derived from the gangliated cords, from the prevertebral plexuses, and also from the smaller ganglia, are principally destined for the blood-vessels and thoracic and abdominal viscera, supplying the involuntary muscular fibre of the coats of the vessels and the hollow viscera, and the secreting cells, as well as the muscular coats of the vessels in the glandular viscera.

Structure of the Sympathetic System.—The sympathetic system is not, as was so long taught, an independent system. It receives fibres from the cerebro-spinal system and arranges them for distribution to the splanchnic blood-vessels and the viscera. It receives fibres from the viscera and transmits them to the cerebro-spinal system, and it transmits fibres by way of the spinal nerves to unstriped muscles, to vessels, and to glands. It is simply an arrangement of spinal nerves to permit of the re-arrangement and transmission of impulses. In order to effect this, the spinal nerves are connected with a series of ganglia, which possess a certain power of government or automatic action. In the sympathetic system non-medullated fibres predominate. The individual nerve-fibres are smaller in diameter than those of the cerebro-spinal system, and the fibres are interrupted by nerve-cells contained in a ganglia chain, known as the **gangliated cord,** and are also sometimes interrupted in gangliated plexuses and in terminal ganglia. The sympathetic nerves have a notable disposition to form plexuses. It is important to note that not all of the visceral branches of the spinal nerves join the gangliated cord—for instance, the visceral branches of the third and fourth sacral do not. The majority, but not all, of the sympathetic fibres are **non-medullated** (*fibres of*

Remak), but in the adult true non-medullated fibres are found only in the sympathetic system. These fibres are of smaller diameter than spinal nerve-fibres, and are prolongations of axones of sympathetic ganglia cells. Each fibre is surrounded by connective-tissue structure which resembles the neurilemma, which contains numerous nuclei, and which is a prolongation of the capsule of a sympathetic cell capsule.

A sympathetic nerve consists of numerous non-medullated and some medullated fibres. The connective tissue which separates the nerve-bundles carries blood-vessels and nervi nervorum, but no lymph vessels.

The **sympathetic ganglia** contain multipolar cells which are smaller than those of the spinal ganglia. Each cell contains two nuclei, and is surrounded by a delicate capsule of connective tissue. The cell gives off one axone and several short

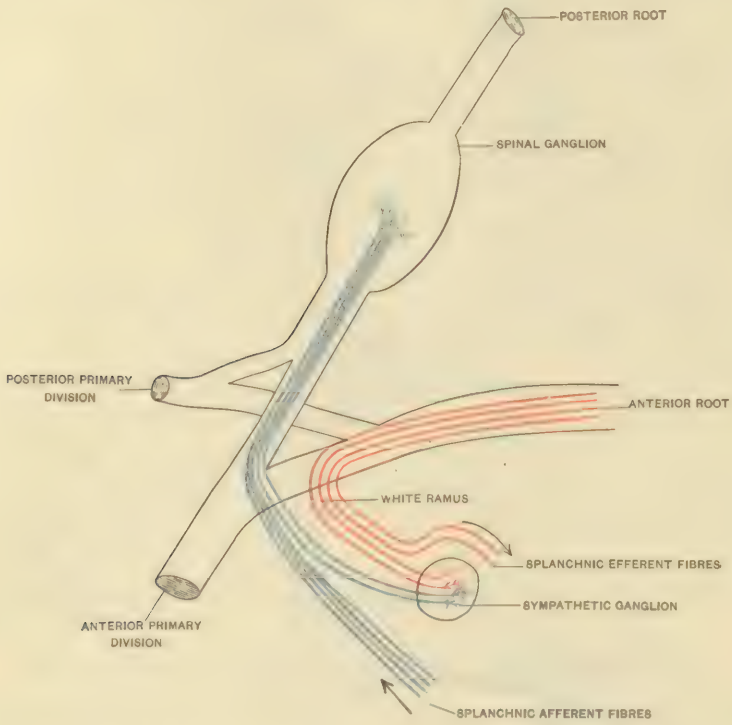

FIG. 689.—The white ramus communicans (schematic). (After Cunningham.)

dendrites. The axone is non-medullated when it begins and may remain so or may become medullated. Fibres which take origin from sympathetic axones, the **commissural fibre**, may pass to an adjacent ganglion cell, may pass toward the centre **central fibre** or **gray ramus communicans**, or may pass toward the periphery, **peripheral fibre**, and reach certain glands, or to unstriped muscle of blood-vessels, intestines, iris, etc. The fibres passing to glands are called **secretory fibres.**

The dendrites of a sympathetic ganglion cell form arborizations about other ganglion cells. The sympathetic ganglia contain fibres, as well as cells. Some of the fibres are medullated and some are non-medullated, the latter taking origin from the sympathetic ganglion cells, the former being motor and sensory cerebrospinal fibres which have reached the sympathetic by the rami communicantes.[1]

[1] Histology and Microscopic Anatomy, by Szymonowicz. Translated and edited by John Bruce MacCallum.

The **medullated fibres**, the **white rami communicantes** or the **visceral branches** of the **spinal nerves** (Figs. 689 and 690) originate from the anterior divisions of certain spinal nerves. Two groups of them can be recognized, one group coming from the nerves from the first or second dorsal to the second or third lumbar nerves; another group from the second or third lumbar to the third or fourth sacral. The

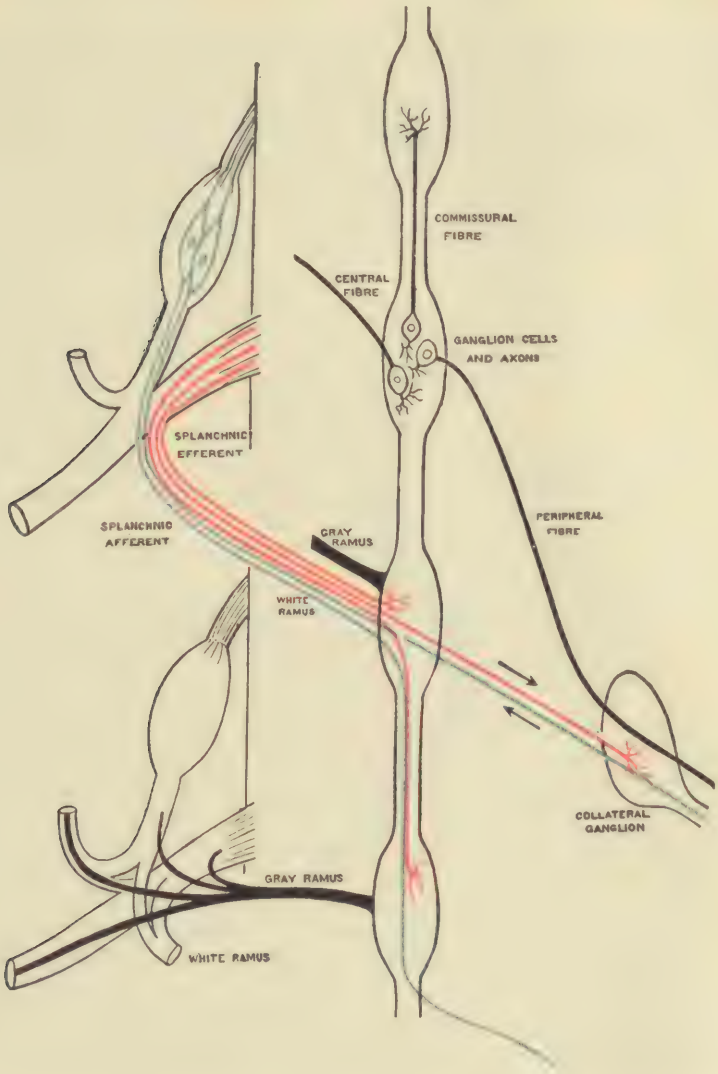

FIG. 690.—Scheme of the constitution and connections of the gangliated cord of the sympathetic. The gangliated cord is indicated on the right with the arrangement of the fibres arising from the ganglion cells. On the left the roots and trunks of spinal nerves are shown, with the arrangement of the white ramus communicans above and the gray ramus below. (Cunningham.)

visceral branches of the third and fourth sacral do not join the gangliated cord; the other visceral branches do join it. The fibres of the visceral branches of the spinal nerves are derived from both the anterior and the posterior nerve-roots, but more largely from the anterior than from the posterior. The visceral fibres of the anterior roots are axones of nerve-cells of the spinal cord, and by way of the white rami enter into the sympathetic ganglia. Some of them end and form networks about the

ganglia cells. Others pass up or down and end in an adjacent ganglion. Others pass through a ganglion of the gangliated cord and end in a peripheral ganglion with non-medullated fibres, which take origin from ganglia of the gangliated cord. The fibres of the white ramus which pass through the ganglion and go to the periphery are known as the **splanchnic efferent fibres**, and constitute the secretory fibres of the splanchnic glands and the motor fibres of the muscular tissue of splanchnic blood-vessels and viscera. The visceral fibres of the posterior nerve-roots aid in the formation of the white rami and *arise* as axones of nerve-cells in the spinal ganglia on the posterior roots, pass through the ganglia of the sympathetic cord, but do not terminate in them, and leave the ganglion directly to pass through a peripheral ganglion to be distributed to the periphery or ascend or descend to an adjacent ganglion and pass through this to a collateral ganglion, and from that to the periphery. They constitute the **splanchnic afferent fibres**, the sensory fibres of the viscera.

The non-medullated fibres take origin from the cells of the sympathetic ganglia and are axones of these cells. Some help to form the commissure, which joins a ganglion to adjacent ganglia and end as networks about the cells of an adjacent ganglion. Others run to the periphery and help to form the splanchnic efferent branches. Some pass from the ganglia to the spinal nerve-roots and to the anterior and posterior divisions of the nerves. The latter are the *gray rami communicantes* (Fig. 690), largely composed of non-medullated but containing some medullated fibres. They give branches to the somatic part of the nerves and not the visceral, and furnish secretory fibres and fibres to unstriated muscle and minute branches to the membranes which enwrap the nerve-roots. The commissures of the gangliated cord are composed of white and gray fibres. The former consist of both splanchnic efferent and splanchnic afferent fibres. The latter are axones from sympathetic ganglion cells, and some of these are truly commissural, but others pass up or down the cord and through a ganglion and become branches which go to the periphery.

From the above it becomes evident that the peripheral branches of the sympathetic contain white fibres, which are composed of splanchnic efferent and splanchnic afferent branches and also contain splanchnic efferent gray fibres. Fig. 690, from Cunningham's *Text-book of Anatomy*, exhibits the constitution and connections of the gangliated cord of the sympathetic.

THE GANGLIATED CORD (TRUNCUS SYMPATHICUS).

The Cervical Portion (Pars Cervicalis) of the Gangliated Cord.

The cervical portion of the gangliated cord is to be regarded as a prolongation upward of the primitive sympathetic along the great vessels of the neck (Prof. Cunningham). It is not connected to the cervical spinal nerves by white rami communicantes. It obtains its spinal fibres from the upper dorsal nerves. These fibres ascend in the commissure of the gangliated cord and join the cells of the cervical ganglia. From the cervical ganglia come fibres to the unstriped muscle (veins and arteries of the head, neck, and limbs, and to the skin of the head and neck, secretory fibres to the salivary glands and fibres to the heart). The fibres to the vessels are called **vasomotor nerves**, and the fibres to the heart are called **cardio-motor nerves**. In the neck the gangliated cord is situated behind the carotid vessels and upon the muscles in front of the vertebrae, and runs from the root of the neck to the base of the skull, being continuous below with the thoracic gangliated cord and ending above in the carotid plexus. There are usually three ganglia on each side, each of which is distinguished, according to its position, as the **superior, middle** and **inferior cervical ganglion.**

The Superior Cervical Ganglion (*ganglion cervicale superius*) (Figs. 691, 692, and 693).—The superior cervical ganglion, the largest of the three, is about three-

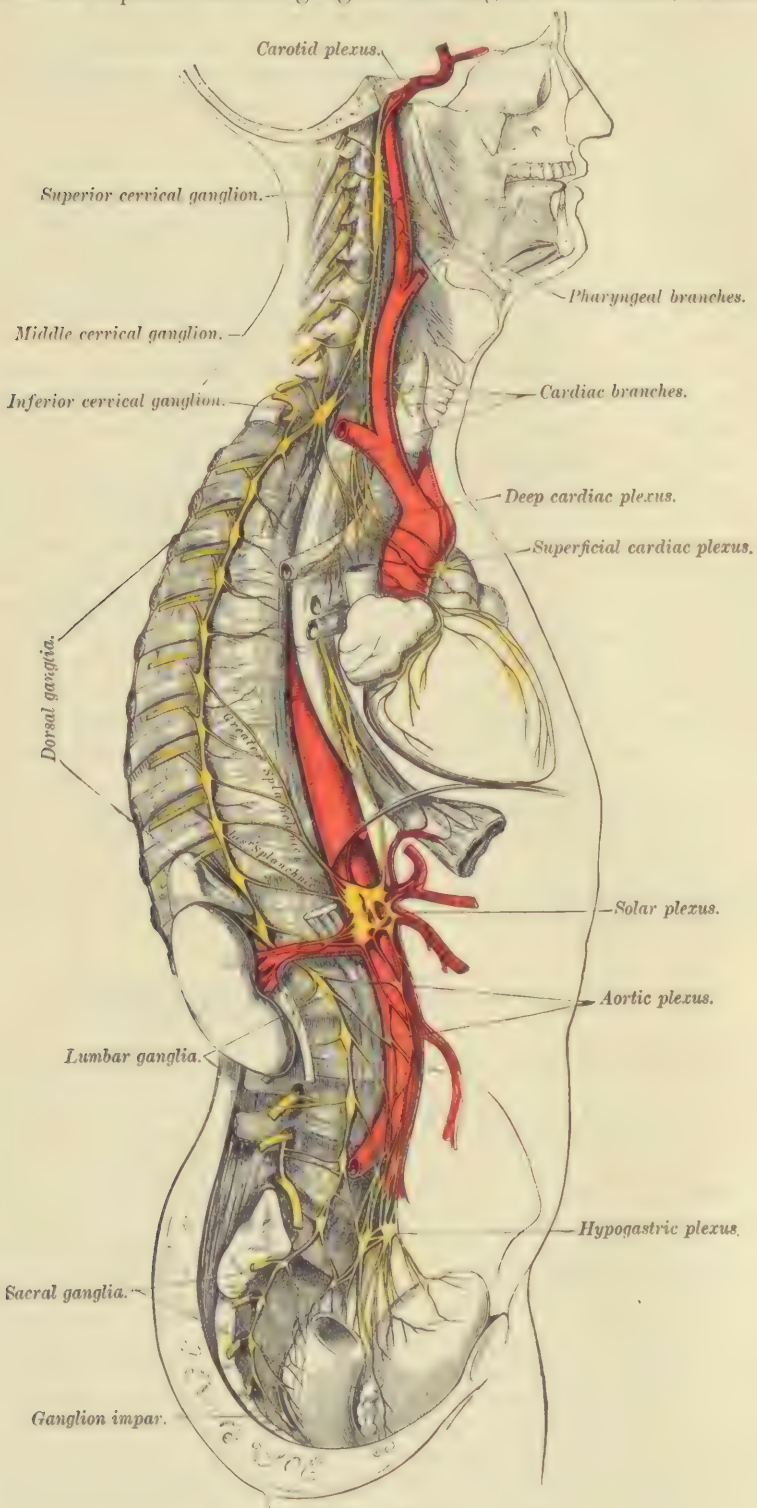

FIG. 691.—The sympathetic nerve.

quarters of an inch in length. It is placed opposite the second and third cervical vertebrae. It is of a reddish-gray color, is usually fusiform in shape, is sometimes broad and flattened, and is occasionally constricted at intervals, so as to give rise to the opinion that it consists of the coalescence of several smaller ganglia; and it is usually believed that it is formed by the coalescence of the four ganglia corresponding to the four upper cervical nerves. It is in relation, in front, with the sheath of the internal carotid artery and internal jugular vein; behind, it lies on the Rectus capitis anticus major muscle. It is connected to the middle cervical ganglion by the commissure of the gangliated cord.

Branches (Fig. 693).—The branches of the superior cervical ganglion are **central** and **peripheral.**

Central or Communicating Branches.—1. Gray rami communicantes arise in the ganglion and pass to the first, second, third, and fourth cervical nerves. 2. Branches are given off to certain cranial nerves in the neck (Figs. 692 and 693). What is known as the **jugular nerve** (*n. jugularis*) (Fig. 693) passes to the ganglion on the trunk of the vagus, a branch from the ganglion passes to the ganglia on the root of the pneumogastric (Fig. 693) and to the petrosal ganglion of the glosso-pharyngeal (Fig. 693), and a branch goes to the hypoglossal (Fig. 693).

Peripheral Branches.—These branches may be divided into **superior, internal** and **anterior.**

The **Superior Branch of the Superior Cervical Ganglion** or the **Internal Carotid Branch** (*n. caroticus internus*) (Fig. 692) appears to be a direct prolongation of the ganglion. It is soft in texture and of a reddish color. It ascends by the side of the internal carotid artery, and, entering the carotid canal in the temporal bone, divides into two branches, which lie, one on the outer, and the other on the inner, side of that vessel.

The **outer branch,** the larger of the two, distributes filaments to the internal carotid artery and forms the **internal carotid plexus.**

The **inner branch** also distributes filaments to the internal carotid, and, continuing onward, forms the **cavernous plexus.**

The Internal Carotid Plexus (*plexus caroticus internus*) (Figs. 691, 692, and 693).—The carotid plexus is situated on the outer side of the internal carotid artery. Filaments from this plexus occasionally form a small gangliform swelling on the under surface of the artery, which is called the **carotid ganglion.** The internal carotid plexus communicates with the Gasserian ganglion, with the sixth nerve, and the spheno-palatine ganglion, and distributes filaments to the wall of the carotid artery and to the dura mater (Valentin), while in the carotid canal it communicates with Jacobson's nerve, which is the tympanic branch of the glosso-pharyngeal.

The *communicating branches with the sixth nerve* (Fig. 693) consist of one or two filaments which join that nerve as it lies upon the outer side of the internal carotid. Other filaments are also connected with the Gasserian ganglion. The communication with the spheno-palatine ganglion is effected by a branch, the **large deep petrosal nerve** (Fig. 677), which is given off from the plexus on the outer side of the artery, and which passes through the cartilage filling up the foramen lacerum medium, and joins the large superficial petrosal from the facial to form the **Vidian nerve** (Figs. 670, 672, and 677). The Vidian nerve then proceeds along the pterygoid or Vidian canal to the spheno-palatine ganglion. The communication with Jacobson's nerve is effected by two branches, one of which is called the **deep petrosal nerve,** and the other the **carotico-tympanic nerve**; the latter may consist of two or three delicate filaments.

The Cavernous Plexus (*plexus cavernosus*) (Figs. 692 and 693).—The cavernous plexus is situated below and internal to that part of the internal carotid which is placed by the side of the sella turcica in the cavernous sinus, and is formed chiefly

by the internal division of the ascending branch from the superior cervical ganglion. It communicates with the third, the fourth, the ophthalmic division of the fifth, and the sixth nerves, and with the ophthalmic ganglion, and distributes filaments to the wall of the internal carotid and to the pituitary body. The branch of communication with the third nerve (Fig. 693) joins it at its point of division; the branch to the fourth nerve (Fig. 693) joins it as it lies on the outer wall of the cavernous sinus; other filaments are connected with the under surface of the trunk of the ophthalmic nerve; and a second filament of communication joins the sixth nerve (Fig. 693).

The filament of connection with the ophthalmic ganglion (Figs. 666 and 693) arises from the anterior part of the cavernous plexus; it accompanies the nasal nerve or continues forward as a separate branch.

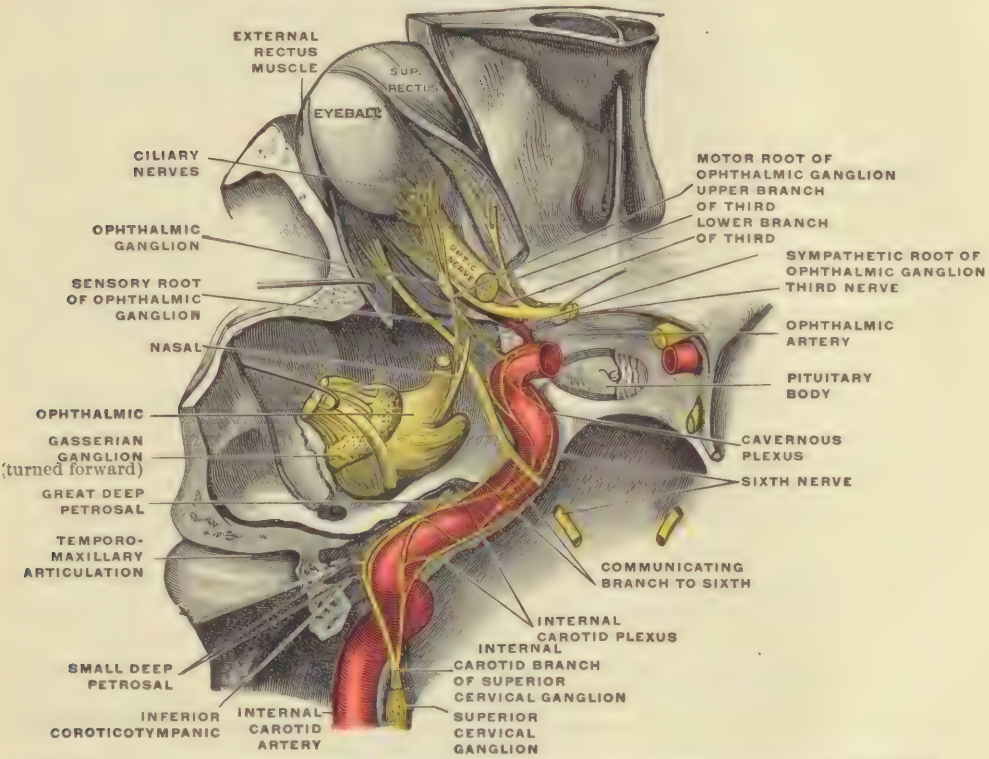

FIG. 692.—The cephalic portion of the sympathetic nervous system, seen obliquely from above and behind. (Toldt.)

Terminal Branches of the Carotid and Cavernous Plexuses.—The terminal filaments from the carotid and cavernous plexuses are prolonged along the internal carotid, forming plexuses which entwine around the cerebral and ophthalmic arteries; along the former vessels they may be traced on to the pia mater; along the latter, into the orbit, where they accompany each of the subdivisions of the vessel, a separate plexus passing, with the arteria centralis retinae, into the interior of the eyeball. The filaments prolonged on to the anterior communicating artery form a small ganglion, the **ganglion of Ribes,**[1] which serves, as mentioned above, to connect the sympathetic nerves of the right and left sides.

The so-called **Inferior** or **Descending Branch of the Superior Cervical Ganglion** communicates with the middle cervical ganglion. It is the commissure of the gangliated cord.

[1] The existence of this ganglion is doubted by some observers.—ED. of 15th English edition.

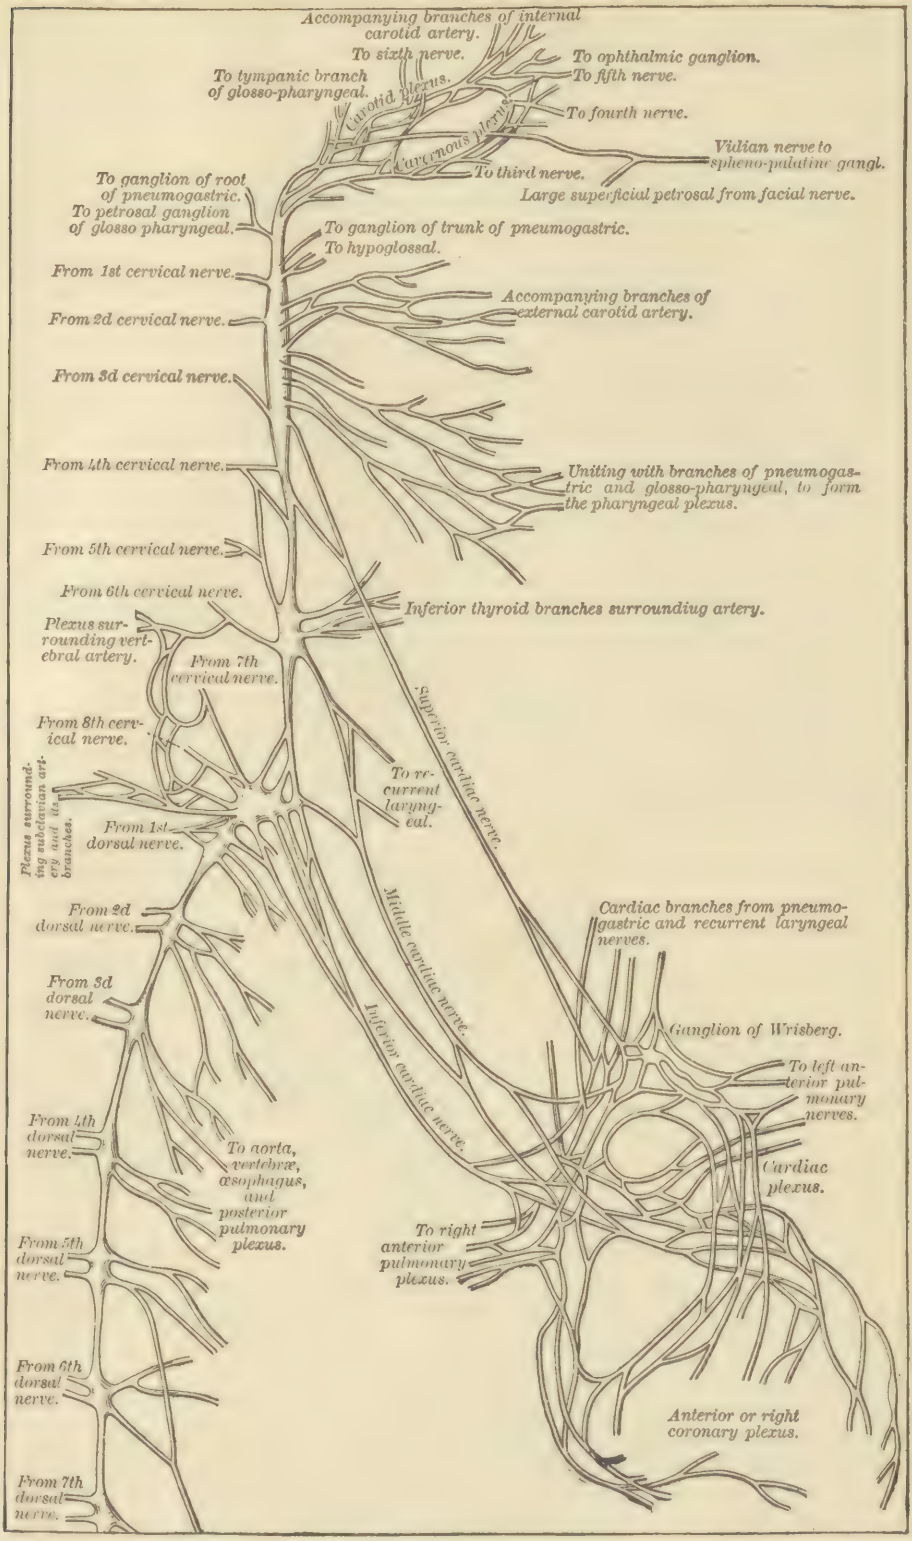

FIG. 693.—Plan of the cervical portion of the sympathetic. (After Flower.)

The **Internal Branches of the Superior Cervical Ganglion** are three in number—the **pharyngeal, laryngeal** and **superior cardiac nerve.**

The **pharyngeal branches** (*rami pharyngei*) (Figs. 691 and 693) pass inward to the side of the pharynx, where they join with branches from the glosso-pharyngeal, pneumogastric, and external laryngeal nerves to form the **pharyngeal plexus** (*plexus pharyngeus*).

The **laryngeal branches** unite with the superior laryngeal nerve and its branches.

The **superior cardiac nerve** or the **nervus superficialis cordis** (*n. cardiacus superior*) (Figs. 691 and 693) arises by two or more branches from the superior cervical ganglion, and occasionally receives a filament from the cord of communication between the first and second cervical ganglia. It runs down the neck behind the common carotid artery, lying upon the Longus colli muscle, and crosses in front of the inferior thyroid artery and recurrent laryngeal nerve. The **right superior cardiac nerve,** at the root of the neck, passes either in front of or behind the subclavian artery, and along the arteria innominata, to the back part of the arch of the aorta, where it joins the **deep cardiac plexus.** This nerve, in its course, is connected with other branches of the sympathetic; about the middle of the neck it receives filaments from the external laryngeal nerve; lower down it obtains one or two twigs from the pneumogastric; and as it enters the thorax it is joined by a filament from the recurrent laryngeal. Filaments from this nerve communicate with the thyroid branches from the middle cervical ganglion. The **left superior cardiac nerve,** in the chest, runs by the side of the left common carotid artery and in front of the arch of the aorta to the superficial cardiac plexus, but occasionally it passes behind the aorta and terminates in the deep cardiac plexus.

The **Anterior Branches** of the **Superior Cervical Ganglion** (*nn. carotici externi*) (Fig. 693) ramify upon the external carotid artery and its branches, forming around each a delicate plexus, on the nerves composing which small ganglia are occasionally found. The plexuses accompanying some of these arteries have important communications with other nerves. That surrounding the **external carotid artery** (*plexus caroticus externus*) is connected with the branch of the facial nerve to the Stylo-hyoid muscle; that surrounding the **facial artery** communicates with the submaxillary ganglion by one or two filaments; and that accompanying the **middle meningeal artery** sends offsets which pass to the otic ganglion and to the geniculate ganglion of the facial nerve and constitute the external superficial petrosal nerve (Fig. 677).

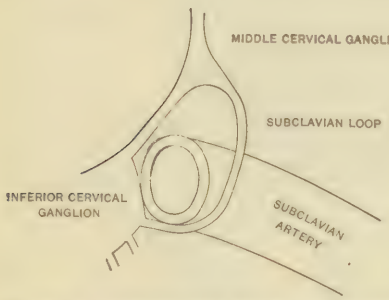

FIG. 694.—The subclavian loop passing from the middle to the inferior cervical ganglia.

The Middle Cervical or Thyroid Ganglion (*ganglion cervical medium*) (Figs. 391 and 693).—The middle cervical or thyroid ganglion is the smallest of the three cervical ganglia, and is occasionally altogether wanting. It varies somewhat in position, but in most individuals is placed opposite the sixth cervical vertebra, usually upon, or close to, the inferior thyroid artery; hence the name, **thyroid ganglion,** assigned to it by Haller. It is probably formed by the coalescence of two ganglia corresponding to the fifth and sixth cervical nerves.

It communicates above with the superior cervical ganglion and below with the inferior cervical ganglion by means of the commissure of the gangliated cord.

The Central Communicating Branches (Fig. 693).—The central communicating branches are: 1. Gray rami communicantes passing from the ganglion to the anterior divisions of the fifth and sixth cervical nerves. 2. The subclavian loop or the **ansa of Vieussens** (*ansa subclavia*) (Fig. 694) arises from the ganglion, passes

down over the front and under the subclavian artery and runs back to join the inferior cervical ganglion. It gives branches to the artery. In some cases this nerve takes origin from the sympathetic trunk below the ganglion.

The Peripheral Branches.—The peripheral branches are the **thyroid** and the **middle cardiac nerve.**

The **Thyroid Branches** (Fig. 693) are small filaments which accompany the inferior thyroid artery to the thyroid gland, forming the **inferior thyroid plexus** (*plexus thyreoideus inferior*); they communicate, on the artery, with the superior cardiac nerve, and, in the gland, with branches from the recurrent and external laryngeal nerves.

The **Middle** or **Great Cardiac Nerve** (*n. cardiacus medius*) (Figs. 691 and 693), the largest of the three cardiac nerves, arises from the middle cervical ganglion or from the cord between the middle and inferior ganglia. On the right side it descends behind the common carotid artery, and at the root of the neck passes either in front of or behind the subclavian artery; it then descends on the trachea, receives a few filaments from the recurrent laryngeal nerve, and joins the right side of the deep cardiac plexus. In the neck it communicates with the superior cardiac and recurrent laryngeal nerves. On the left side the middle cardiac nerve enters the chest between the left carotid and subclavian arteries, and joins the left side of the deep cardiac plexus. If the middle cervical ganglion is absent, the above-named branches arise from the gangliated cord.

The Inferior Cervical Ganglion (*ganglion cervicale inferius*)(Figs. 691 and 693). —The inferior cervical ganglion is situated between the base of the transverse process of the last cervical vertebra and the neck of the first rib on the inner side of the superior intercostal artery. Its form is irregular; it is larger in size than the preceding, and is frequently joined with the first thoracic ganglion. It is probably formed by the coalescence of two ganglia which correspond to the two last cervical nerves. It joins the middle ganglion above and the first thoracic ganglion below by the commissural cord, and is usually also joined to the middle ganglion by the subclavian loop.

The Central Communicating Branches.—Its central communicating branches are: 1. Gray rami communicantes passing to the anterior divisions of the seventh and eighth cervical nerves (Fig. 693). 2. The subclavian loop (Fig. 694), which has been previously described and which passes under and in front of the subclavian artery to reach the middle cervical ganglion or the commissural cord.

The Peripheral Branches.—The peripheral branches are: 1. **Vascular.** The **vertebral plexus** (*plexus vertebralis*) (Fig. 693) lies upon the vertebral artery and its branches in the neck and in the cranial cavity. The **subclavian plexus** (*plexus subclavius*) (Fig. 693) arises from the subclavian loop, which may be regarded as a branch of the inferior or of the middle ganglion. 2. **Cardiac.** The **inferior** or **minor cardiac nerve** (*n. cardiacus inferior*) (Fig. 693) arises from the inferior cervical or first thoracic ganglion. It passes down behind the subclavian artery and along the front of the trachea to join the deep cardiac plexus. It communicates freely behind the subclavian artery with the recurrent laryngeal and middle cardiac nerves.

Surgical Anatomy.—The situation of the cervical sympathetic makes wounds of it rare. Thirteen cases of sympathetic traumatic injury were collected by Seeligmüller. In ten cases paralysis existed; in three, irritation. Tumors of the neck may cause irritation or paralysis. In *irritation* of the sympathetic the corresponding side of the face becomes pale, the pupil dilates, the palpebral fissure widens, and the eyeball protrudes. In many cases there is acceleration of the heart beats. In *paralysis* of the sympathetic the pupil contracts, the palpebral fissure is narrowed by partial ptosis, the corresponding side of the face reddens, there is an increase in the flow of tears, and recession of the eyeball.

The surgeon occasionally resects the sympathetic. Jonnesco recommends bilateral removal of the superior cervical ganglia for glaucoma, and bilateral removal of all the cervical sympathetic ganglia for epilepsy and for exophthalmic goitre.

The Thoracic Portion (Pars Thoracalis) of the Gangliated Cord (Fig. 695).

The thoracic portion of the gangliated cord consists of a series of ganglia which usually correspond in number to that of the vertebrae, but, from the occasional coalescence of two, their number is uncertain. These ganglia are placed on each side of the spine, resting against the heads of the ribs, and are covered by

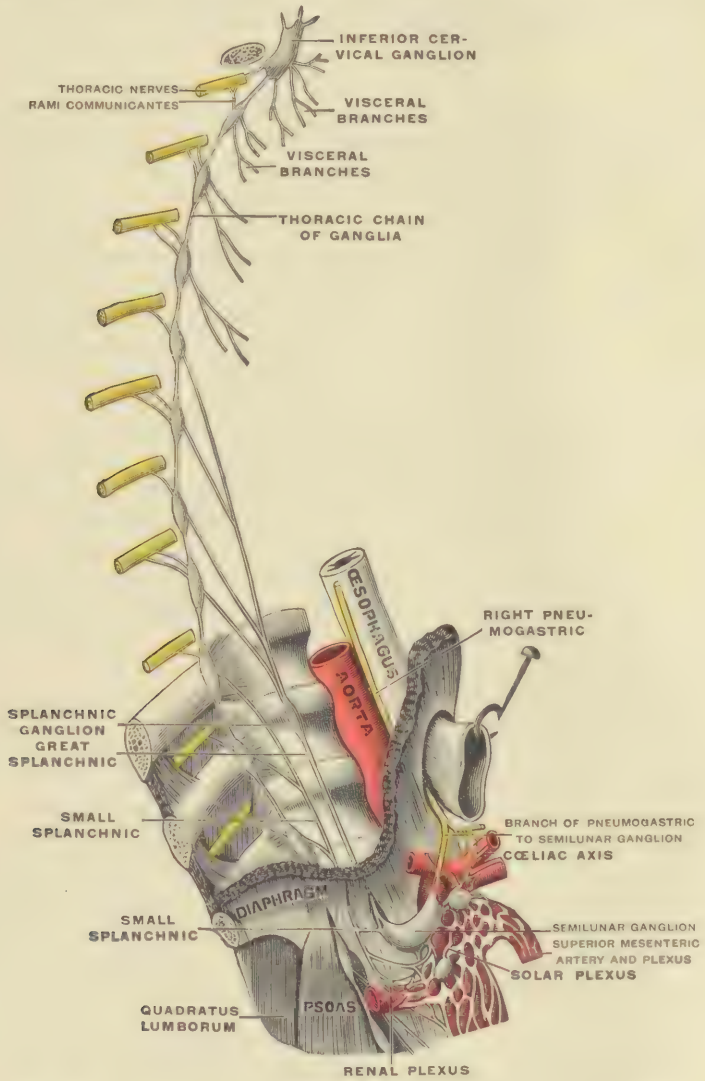

FIG. 695.—Plan of the right sympathetic cord and splanchnic nerves. (Testut.)

the pleura costalis; the last two ganglia are, however, anterior to the rest, being placed on the side of the bodies of the eleventh and twelfth dorsal vertebrae. The ganglia are small in size and of a grayish color. The first ganglion, larger than the rest, is of an elongated form and is frequently blended with the last cervical ganglion. They are connected together by cord-like prolongations from the substance. In the thorax each thoracic or dorsal spinal nerve, with occasionally the exception of the first, sends a **visceral branch** or **white ramus communicans** to the thoracic gangliated cord (Figs. 693 and 695). As Prof. Cunningham points out,

the white rami "separate into two main streams in relation to the sympathetic cord. Those of the upper five nerves are, for the most part, directed upward in the gangliated cord to be distributed through the cervical part of the sympathetic in the manner already described. The white rami of the lower thoracic nerves are, for the most part, directed downward in the lower part of the sympathetic cord, and its branches, to be distributed to the abdomen; at the same time some of their fibres are directly associated with the supply of certain thoracic viscera — lungs, aorta, oesophagus."[1] The white rami are composed of splanchnic afferent fibres and somatic and splanchnic efferent fibres.

Central Communicating Branches.—1. **White rami communicantes** (see above).

2. **Gray rami communicantes** arise from each one of the thoracic ganglia, pass backward with the white rami, and enter into the anterior divisions of the thoracic nerves.

Peripheral Branches (Fig. 693).—1. **Aortic Branches** (Fig. 693) come off from the first five or six upper ganglia. They send filaments to the aorta and its branches, to the vertebral bodies, and to the vertebral ligaments. The aortic branches help to form the **thoracic aortic plexus** (*plexus aorticus thoracalis*). This plexus is completed by branches from the cardiac plexus.

2. **Pulmonary Branches** (Fig. 693) come off from the third and fourth and sometimes from the first and second ganglia.

3. **The Splanchnic Nerves** (Figs. 688, 691, and 695).—From the six or seven lower ganglia and from the commissural cord a number of large white branches arise. They give filaments to the aorta and unite to form the three splanchnic nerves on each side. These are named the **great**, the **lesser**, and the **smallest** or **renal splanchnic**.

The **superior** or **great splanchnic nerve** (*n. splanchnicus major*) is of a white color, firm in texture, and presents a marked contrast to the ganglionic nerves. It is formed by branches from the thoracic ganglia between the fifth or sixth and the ninth or tenth, but the fibres in the higher roots may be traced upward in the sympathetic cord as far as the first or second thoracic ganglion. These roots unite to form a large round cord of considerable size. It descends obliquely inward in front of the bodies of the vertebrae along the posterior mediastinum, perforates the crus of the Diaphragm, and terminates in the **semilunar ganglion of the solar plexus** (Fig. 695), distributing filaments to the **renal** and **suprarenal plexus**.

The **middle, lesser** or **small splanchnic nerve** (*n. splanchnicus minor*) is formed by filaments from the tenth and eleventh ganglia, and from the cord between them. It pierces the Diaphragm with the preceding nerve, and joins the **solar plexus** (Fig. 695). It communicates in the chest with the great splanchnic nerve, and occasionally sends filaments to the renal plexus.

The **inferior, smallest, least** or **renal splanchnic nerve** (*n. splanchnicus imus*) arises from the last thoracic ganglion, and, piercing the Diaphragm, terminates in the **renal plexus** and lower part of the **solar plexus**. It occasionally communicates with the preceding nerve (Fig. 688).

A striking analogy appears to exist between the splanchnic and the cardiac nerves. The cardiac nerves are three in number; they arise from the three cervical ganglia, and are distributed to a large and important organ in the thoracic cavity. The splanchnic nerves, also three in number, are connected probably with all the dorsal ganglia, and are distributed to important organs in the abdominal cavity.

The Lumbar Portion (Pars Lumbalis) of the Gangliated Cord (Figs. 688, 691).

The lumbar portion of the gangliated cord is situated in front of the vertebral column along the inner margin of the Psoas muscle. It consists usually of four

[1] Text-book of Anatomy.

ganglia, but there may be as many as eight, connected together by interganglionic cords. The ganglia are of small size, of a grayish color, shaped like a barleycorn, and placed much nearer the median line than the thoracic ganglia. Sometimes several ganglia are fused together.

It is connected with the thoracic portion by a thin commissure, which passes back of or through the Diaphragm. It is connected with the sacral portion by a commissure which is under the common iliac artery.

The upper lumbar ganglia or the upper portion of the gangliated cord receives **white rami communicantes** from the first two or three lumbar spinal nerves.

Central Communicating Branches.—**Gray rami communicantes** pass irregularly from the gangliated cord to the anterior divisions of the lumbar spinal nerves, the gray rami accompanying the white rami.

From the situation of the lumbar ganglia these branches are longer than in the other regions. They are usually two in number from each ganglion, but their connection with the spinal nerves is not so uniform as in other regions. They accompany the lumbar arteries around the sides of the bodies of the vertebrae, passing beneath the fibrous arches from which some of the fibres of the Psoas muscle arise.

Peripheral Branches.—Some branches pass inward, in front of the aorta, and help to form the **abdominal aortic plexus** (*plexus aorticus abdominalis*) (Fig. 691), which plexus is, however, developed chiefly by filaments from the cœliac plexus. Other branches descend in front of the common iliac arteries, and join over the promontory of the sacrum, helping to form the **hypogastric plexus** (*plexus hypogastricus*) (Fig. 691). Numerous delicate filaments are also distributed to the bodies of the vertebrae and the ligaments connecting them.

Pelvic or Sacral Portion (Pars Sacralis) of the Gangliated Cord (Figs. 688, 691).

The pelvic portion of the gangliated cord is situated in front of the sacrum along the inner side of the anterior sacral foramina. It consists of four or five small ganglia on each side, connected together by interganglionic cords. Below, these cords converge and unite on the front of the coccyx by means of a small ganglion, the **coccygeal ganglion** or **ganglion impar** (*ganglion coccygeum impar*) (Fig. 691). The commissural cord joins the pelvic portion to the lumbar portion of the gangliated cord. Like the cervical portion and the lower lumbar portion the sacral portion receives no **white rami communicantes.**

The visceral branches of the third sacral, and usually of the second and fourth sacral spinal nerves, are not connected with the ganglionic cord.

Central Communicating Branches.—**Gray rami communicantes,** which arise in the sacral ganglia and pass to the anterior divisions of the sacral and coccygeal nerves.

Peripheral Branches.—1. **Visceral branches** arise from the upper portion of the gangliated cord and pass to the pelvic plexus.

2. **Parietal branches** communicate, on the front of the sacrum, with the corresponding branches from the opposite side; some, from the first two ganglia, pass to join the pelvic plexus, and others form a plexus which accompanies the middle sacral artery and sends filaments to the coccygeal gland.

THE GREAT PLEXUSES OF THE SYMPATHETIC (Fig. 688).

The great plexuses of the sympathetic are the large aggregations of nerves and ganglia, previously alluded to, situated in the thoracic, abdominal, and pelvic cavities respectively. From them are derived the branches which supply the viscera.

The Cardiac Plexus (Plexus Cardiacus) (Figs. 688, 691).

The cardiac plexus is situated at the base of the heart, and is divided into a **superficial part,** which lies in the concavity of the arch of the aorta, and a **deep part,** which lies between the trachea and aorta. The two plexuses are, however, closely connected.

The Great or Deep Cardiac Plexus.—The great or deep cardiac plexus, the **plexus magnus profundus of Scarpa,** is situated in front of the trachea at its bifurcation, above the point of division of the pulmonary artery and behind the arch of the aorta. It is formed by the cardiac nerves derived from the cervical ganglia of the sympathetic and the cardiac branches of the recurrent laryngeal and pneumogastric. The only cardiac nerves which do not enter into the formation of this plexus are the left superior cardiac nerve and the inferior cervical cardiac branch from the left pneumogastric.

The branches from the **right side** of this plexus pass, some in front of, and others behind, the right pulmonary artery; the former, the more numerous, transmit a few filaments to the anterior pulmonary plexus, and are then continued onward to form part of the **left** or **anterior coronary plexus**; those behind the pulmonary artery distribute a few filaments to the right auricle, and are then continued onward to form a part of the **right** or **posterior coronary plexus.**

The branches from the **left side** of the deep cardiac plexus distribute a few filaments to the superficial cardiac plexus, to the left auricle of the heart, and to the anterior pulmonary plexus, and then pass on to form the greater part of the posterior coronary plexus.

The Anterior or Left Coronary Plexus (*plexus coronarius cordis anterior*).—The anterior or left coronary plexus is formed chiefly from the superficial cardiac plexus, but receives filaments from the deep cardiac plexus. Passing forward between the aorta and pulmonary artery, it accompanies the left coronary artery on the anterior surface of the heart.

The Posterior or Right Coronary Plexus (*plexus coronarius cordis posterior*).—The posterior or right coronary plexus is chiefly formed by filaments prolonged from the left side of the deep cardiac plexus, and by a few from the right side. It surrounds the branches of the coronary artery at the back of the heart, and its filaments are distributed with those vessels to the muscular substance of the ventricles.

The Superficial or Anterior Cardiac Plexus.—The superficial or anterior cardiac plexus lies beneath the arch of the aorta, in front of the right pulmonary artery. It is formed by the left superior cardiac nerve, the left (and occasionally also the right) inferior cervical cardiac branches of the pneumogastric, and filaments from the deep cardiac plexus. A small ganglion, the **cardiac ganglion of Wrisberg** (*ganglion cardiacum* [*Wrisbergi*]) is occasionally found connected with these nerves at their point of junction. This ganglion, when present, is situated immediately beneath the arch of the aorta, on the right side of the ductus arteriosus. The superficial cardiac plexus forms the chief part of the anterior coronary plexus, and several filaments pass along the pulmonary artery to the left anterior pulmonary plexus.

Valentin has described nervous filaments ramifying under the endocardium; and Remak has found, in several mammalia, numerous small ganglia on the cardiac nerves, both on the surface of the heart and in its muscular substance.

The Pulmonary Plexus (Plexus Pulmonalis).

The larger **posterior pulmonary plexus** is situated back of the root of the lung. It is formed by the pneumogastric nerve and branches from the second, third, and fourth thoracic sympathetic ganglia. It sends branches along the bronchi and

blood-vessels into the lung and some fibres pass to the front of the root of the lung to form the anterior pulmonary plexus. The smaller **anterior pulmonary plexus** is in front of and above the root of the lung. It is formed on each side by the fibres from the posterior pulmonary plexus. The left plexus receives branches from the superficial cardiac plexus. The anterior plexus supplies the structures of the root of the lung.

The Oesophageal Plexus (Plexus Oesophageus).

The oesophageal plexus is in the posterior mediastinum and surrounds the oesophagus. It is formed by the pneumogastric nerves which have come from

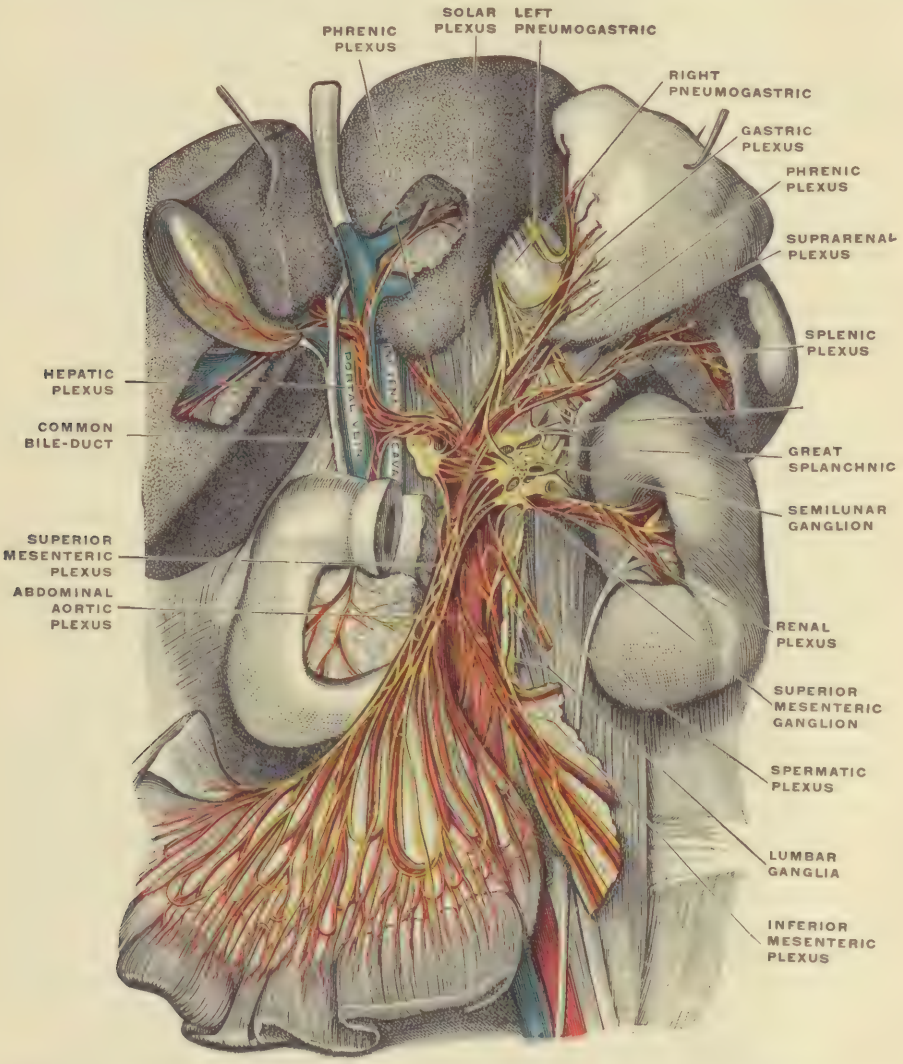

FIG. 696.—The semilunar ganglia with the sympathetic plexuses of the abdominal viscera radiating from the ganglia. (Toldt.)

the posterior pulmonary plexuses, and by fibres from the great splanchnic nerve and ganglion. The oesophageal plexus is usually considered as a portion of the pneumogastric nerve (p. 1061).

The Epigastric or Solar Plexus (Plexus Coeliacum) (Figs. 688, 691, 696, 697).

The epigastric or solar plexus supplies all the viscera in the abdominal cavity. It consists of a great network of nerves and ganglia, situated behind the pancreas

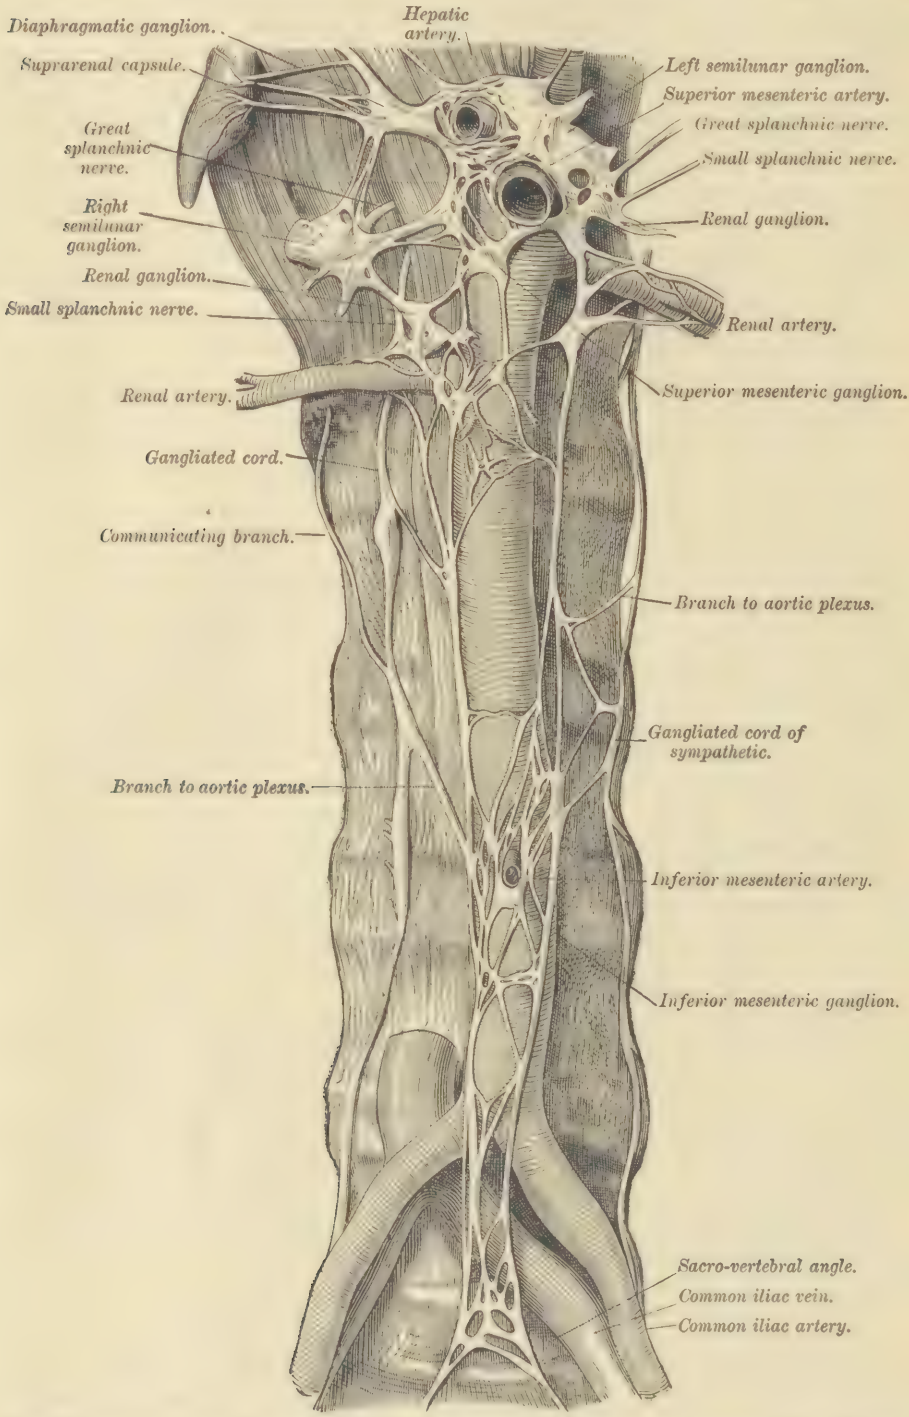

FIG. 697.—Lumbar portion of the gangliated cord, with the solar and hypogastric plexuses. (After Henle.)

and the lesser peritoneal cavity and in front of the aorta and crura of the Diaphragm. It surrounds the cœliac axis and root of the superior mesenteric artery, extending downward as low as the pancreas and outward to the suprarenal capsules. This plexus, and the ganglia connected with it, receive the **great**, the **small** and the **least splanchnic nerves** of both sides, and some filaments from the **right pneumogastric nerve**. It distributes filaments which accompany, under the name of plexuses, all the branches from the front of the abdominal aorta.

Of the ganglia of which the solar plexus is partly composed the principal are the two **semilunar ganglia** (*ganglia cœliaca*) (Figs. 688, 696, and 697), which are situated one on each side of the plexus, and are the largest ganglia in the body. They are large, irregular, gangliform masses formed by the aggregation of smaller ganglia, having interspaces between them. They are situated in front of the crura of the Diaphragm, close to the suprarenal capsules: the one on the right side lies beneath the inferior vena cava; the upper part of each ganglion is joined by the greater splanchnic nerve, and to the inner side of each the branches of the solar plexus are connected.

From the epigastric or solar plexus are derived the following:

Phrenic or Diaphragmatic plexus.
Suprarenal plexus.
Renal plexus.
Spermatic plexus.
Cœliac plexus { Gastric plexus. Splenic plexus. Hepatic plexus.
Superior mesenteric plexus.
Aortic plexus.

The Phrenic Plexus (*plexus phrenicus*) (Fig. 696).—The phrenic plexus accompanies the phrenic artery to the Diaphragm, which it supplies, some filaments passing to the suprarenal capsule. It arises from the upper part of the semilunar ganglion, and is larger on the right than on the left side. It receives one or two branches from the phrenic nerve. In connection with this plexus, on the right side, at its point of junction with the phrenic nerve, is a small ganglion, the **diaphragmatic** or **phrenic ganglion** (*ganglion phrenicum*) (Fig. 697). This ganglion is placed on the under surface of the Diaphragm, near the right suprarenal capsule. Its branches are distributed to the inferior vena cava, suprarenal capsule, and hepatic plexus. There is no ganglion on the left side.

The Suprarenal Plexus (*plexus suprarenalis*) (Fig. 696).—The suprarenal plexus is formed by branches from the solar plexus, from the semilunar ganglion, and from the phrenic and great splanchnic nerves, a ganglion being formed at the point of junction of the latter nerve. It supplies the suprarenal capsule. The branches of this plexus are remarkable for their large size in comparison with the size of the organ they supply.

The Renal Plexus (*plexus renalis*) (Figs. 696 and 697).—The renal plexus is formed by filaments from the solar plexus, the outer part of the semilunar ganglion, and the aortic plexus. It is also joined by filaments from the lesser and smallest splanchnic nerves. The nerves from these sources, fifteen or twenty in number, have numerous ganglia developed upon them. They accompany the branches of the renal artery into the kidney, some filaments on the right side being distributed to the inferior vena cava, and others, on both sides, to the spermatic plexuses.

The Spermatic Plexus (*plexus spermaticus*) (Fig. 696).—The spermatic plexus is derived from the renal plexus, receiving branches from the aortic plexus. It accompanies the spermatic vessels to the testes.

The Ovarian Plexus (*plexus arteriae ovaricae*).—In the female the ovarian plexus is distributed to the ovaries and fundus of the uterus.

The Cœliac Plexus (*plexus cœliacus*).—The cœliac plexus, of large size, is a direct continuation from the solar plexus; it surrounds the cœliac axis and subdivides into the gastric, hepatic, and splenic plexuses. It receives branches from

the lesser splanchnic nerves, and, on the left side, a filament from the right pneumogastric.

The **Gastric** or **Coronary Plexus** (*plexus gastricus superior*) (Fig. 696) accompanies the gastric artery along the lesser curvature of the stomach, and joins with branches from the left pneumogastric nerve. It is distributed to the stomach.

The **Splenic Plexus** (*plexus lienalis*) (Fig. 696) is formed by branches from the cœliac plexus, the left semilunar ganglion, and from the right pneumogastric nerve. It accompanies the splenic artery and its branches to the substance of the spleen, giving off, in its course, filaments to the pancreas, the **pancreatic plexus,** and the **left gastro-epiploic plexus,** which accompanies the gastro-epiploica sinistra artery along the convex border of the stomach.

The **Hepatic Plexus** (*plexus hepaticus*) (Fig. 696), the largest offset from the cœliac plexus, receives filaments from the left pneumogastric and right phrenic nerves. It accompanies the hepatic artery, ramifying in the substance of the liver upon its branches and upon those of the vena portae.

Branches from this plexus accompany all the divisions of the hepatic artery. Thus there is a **pyloric plexus** accompanying the pyloric branch of the hepatic, which joins with the gastric plexus and pneumogastric nerves. There is also a **gastro-duodenal plexus,** which subdivides into the **pancreatico-duodendal plexus,** which accompanies the pancreatico-duodenal artery, to supply the pancreas and duodenum, joining with branches from the mesenteric plexus. The **gastro-epiploic plexus,** which accompanies the right gastro-epiploic artery along the greater curvature of the stomach, and which is said to anastomose with branches from the splenic plexus, is in reality derived from the splenic plexus. A **cystic plexus,** which supplies the gall-bladder, also arises from the hepatic plexus near the liver.

The Superior Mesenteric Plexus (*plexus mesentericus superior*) (Fig. 696).—The superior mesenteric plexus is a continuation of the lower part of the great solar plexus, receiving a branch from the junction of the right pneumogastric nerve with the cœliac plexus. It surrounds the superior mesenteric artery, which it accompanies into the mesentery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery—viz., **pancreatic branches** to the pancreas; **intestinal branches,** which supply the whole of the small intestine; and **ileo-colic, right colic,** and **middle colic branches,** which supply the corresponding parts of the large intestine. The nerves composing this plexus are white in color and firm in texture, and have numerous ganglia developed upon them near their origin.

The Abdominal Aortic Plexus (*plexus aorticus abdominalis*) (Figs. 691, 696, and 697).—The abdominal aortic plexus is formed by branches derived, on each side, from the solar plexus and the semilunar ganglia, receiving filaments from some of the lumbar ganglia. It is situated upon the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. From this plexus arise part of the spermatic, the inferior mesenteric, and the hypogastric plexuses; and it distributes filaments to the inferior vena cava.

The **Inferior Mesenteric Plexus** (*plexus mesentericus inferior*) (Fig. 696) is derived chiefly from the left side of the aortic plexus. It surrounds the inferior mesenteric artery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery—viz., the **left colic** and **sigmoid plexuses,** which supply the descending and sigmoid flexure of the colon; and the **superior haemorrhoidal plexus** (*plexus haemorrhoidalis superior*), which supplies the upper part of the rectum and joins in the pelvis with branches from the pelvic plexus.

The Hypogastric Plexus (Plexus Hypogastricus) (Figs. 688, 691, 697).

The hypogastric plexus supplies the viscera of the pelvic cavity. It is situated in front of the promontory of the sacrum, between the two common iliac arteries,

and is formed by the union of numerous filaments, which descend on each side from the abdominal aortic plexus and from the lumbar ganglia. This plexus contains no evident ganglia; it bifurcates, below, into two lateral portions, which form the **pelvic plexuses.**

The Pelvic or Sacral Plexus (Plexus Sacralis).

The pelvic plexus, sometimes called the **inferior hypogastric,** supplies the viscera of the pelvic cavity, is situated at the side of the rectum in the male, and at the side of the rectum and vagina in the female. It is formed by a continuation of the hypogastric plexus, by branches from the second, third, and fourth sacral nerves, and by a few filaments from the first two sacral ganglia. At the point of junction of these nerves small ganglia are found. From this plexus numerous branches are distributed to all the viscera of the pelvis. They accompany the branches of the internal iliac artery.

The Inferior Haemorrhoidal Plexus (*plexus haemorrhoidalis inferior*).—The inferior haemorrhoidal plexus *arises* from the back part of the pelvic plexus. It supplies the rectum, joining with branches of the superior haemorrhoidal plexus.

The Vesical Plexus (*plexus vesicalis*).—The vesical plexus arises from the forepart of the pelvic plexus. The nerves composing it are numerous, and contain a large proportion of spinal nerve-fibres. They accompany the vesical arteries, and are distributed at the side and base of the bladder. Numerous filaments also pass to the vesiculae seminales and vasa deferentia; those accompanying the vas deferens join, on the spermatic cord, with branches from the spermatic plexus.

The Prostatic Plexus (*plexus prostaticus*).—The prostatic plexus is continued from the lower part of the pelvic plexus. The nerves composing it are of large size. They are distributed to the prostate gland, vesiculae seminales, and erectile structure of the penis. The nerves supplying the erectile structure of the penis consist of two sets, the **small** and **large cavernous nerves.** They are slender filaments, which arise from the forepart of the prostatic plexus, and, after joining with branches from the **internal pudic nerve,** pass forward beneath the pubic arch.

The **Small Cavernous Nerve** (*n. cavernosus penis minor*) perforates the fibrous covering of the penis near its roots.

The **Large Cavernous Nerve** (*n. cavernosus penis major*) passes forward along the dorsum of the penis, joins with the dorsal branch of the pudic nerve, and is distributed to the corpora cavernosa and corpus spongiosum.

The uterine and vaginal plexuses in reality constitute one plexus, the **uterovaginal plexus** (*plexus uterovaginalis*).

The **Vaginal Plexus** *arises* from the lower part of the pelvic plexus. It is lost on the walls of the vagina, being distributed to the erectile tissue at its anterior part and to the mucous membrane. The nerves composing this plexus contain, like the vesical nerves, a large proportion of spinal nerve-fibres.

The **Uterine Plexus** *arises* from the upper part of the pelvic plexus above the point where the branches from the sacral nerves join the plexus. Its branches accompany the uterine arteries to the sides of the organ between the layers of the broad ligaments, and are distributed to the cervix and lower part of the body of the uterus, penetrating its substance.

Other filaments pass separately to the body of the uterus and the Fallopian tube.

Branches from the plexus accompany the uterine arteries into the substance of the uterus. Upon these filaments ganglionic enlargements are found.

THE ORGANS OF SPECIAL SENSE.

THE Organs of the Senses are five in number—viz., those of **Taste**, of **Smell**, of **Sight**, of **Hearing**, and of **Touch**.

THE TONGUE (LINGUA) (Fig. 698).

The tongue is a very mobile muscular organ, undergoing changes in length and width at every contraction of its muscle. It is the organ of the special sense of taste, and is also an organ of speech, mastication, and deglutition. It is situated in the floor of the mouth, in the interval between the two lateral portions of the body of the lower jaw, and when at rest is about three and one-half inches in length. We describe the **body, base, apex, dorsum, margin,** and **inferior surface.**

The Body (*corpus linguae*).—The body forms the great bulk of the organ and is composed of striated muscle.

The Base or Root (*radix linguae*).—The base or root is directed backward, and connected with the os hyoideum by the Hyo-glossi and Genio-hyo-glossi muscles and the hyo-glossal membrane; with the epiglottis by three folds of mucous membrane, the **glosso-epiglottic folds**; with the soft palate by means of the anterior pillars of the fauces; and with the pharynx by the Superior constrictors and the mucous membrane.

The Apex or Tip (*apex linguae*).—The apex or tip is thin and narrow, and is directed forward against the inner surface of the lower incisor teeth.

The Dorsum of the Tongue (*dorsum linguae*).—The dorsum when the tongue of a living person is at rest is markedly arched from before backward. On the dorsum is a **median longitudinal raphé** (*sulcus medianus linguae*). This slight depression terminates posteriorly in the depression known as the **foramen caecum** (*foramen caecum linguae* [*Morgagnii*]), from which a shallow-shaped groove, the **sulcus terminalis** of His, runs outward and forward on each side to the lateral margin of the tongue. The part of the dorsum of the tongue in front of this groove, known as the **anterior** or **oral part,** forming about two-thirds of its upper surface, is rough and covered with papillae; the posterior third of the dorsum is back of the sulcus terminalis, is known as the **posterior** or **pharyngeal portion,** is smoother, and contains numerous muciparous glands and lymphoid follicles.

The Margin of the Tongue (*margo lateralis linguae*).—The margin of the tongue is free in front of the anterior arch of the palate. Just in front of the arch are several vertical folds, the **folia linguae.**

The Under or Inferior Surface (*facies inferior linguae*).—The under or inferior surface of the tongue is connected with the lower jaw by the Genio-hyo-glossi muscles, from its sides the mucous membrane is reflected to the inner surface of the gums; and from its under surface on to the floor of the mouth, where, in the middle line, it is elevated into a distinct vertical fold, the **fraenum linguae** (*frenulum linguae*). To each side of the fraenum is a slight fold of the mucous membrane, the **plica fimbriata,** the free edge of which exhibits a series of fringe-like processes.

The tip of the tongue, part of the under surface, its sides, and dorsum are free.

Structure of the Tongue.—The tongue is partly invested by mucous membrane and a submucous fibrous layer. It consists of symmetrical halves, separated from each other, in the middle line, by a fibrous septum. Each half is composed of muscular fibres arranged in various directions (page 398), containing much interposed fat, and supplied by vessels and nerves.

The Mucous Membrane (*tunica mucosa linguae*).—The mucous membrane invests the entire extent of the free surface of the tongue. On the dorsum it is thicker behind than in front, and is continuous with the sheath of the muscles attached to it, through the submucous fibrous layer. On the under surface of the organ, where it is thin and smooth, it can be traced on each side of the fraenum

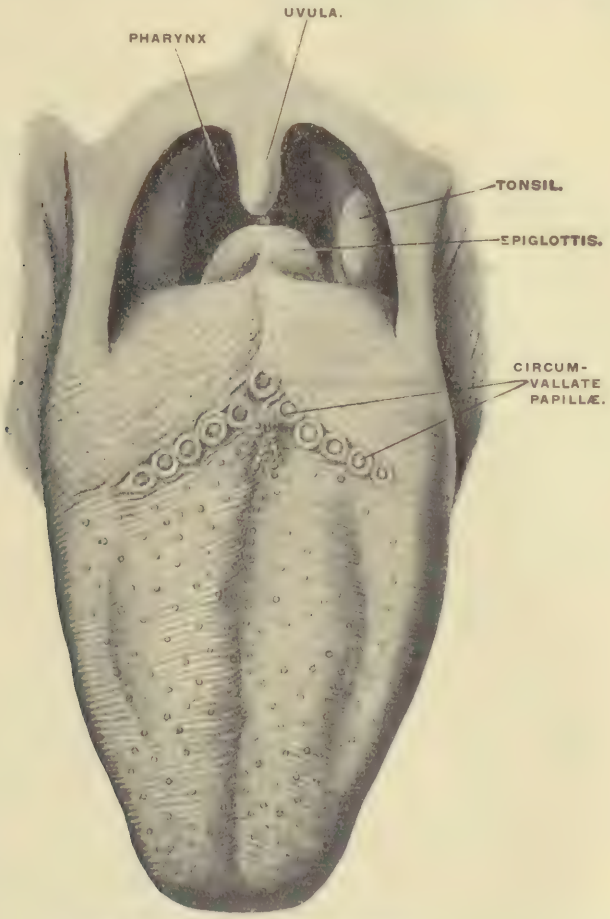

FIG. 698.—Upper surface of the tongue.

through the ducts of the submaxillary and the sublingual glands. As it passes over the borders of the organ it gradually assumes a papillary character.

Structure.—The structure of the mucous membrane of the tongue differs in different parts. That covering the under surface of the organ is thin, smooth, and identical in structure with that lining the rest of the oral cavity. The mucous membrane covering the tongue behind the foramen caecum and sulcus terminalis is thick and freely movable over the subjacent parts. It contains a large number of **lymphoid follicles** (*folliculi linguales*), which together constitute what is sometimes termed the **lingual tonsil** (*tonsilla lingualis*). Each follicle forms a rounded eminence, the centre of which is perforated by a minute orifice leading into a

funnel-shaped cavity or recess; around this recess are grouped numerous oval or rounded nodules of lymphoid tissue, each enveloped by a capsule derived from the submucosa, while opening into the bottom of the recesses are also seen the ducts of **mucous glands** (*glandulae linguales*). The mucous membrane on the anterior part of the dorsum of the tongue is thin and intimately adherent to the muscular tissue, and covered with minute eminences, the **papillae of the tongue.** It consists of a layer of connective tissue, the **corium** or **mucosa,** supporting numerous papillae, and covered, as well as the papillae, with epithelium.

The epithelium is of the scaly variety, like that of the epidermis. It covers the free surface of the tongue, as may be readily demonstrated by maceration or boiling, when it can be easily detached entire; it is much thinner than that of the skin; the intervals between the large papillae are not filled up by it, but each papilla has a separate investment from root to summit. The deepest cells may sometimes be detached as a separate layer, corresponding to the rete mucosum, but they never contain coloring matter.

The Corium.—The corium consists of a dense feltwork of fibrous connective tissue, with numerous elastic fibres, firmly connected with the fibrous tissue forming the septa between the muscular bundles of the tongue. It contains the ramifications of the numerous vessels (Fig. 699) and nerves from which the papillae are supplied, large plexuses of lymphatic vessels, and the glands of the tongue.

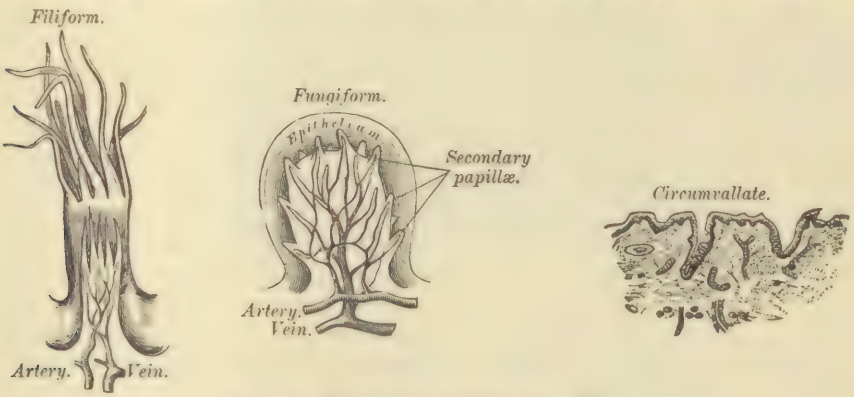

Fig. 699.—Three kinds of papillae, magnified.

The Papillae of the Tongue (*papillae linguales*) (Figs. 698, 699, 700, and 701).—These are papillary projections of the corium. They are thickly distributed over the anterior two-thirds of the upper surface of the tongue, giving to it its characteristic roughness. The varieties of papillae met with are—the **papillae maximae** or **circumvallate papillae, papillae mediae** or **fungiforme papillae, papillae minimae, conical** or **filiforme papillae,** and **papillae simplices** or **simple papillae.**

The **Papillae Maximae** or **Circumvallate Papillae** (*papillae vallatae*) (Figs. 698, 699, and 700) are of large size, and vary from eight to twelve in number. They are situated at the back part of the dorsum of the tongue, near its base, in front of the foramen caecum and sulcus terminalis, forming a row on each side, which, running backward and inward, meet in the middle line, like the two lines of the letter V inverted Λ. Each papilla consists of a projection of mucous membrane from $\frac{1}{20}$ to $\frac{1}{12}$ of an inch wide, attached to the bottom of a cup-shaped depression of the mucous membrane; the papilla is in shape like a truncated cone, the smaller end being directed downward and attached to the tongue, the broader part or base projecting on the surface and being studded with numerous small secondary papillae (Fig. 699), which, however, are covered by a smooth layer of the epithelium. The cup-shaped depression forms a kind of fossa around the papilla, having a circular margin of about the same elevation covered with smaller papillae.

Immediately behind the apex of the V is the foramen cæcum, mentioned above. This foramen, according to His, represents the remains of the invagination which forms the median rudiment of the thyroid body, and which for a time opens by a duct, the **thyroglossal duct**, on to the dorsum of the tongue. It may extend downward toward the hyoid bone. Kanthack, however, disputes this view.[1]

The **Fungiform Papillae** or **Papillae Mediae** (*papillæ fungiformes et papillæ lenticulares*) (Fig. 699), more numerous than the preceding, are scattered irregularly and sparingly over the dorsum of the tongue, but are found chiefly at its sides and apex. They are easily recognized among the other papillæ, by their large size, rounded eminences, and deep-red color. They are narrow at their attachment to the tongue, but broad and rounded at their free extremities, and are covered with secondary papillæ. Their epithelial investment is very thin.

The **Conical** or **Filiform Papillae** or **Papillae Minimae** (*papillæ conicæ et papillæ filiformes*) (Fig. 699) cover the anterior two-thirds of the dorsum of the tongue. They are very minute, more or less conical or filiform in shape, and arranged in lines corresponding in direction with the two rows of the papillæ circumvallatæ, excepting at the apex of the organ, where their direction is transverse. Projecting from their apices are numerous filiform processes or secondary papillæ; these are of a whitish tint, owing to the thickness and density of the epithelium of which they are composed, and which has here undergone a peculiar modification, the cells having become cornified and elongated into dense, imbricated, brush-like processes. They contain also a number of elastic fibres, which render them firmer and more elastic than the papillæ of mucous membrane generally.

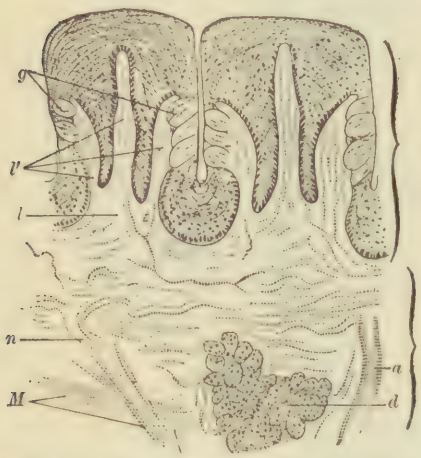

FIG. 700.—Circumvallate papillæ of tongue of rabbit, showing position of taste-goblets. *a*. Duct of gland. *d*. Serous gland. *g*. Taste-buds. *l*. Primary septa, and *l'*, secondary septa, of papillæ. *n*. Medullated nerve. *M*. Muscular fibres. (Stöhr.)

Simple Papillae, similar to those of the skin, cover the whole of the mucous membrane of the tongue, as well as the larger papillæ. They consist of closely set, microscopic elevations of the corium, containing a capillary loop, covered by a layer of epithelium.

Structure of the Papillae (Figs. 699 and 700).—The papillæ apparently resemble in structure the papillæ of the cutis, consisting of a cone-shaped projection of connective tissue, covered with a thick layer of squamous epithelium, and contain one or more capillary loops, amongst which nerves are distributed in great abundance. If the epithelium is removed, it will be found, however, that they are not simple elevations like the papillæ of the skin, for the surface of each is studded with minute conical processes of the mucous membrane, which form secondary papillæ (Todd and Bowman). In the papillæ circumvallatæ the nerves are numerous and of large size; in the papillæ fungiformes they are also numerous, and terminate in a plexiform network, from which brush-like branches proceed; in the papillæ filiformes their mode of termination is uncertain. Buried in the epidermis of the papillæ circumvallatæ, and in some of the fungiformes, are certain peculiar bodies, called **taste-buds**[2] (Fig. 701). Each is flask-like in shape, the broad base resting on the corium, and the neck opening by an orifice, the **gustatory pore**, between the cells of the epithelium.

[1] Journal of Anatomy and Physiology, 1891.

[2] These bodies are also found in considerable numbers at the side of the base of the tongue, just in front of the anterior pillars of the fauces, and also on the posterior surface of the epiglottis and anterior surface of the soft palate.—ED. of 15th English edition.

They are formed by two kinds of cells, supporting cells and gustatory cells. The **supporting cells** are mostly arranged like the staves of a cask, and form an outer envelope for the bud. Some, however, are found in the interior of the bud between the gustatory cells. The **gustatory cells** occupy the central portion of the bud; they are spindle-shaped, and each possesses a large spherical nucleus near the middle of the cell. Until recently the teaching was as follows: The peripheral end of the cell terminates as the gustatory pore in a fine, hair-like filament, the **gustatory hair**. The central process passes toward the deep extremity of the bud, and there ends in a single or bifurcated varicose filament, which was formerly supposed to be continuous with the terminal fibril of a nerve; the investigations of Lenhossék and others would seem to prove, however, that this is not so, but that the nerve-fibrils after losing their medullary sheaths enter the taste-bud, and

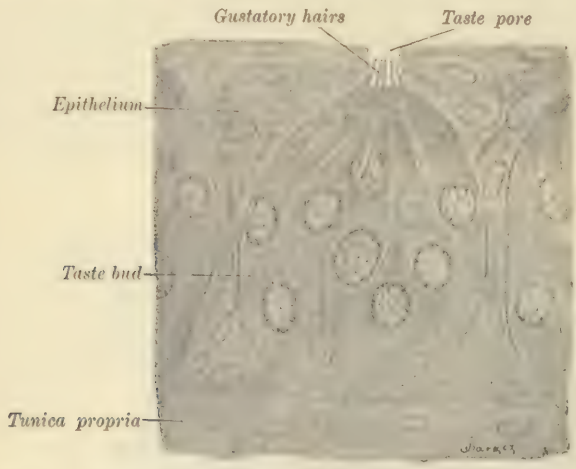

FIG. 701.—Taste-buds from the papilla foliata of a rabbit. × 850. (Szymonowicz.)

terminate in a fine extremity between the gustatory cells. Other nerve-fibrils may be seen ramifying between the cortical cells and terminating in fine extremities; these, however, are believed to be nerves of ordinary sensation, and not gustatory. It is now not believed that the epithelia of the taste-buds are directly connected with the nerve-fibres by long processes. "The latest researches have shown that dendrites of sensory neurones (sensory nerves) enter the taste-buds and end free in telodendria. The latter surround the neuro-epithelial, and, to some extent, the sustentacular cells, their relations depending on contact."[1]

Glands of the Tongue.—The tongue is provided with **mucous** and **serous glands.** The **mucous glands** are similar in structure to the labial and buccal glands. They are found especially at the back part, behind the circumvallate papillae, but are also present at the apex and marginal parts. In connection with these glands special ones have been described by Blandin and Nuhn. They are known as the **glands of Nuhn and Blandin** or **apical glands** (*glandulae linguales anteriores of Nuhn and Blandin*) (Fig. 702). They are situated near the apex of the tongue on either side of the fraenum, and each is covered over by a fasciculus of muscular fibre derived from the Stylo-glossus and Inferior lingualis muscles. Each gland is from half an inch to nearly an inch long and about the third of an inch broad. It has from four to six ducts, which open on the under surface of the apex.

The **Serous Glands** or **Glands of v. Ebner** occur only at the back of the tongue in the neighborhood of the taste-buds, their ducts opening for the most part into the

[1] Text-book of Histology. By A. A. Böhm and M. von Davidoff. Edited by G. Carl Huber.

fossae of the papillae circumvallatae. These glands are racemose, the duct branching into several minute ducts, which terminate in alveoli lined by a single layer of more or less columnar epithelium. Their secretion is of a watery nature, and probably assists in the distribution of the substance to be tasted over the taste-area (Ebner).

The **Hyo-glossal membrane** is a strong fibrous lamina which is derived from the septum of the tongue and which connects the under surface of the base of the tongue to the body of the hyoid bone. This membrane receives, in front, some of the posterior fibres of the Genio-hyo-glossi muscles.

The Vessels of the Tongue.—The **arteries of the tongue** are derived from the **lingual,** the **facial,** and **ascending pharyngeal.** The **veins of the tongue** open into the **internal jugular.**

The **lingual artery** (Fig. 704) on each side passes forward beneath the Hyo-glossus muscle and courses to the apex of the tongue, between the Genio-glossus and the Inferior lingual muscles, about one-eighth of an inch from the surface. It divides into the **ranine** (Fig.702) and **sublingual** (Fig. 704). Near the apex a branch is given off from the ranine artery, which penetrates the septum and joins a like branch from the other side. The **dorsalis linguae** is a branch of the lingual

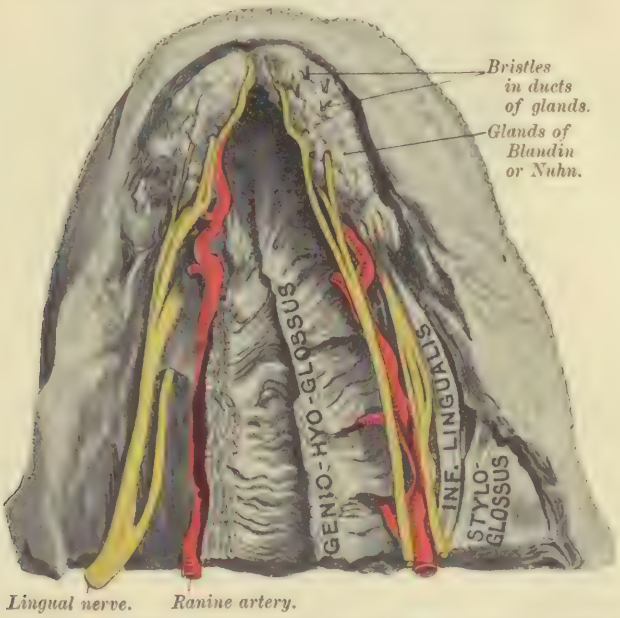

FIG. 702.—Under surface of tongue, showing position and relations of gland of Blandin or Nuhn. (From a preparation in the Museum of the Royal College of Surgeons of England.)

supplying the posterior part of the tongue, and rami from the **tonsillar branch of the facial** go to the same region. A network of capillary vessels is placed beneath the epithelium.

The **ranine veins** lie to the sides of the fraenum underneath the mucous membrane. Each ranine vein runs backward, superficial to and upon the Hyo-glossus muscle and near to the hypo-glossal nerve. The venae comites of the lingual artery usually join the ranine vein, and the trunk opens into the internal jugular vein, but the vessels may open separately into the jugular (Fig. 445).

The Muscles of the Tongue.—The muscular fibres of the tongue run in various directions. These fibres are divided into two sets, Extrinsic and Intrinsic, which have already been described (pp. 396, 397, 398, 399, and 400).

The Extrinsic come from the Stylo-glossus, Hyo-glossus, Genio-glossus, Palato-glossus, and Chondro-glossus. The Intrinsic muscles are the **Superior lingualis** (*m. longitudinalis superior*), the **Inferior lingualis** (*m. longitudinalis inferior*), the **Transverse lingual** (*m. transversus linguae*), and the **Vertical lingual** (*m. verticalis linguae*). The **outer** or **cortical portion** of the tongue is composed chiefly of longitudinal fibres. The **central** or **medullary portion** is composed chiefly of vertical and transverse fibres and is divided into two parts by a **vertical septum** (*septum linguae*), which is a fibrous structure, beginning at the apex and passing back. As it approaches the back it becomes narrower vertically and broadens out transversely to form the **hyo-glossal membrane.** The fibrous septum is well displayed by making a vertical section of the tongue.

The Lymphatic Vessels of the Tongue (Fig. 491).—The lymphatic vessels from the anterior half of the tongue pass to the **submaxillary lymph glands.**

Lymph vessels from the posterior half of the tongue are connected with satellite **glands on the Hyo-glossus muscle** and terminate in the **deep cervical glands.** The last-named lymph-vessel accompanies the ranine vein. The lingual lymphatics arise from a network beneath the epithelium. Across the anterior two-thirds of the tongue there is little or no lymphatic connection between the two sides; in the posterior one-third there is free connection.

FIG. 703.—Frontal section through the body of the tongue of a new-born babe. × 3. (Spalteholz.)

The Nerves of the Tongue (Fig. 704).—The nerves of the tongue are five in number in each half; the **lingual branch** of the **inferior maxillary division of the fifth,** which is distributed to the papillae at the forepart and sides of the tongue, and forms the nerve of ordinary sensibility for its anterior two-thirds; the **chorda tympani,** which runs in the sheath of the lingual, is generally regarded as the nerve of taste for the same area; the **lingual branch** of the **glosso-pharyngeal,** which is distributed to the mucous membrane at the base and sides of the tongue, and to the papillae circumvallatae, and which supplies both sensory and gustatory filaments to this region; the **hypo-glossal nerve,** which is the motor nerve to the muscular substance of the tongue; and the **internal laryngeal** branch of the **superior laryngeal,** which sends some fine branches to the root near to the epiglottis. **Sympathetic** filaments also pass to the tongue from the nervi molles on the lingual and other arteries supplying it. Some of the nerves end free between the cells of epithelium; others terminate as end organs (Meissner's corpuscles and the end-bulbs of Krause), and in taste-buds as sensory dendrites.

Surgical Anatomy.—The diseases to which the tongue is liable are numerous, and its surgical anatomy is of importance, since any or all the structures of which it is composed—muscles, connective tissue, mucous membrane, glands, vessels, nerves, and lymphatics—may be the seat of morbid changes. It is not often the seat of congenital defects, though a few cases of *vertical*

cleft have been recorded, and it is occasionally, though much more rarely than is commonly supposed, the seat of *tongue-tie*, from shortness of the fraenum.

There is, however, one condition which must be regarded as congenital, though not uncommonly it does not exhibit the significant changes until a year or two after birth. This is an enlargement of the tongue which is due primarily to a dilatation of the lymph-channels and a greatly increased development of the lymphatic tissue throughout the tongue (*macroglossia*). This is often aggravated by inflammatory changes induced by injury or exposure, and the tongue may assume enormous dimensions and hang out of the mouth, giving the child an imbecile expression. The treatment consists in excising a V-shaped portion and bringing the cut surfaces together with deeply placed silver sutures. Compression has been resorted to in some cases with occasional success, but it is difficult to apply. Acute inflammation of the tongue (*acute glossitis*), which may be caused by injury or the introduction of some septic or irritating matter, and it is attended by great swelling from infiltration of the connective tissue of the tongue; this connective tissue is present in considerable quantity. The great swelling renders the patient incapable of swallowing or speaking, and may seriously impede respiration. The condition may eventuate in suppuration and the formation of an *acute abscess*. *Chronic abscess*, which has been mistaken for cancer, may also occur in the substance of the tongue.

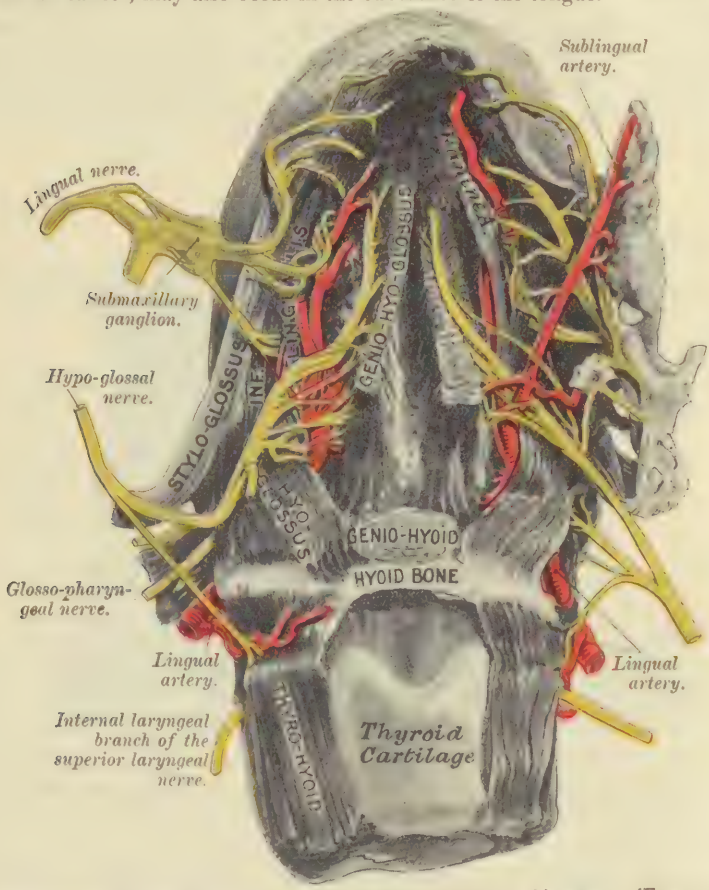

FIG. 704.—Under surface of tongue, showing the distribution of nerves to this organ. (From a preparation in the Museum of the Royal College of Surgeons of England.)

The mucous membrane of the tongue may become chronically inflamed, and presents different appearances in different stages of the disease, to which the terms *leucoplakia*, *psorias*, and *ichthyosis* have been given.

The tongue, being very vascular, is often the seat of *naevoid growths*, and these have a tendency to grow rapidly.

The tongue is frequently the seat of *ulceration*, which may arise from many causes, as from the irritation of jagged teeth, dyspepsia, *tuberculosis*, *syphilis*, and *cancer*. Of these the cancerous ulcer is the most important, and probably also the most common. The variety is the *squamous epithelioma*, which soon develops into an ulcer with an indurated base. It produces great pain, which speedily extends to all parts supplied with sensation by the fifth nerve, especially to the

region of the ear. The pain in these cases is conducted to the ear and temporal region by the lingual nerve, and from this nerve pain radiates to the other branches of the inferior maxillary nerve, especially the auriculo-temporal. Possibly pain in the ear itself may be due to implication of the fibres of the glosso-pharyngeal nerve, which by its tympanic branch reaches the tympanic plexus. Cancer of the tongue spreads through the organ very rapidly because of the almost constant muscular movements.

Cancer of the tongue may necessitate removal of a part or the whole of the organ, and many different methods have been adopted for its excision. It may be removed from the mouth by the écraseur or the scissors. The better method is by the scissors, usually known as Whitehead's method. The mouth is widely opened with a gag the tongue is transfixed with a stout silk ligature, by which to hold and make traction on it and the reflection of mucous membrane from the tongue to the jaw, and the insertion of the Genio-hyo-glossi first divided with a pair of curved blunt scissors. The Palato-glossi are also divided. The tongue can now be pulled well out of the mouth. The base of the tongue is cut through by a series of short snips, each bleeding vessel being dealt with as soon as divided, until the situation of the ranine artery is reached. The remaining undivided portion of tissue is to be seized with a pair of Wells's forceps, the tongue removed, and the vessel secured. In the event of the ranine artery being accidentally injured early in the operation, hemorrhage can be at once controlled by passing two fingers over the dorsum of the tongue as far as the epiglottis and dragging the root of the tongue forcibly forward.

In cases where the disease is confined to one side of the anterior portion of the tongue this operation may be modified by splitting the tongue down the centre and removing only the affected half. If the posterior portion of the tongue is attacked by cancer the entire tongue must be removed, even if but one side of the organ is *apparently* involved. The exchange of lymph between the halves of the posterior portion of the tongue makes it certain that the opposite half becomes involved soon after the origin of the disease. Whatever operation is performed for cancer of the tongue, the glands must be removed from *both sides of the neck*. This is to be done, even if but one side of the tongue is removed. Kocher, after performing a preliminary tracheotomy, removes the tongue from the neck, by an incision taken from near the lobule of the ear, down the anterior border of the Sterno-mastoid to the level of the great cornu of the hyoid bone, then forward to the body of the hyoid bone, and upward to near the symphysis of the jaw. The lingual artery is now secured, and by a careful dissection the submaxillary lymphatic glands and the tongue removed. Regnoli advocated the removal of the tongue by a semilunar incision in the submaxillary triangle along the line of the lower jaw, and a vertical incision from the centre of the semilunar one backward to the hyoid bone. Care must be taken not to carry the first incision too far backward, so as to wound the facial arteries. The tongue is thus reached through the floor of the mouth, pulled out through the external incision, and removed with the knife. The great objection to this operation is that all the muscles which raise the hyoid bone and larynx are divided, and that therefore the movements of deglutition and respiration are interfered with.

Finally, where both sides of the floor of the mouth are involved in the disease, or where very free access is required on account of the extension backward of the disease to the pillars of the fauces and the tonsil, or where the lower jaw is involved, the operation recommended by Syme must be performed. This is done by an incision through the central line of the lip across the chin, and down as far as the hyoid bone. The lower jaw is sawed through at the symphysis, and the two halves of the bone forcibly separated from each other. The mucous membrane is separated from the bone, and the Genio-hyo-glossi detached from the bone, and the Hyo-glossi divided. The tongue is then drawn forward and removed close to its attachment to the hyoid bone. Adjacent lymph glands can be removed, and if the bone is implicated in the disease, it can also be removed by freeing it from the soft parts externally and internally, and making a second section with the saw beyond the diseased part.

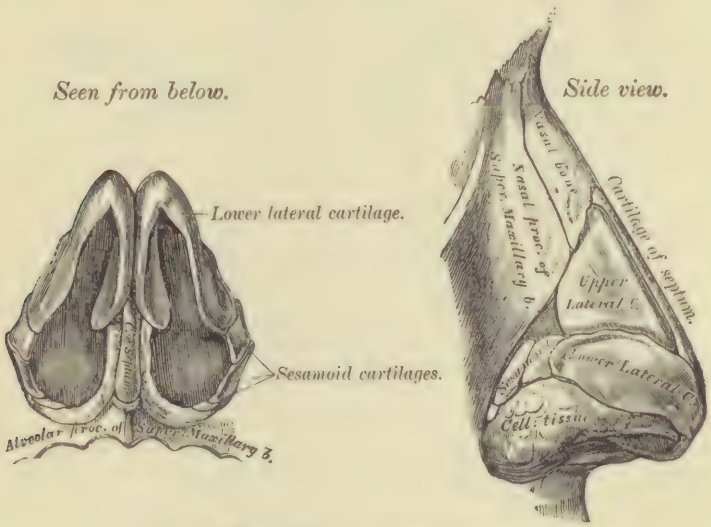
Formerly many surgeons before removing the tongue performed a preliminary tracheotomy: (1) to prevent blood entering the air-passages; and (2) to allow the patient to breathe through the tube and not inspire air which had passed over a sloughy wound, and which was loaded with septic organisms and likely to induce septic pneumonia. By operating with the patient in the Trendelenburg position, the blood is caused to flow away from the air-passages. By the judicious use of iodoform the evil mentioned secondly may be obviated, and the preliminary tracheotomy is now usually dispensed with.

THE NOSE.

The nose is the peripheral portion of the organ of smell (*organon olfactus*): by means of the peculiar properties of its nerves it protects the lungs from the inhalation of deleterious gases and assists the organ of taste in discriminating the properties of food. The organ of smell consists of two parts; one external, the **outer nose**; the other internal, the **nasal fossae**.

THE OUTER NOSE (NASUS EXTERNUS).

The outer nose is the more anterior and prominent part of the organ of smell. Of a triangular form, it is directed downward, and projects from the centre of the face, immediately above the upper lip. Its **summit** or **root** (*radix nasi*) is connected directly with the forehead. Its **inferior part** or **base** (*basis nasi*) presents two elliptical orifices, the **nostrils** or **anterior nares** (*nares*), separated from each other by an antero-posterior septum, the **mobile septum** or **columna nasi** (*septum mobile nasi*). The margins of the nostrils are provided with a number of stiff hairs or **vibrissae**, which arrest the passage of foreign substances carried with the current of air intended for respiration. The **point** (*apex nasi*) is the free extremity of the nose. The **lateral surfaces** of the nose form, by their union in the middle line, the **dorsum** (*dorsum nasi*), the direction of which varies considerably in different individuals. The portion of the dorsum over the nasal bones is the **bridge**. Each lateral surface terminates below in a rounded eminence, the **wing** or **ala nasi**, which, by its lower margin (*margo nasi*), forms the outer boundary of the corresponding nostril. Above the ala is a depression, the **alar sulcus**.



FIGS. 705 and 706.—Cartilages of the nose.

Structure.—The nose is composed of a **framework of bones** and **cartilages**, the latter being slightly acted upon by certain muscles. It is covered externally by the **integument**, internally by **mucous membrane**, and is supplied with **vessels** and **nerves**.

The Bony Framework.—The bony framework occupies the upper part of the organ; it consists of the **nasal bones** and the **nasal processes of the superior maxillary bones** (pp. 104 and 109).

The Cartilaginous Framework (*cartilagines nasi*) (Figs. 705 and 706).—The cartilaginous framework consists of five pieces, the **two upper** and the **two lower lateral cartilages** and the **cartilage of the septum**.

The **Upper Lateral Cartilage** (*cartilago nasi lateralis*) of each side is situated below the free margin of the nasal bone. It is flattened and triangular in shape. Its anterior margin is thicker than the posterior, and continuous with the cartilage of the septum. Its posterior margin is attached to the nasal process of the superior maxillary and nasal bones. Its inferior margin is connected by fibrous tissue with the lower lateral cartilage; one surface is turned outward, the other inward toward the nasal cavity.

The **Lower Lateral Cartilage**, the **Cartilage of the Aperture** or the **Greater Alar Cartilage** (*cartilago alaris major*) of each side consists of two thin, flexible plates situated immediately below the preceding, and bent upon themselves in such a manner as to form the inner and outer walls of the orifice of the nostril. The portion which forms the **inner wall** (*crus mediale*), thicker than the rest, is loosely connected with the corresponding portion of the opposite cartilage, and forms a small part of the columna. Its inferior border, free, rounded, and projecting, forms, with the thickened integument and subjacent tissue and the corresponding parts of the opposite side, the mobile septum. The part of the cartilage which forms the **outer wall** (*crus laterale*) is curved to correspond with the ala of the nose; it is oval and flattened, narrow behind, where it is connected with the nasal process of the superior maxilla by a tough fibrous membrane, in which are found three or four small cartilaginous plates, the **sesamoid, accessory quadrate** or **lesser alar cartilages** (*cartilagines alares minores*). Above, it is connected by fibrous tissue to the upper lateral cartilage and front part of the cartilage of the septum; below, it falls short of the margin of the nostril; the ala being formed by dense cellular tissue covered by skin. In front the lower lateral cartilages are separated by a notch which corresponds with the point of the nose.

The **Triangular Cartilage of the Septum** (*cartilago septi nasi*) (Figs. 705 and 707) is somewhat quadrilateral in form, thicker at its margins than at its centre, and completes the separation between the nasal fossae in front. Its *anterior margin*, thickest above, is connected with the nasal bones, and is continuous with the anterior margins of the two upper lateral cartilages. Below, it is connected to the inner portions of the lower lateral cartilages by fibrous tissue. Its *posterior margin* is connected with the perpendicular lamella of the ethmoid; its inferior margin with the vomer and the palate processes of the superior maxillary bones (Fig. 103).

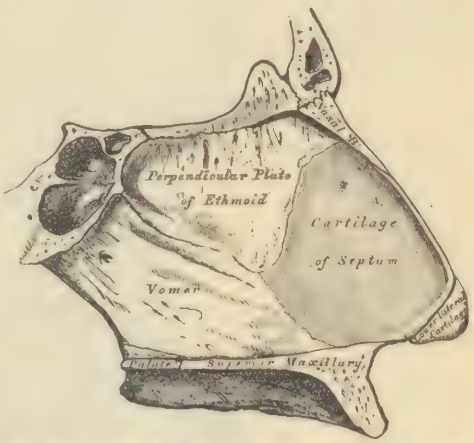


Fig. 707.—Bones and cartilages of septum of the nose. Right side.

It may be prolonged backward (especially in children) for some distance between the vomer and perpendicular plate of the ethmoid, forming what is termed the **sphenoidal process** (*processus sphenoidalis septi cartilaginei*). The septal cartilage does not reach as far as the lowest part of the nasal septum. This is formed by the inner portions of the lower lateral cartilages and by the skin; it is freely movable, and hence is termed the **mobile septum** (*septum mobile nasi*).

Along the lower margin of the anterior half of the cartilage of the septum is another cartilage which is attached to the vomer and is known as the **vomerine cartilage** or **cartilage of Jacobson** (*cartilago vomeronasalis*).

These various cartilages are connected to each other and to the bones by a tough fibrous membrane, which allows the utmost facility of movement between them.

The Muscles of the Nose.—The muscles of the nose are situated beneath the integument; they are (on each side) the Pyramidalis nasi, the Levator labii superiores alaeque nasi, the Dilatator naris, anterior and posterior, the Compressor nasi, the Compressor narium minor, and the Depressor alae nasi. They have been previously described (p. 375).

The **Integument** covering the dorsum and sides of the nose is thin, and loosely connected with the subjacent parts; but the integument of the tip and the alae of

the nose is thicker and more firmly adherent, and is furnished with a large number of sebaceous follicles, the orifices of which are usually very distinct.

The **Mucous Membrane** lining the interior of the nose is continuous with the skin externally and with the mucous membrane which lines the nasal fossae within.

The Arteries of the Outer Nose.—The arteries of the nose are the **lateralis nasi from the facial,** and the **inferior artery of the septum from the superior coronary,** which supply the alae and septum, the sides and dorsum being supplied from the **nasal branch of the ophthalmic** and the **infraorbital.**

The Veins of the Outer Nose.—The veins of the nose terminate in the **facial** and **ophthalmic.**

The Lymphatics of the Outer Nose.—These vessels are shown in Figs. 487, 489, and 490. They empty chiefly into the **submaxillary lymph glands.**

The Nerves of the Outer Nose.—The nerves for the muscles of the nose are derived from the **facial,** while the skin receives its branches from the **infraorbital, infratrochlear,** and **nasal branches of the ophthalmic.**

THE NASAL FOSSAE (CAVUM NASI).

The nasal fossae are two irregular cavities situated in the middle of the face, one on each side of the middle line, and extending from before backward. They open in front, when the soft parts are in place, by the two **nostrils** or **anterior nares,** and terminate, behind, in the naso-pharynx by the **posterior nares.**

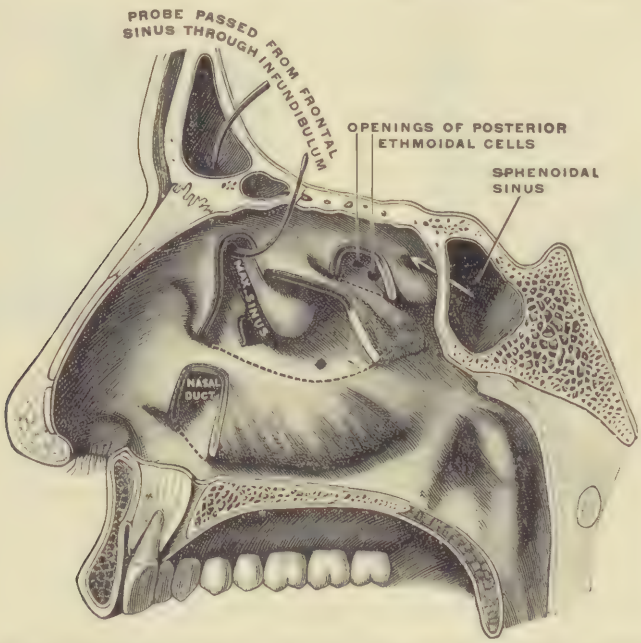

FIG. 708.—External wall of right nasal fossa, parts of the turbinates having been cut away to show the orifices of the sinuses which open into the meatuses. (Testut.)

The Anterior Nares (*nares*).—The anterior nares are somewhat pear-shaped apertures, each measuring about one inch antero-posteriorly and half an inch transversely at their widest part. The nasal fossae in the dry skull open in front by the anterior nasal aperture (*apertura pyriformis*).

The Posterior Nares (*choanae*).—The posterior nares are two oval openings, which are smaller in the living or recent subject than in the skeleton, because they

are narrowed by the mucous membrane. Each measures an inch in the vertical and half an inch in the transverse direction in a well-developed adult skull.

For the description of the bony boundaries of the nasal fossae see section on Osteology (p. 143).

Inside the aperture of the nostril is a slight dilatation, the **vestibule** (*vestibulum nasi*), which extends as a small pouch, the **ventricle**, toward the point of the nose. Above and behind the vestibule is surrounded by a prominence (*limen nasi*). Below the prominence the vestibule is lined with skin; above and behind it the fossa is lined with mucous membrane. The fossa, above and behind the vestibule, has been divided into two parts: an **olfactory portion** (*regio olfactoria*), a slit-like cavity, comprising the upper and central part of the septum and probably the superior turbinated bone, and a **respiratory portion** (*regio respiratoria*), which comprises the rest of the fossa.

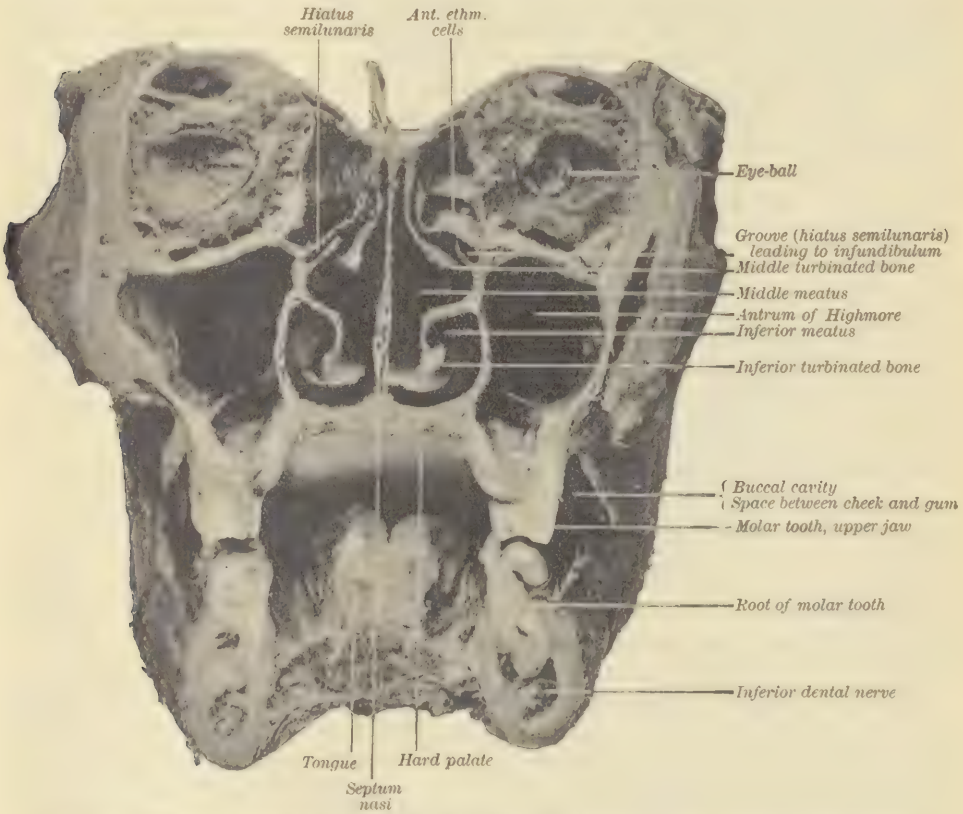

FIG. 709.—Transverse vertical section of the nasal fossae. The section is made anterior to the superior turbinated bones. (Cryer.)

Outer Wall (Figs. 708, 709).—The **superior, middle,** and **inferior meatus** (*meatus nasi superior, medius and inferior*) are described on pages 144 and 145. The **sphenoidal air sinus** opens into the **spheno-ethmoidal recess** (*recessus sphenoethmoidalis*), a narrow recess above the superior turbinated bone (Fig. 708). The **posterior ethmoidal cells** open into the front and upper part of the **superior meatus** (Fig. 708). On raising or cutting away the middle turbinated bone the outer wall of the middle meatus is fully exposed (Figs. 708 and 709) and presents (1) a rounded elevation, termed the **bulla ethmoidalis,** opening on or immediately above which are the orifices of the middle ethmoidal cells; (2) a deep, narrow, curved groove, in front of the bulla ethmoidalis, termed the **hiatus semilunaris,** into which the **anterior ethmoidal cells**

and the **antrum of Highmore** (*sinus maxillaris*) open, the orifice of the latter being placed near the level of its roof. The middle meatus is prolonged, above and in front, into the **infundibulum** (*infundibulum ethmoidale*), which leads into the **frontal sinus.** The anterior extremity of the meatus is continued into a depressed area which lies above the vestibule and is named the **atrium** (*atrium meatus medii nasi*). The **nasal duct** opens into the anterior part of the inferior meatus, the opening being frequently overlapped by a fold of mucous membrane, and from the orifice of the duct a groove leads downward and forward.

The Inner Wall (Fig. 709).—The inner wall or septum is frequently more or less deflected from the mesial plane (Figs. 101 and 709), thus limiting the size of one fossa and increasing that of the other. **Ridges** or **spurs of bone** growing outward from the septum are also sometimes present. Immediately over the incisive foramen at the lower edge of the cartilage of the septum a depression, the **naso-palatine recess** (*recessus nasopalatinus*), may be seen. In the septum close to this recess a minute orifice may be discerned; it leads into a blind pouch, the **rudimentary organ of Jacobson** (*organon vomeronasale*), which is well developed in some of the lower animals, but is rudimentary in man. The organ is supported by a plate of cartilage, distinct from the cartilage of the septum, the **cartilage of Jacobson** (p. 1097). The cartilage of Jacobson is to the outer side of the lower edge of the cartilage of the septum. The diverticulum opens anteriorly near the floor of the nose and close by Stenson's foramen. Just below the opening of the blind pouch is an elevation, the **eminence of Jacobson.**

The Mucous Membrane (*membrana mucosa nasi*).—The mucous membrane lining the nasal fossae is called the **pituitary,** from the nature of its secretion; or **Schneiderian,** from Schneider, the first anatomist who showed that the secretion proceeded from the mucous membrane, and not, as was formerly imagined, from the brain. It is intimately adherent to the periosteum or perichondrium, over which it lies. It is continuous externally with the skin through the anterior nares, and with the mucous membrane of the naso-pharynx through the posterior nares. From the nasal fossae its continuity may be traced with the conjunctiva through the nasal duct and lachrymal canals; with the lining membrane of the tympanum and mastoid cells through the Eustachian tube; and with the frontal, ethmoidal, and sphenoidal sinuses, and the antrum of Highmore through the several openings in the meatuses. The mucous membrane is thickest and most vascular over the turbinated bones. It is also thick over the septum, but in the intervals between the spongy bones and on the floor of the nasal fossae it is very thin. Where it lines the various sinuses and the antrum of Highmore it is thin and pale.

Owing to the great thickness of this membrane, the nasal fossae are much narrower, and the turbinated bones, especially the lower ones, appear larger and more prominent than in the skeleton. From the same circumstances also the various apertures communicating with the meatuses are considerably narrowed or completely closed. The vestibule is lined by modified skin, and contains hairs (*vibrissae*) which guard the entrance of the nostril.

Structure of the Mucous Membrane (Fig. 710).—The epithelium covering the mucous membrane differs in its character according to the functions of the part of the nose in which it is found. In the respiratory portion of the nasal cavity the epithelium is columnar and ciliated. Interspersed among the columnar ciliated cells are goblet or mucin cells, while between their bases are found smaller pyramidal cells. In this region, beneath the epithelium and its basement membrane, is a fibrous layer infiltrated with lymph-corpuscles, so as to form in many parts a diffuse adenoid tissue, which is particularly plentiful in children, and beneath this a nearly continuous layer of smaller and larger glands, some mucous and some serous, the ducts of which open upon the surface. In the respiratory portion of the mucous membrane there is an extensive anastomosing plexus of veins, which

in some regions forms a distinct **cavernous tissue** (*plexus cavernosus concharum*). The cavernous tissue is particularly distinct over the inferior turbinated bones. In the olfactory region the mucous membrane is yellowish in color and the epithelial cells are columnar and non-ciliated; they are of two kinds, **supporting cells** and **olfactory cells.**

The **Supporting Cells** contain oval nuclei, situated in the deeper parts of the cells; the free surface of each cell presents a sharp outline, and its deep extremity is prolonged into a process which runs inward, branching to communicate with similar processes from neighboring cells, so as to form a network in the deep part of the mucous membrane. Lying between these central processes of the supporting cells are a large number of spindle-shaped cells, the **olfactory cells,** which consist of a large spherical nucleus surrounded by a small amount of granular protoplasm, and possessing two processes, of which one runs outward between the columnar epithelial cells, and projects on the surface of the mucous membrane as a fine, hair-like process, the **olfactory hair**; the other or deep process runs inward, is frequently beaded like a nerve-fibre, and is believed by most observers to be in connection with one of the terminal filaments of the olfactory nerve. Beneath the

FIG. 710.—Section of the olfactory mucous membrane: *a*, epithelium; *b*, glands of Bowman; *c*, nerve bundles. (Cadiat.)

epithelium, extending through the thickness of the mucous membrane, is a layer of tubular, often branched, glands, the **glands of Bowman** (*glandulae olfactoriae*), identical in structure with serous glands.

The Arteries of the Nasal Fossae.—The arteries of the nasal fossae are the **anterior** and **posterior ethmoidal,** from the ophthalmic, which supply the ethmoidal cells, frontal sinuses, and roof of the nose; the **spheno-palatine,** from the internal maxillary, which supplies the mucous membrane covering the spongy bones, the meatuses, and septum; the **inferior artery of the septum,** from the superior coronary of the facial; and the **infraorbital** and **alveolar branches** of the internal maxillary, which supply the lining membrane of the antrum. The ramifications of these vessels form a close, plexiform network, beneath and in the substance of the mucous membrane.

The Veins of the Nasal Fossae.—The veins of the nasal fossae form a close, cavernous-like network beneath the mucous membrane. This cavernous appearance is especially well marked over the lower part of the septum and over the middle and inferior turbinated bones. Some of the veins pass, with those accompanying the spheno-palatine artery, through the spheno-palatine foramen; and others, through the alveolar branch, to join the **facial vein**; some accompany the eth-

moidal arteries, and terminate in the **ophthalmic vein**; and, lastly, a few communicate with the veins in the interior of the skull, through the foramina in the cribriform plate of the ethmoid bone, and the foramen caecum.

The Lymphatics of the Nasal Fossae.—The lymphatics can be injected from the subdural and subarachnoid spaces, and form a plexus in the superficial portion of the mucous membrane. The lymph is drained partly into one or two glands which lie near the great cornu of the hyoid bone and partly into a gland situated in front of the axis.

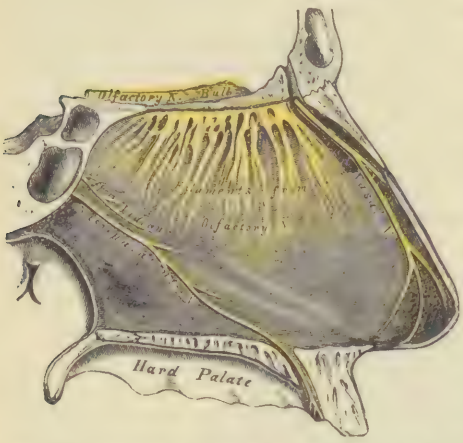

FIG. 711.—Nerves of septum of nose. Right side.

The Nerves of the Nasal Fossae (Fig. 711).—The nerves are: the **olfactory**, the **nasal branch** of the **ophthalmic**, filaments from the **anterior dental branch** of the superior maxillary, the Vidian, the naso-palatine, descending anterior palatine, and nasal branches of Meckel's ganglion. The **olfactory**, the special nerve of the sense of smell, is distributed to the olfactory region, and has been already referred to (p. 1019). The **nasal branch of the ophthalmic division of the fifth nerve** distributes filaments to the forepart of the septum and outer wall of the nasal fossae. **Filaments from the anterior dental branch of the superior maxillary** supply the inferior meatus and inferior turbinated bone. The **Vidian nerve** supplies the upper and back part of the septum and superior spongy bone, and the **upper anterior nasal branches** from the **spheno-palatine ganglion** have a similar distribution. The **naso-palatine nerve** supplies the middle of the septum. The **larger** or **anterior palatine nerve** supplies the **lower nasal branches** to the middle and lower spongy bones.

Surgical Anatomy.—Instances of *congenital deformity* of the nose are occasionally met with, such as complete absence of the nose, an aperture only being present; or perfect development on one side, and suppression or malformation on the other; or there may be imperfect apposition of the nasal bones, so that the nose presents a median cleft or furrow. Deformities which have been acquired are much more common, such as *flattening of the nose* (*saddle nose*), the result of *syphilitic necrosis*, imperfect development of the nasal bones in cases of *congenital syphilis*, or a lateral deviation of the nose the result of *fracture*.

The skin over the alae and tip of the nose is thick and closely adherent to subjacent parts. *Inflammation* of this part is therefore very painful, on account of the tension. The skin is largely supplied with blood, and, the circulation here being terminal, vascular engorgement is liable to occur, especially in women at the menopause and in both sexes from disorders of digestion, exposure to cold, etc. The skin of the nose also contains a large number of sebaceous follicles, and these, as a result of intemperance, are apt to become affected, and the nose becomes reddened, congested, and irregularly swollen. To this condition the term *grog-blossom* is popularly applied. In some of these cases there is enormous hypertrophy of the skin and subcutaneous tissues, producing pendulous masses, termed *lipomata nasi*. *Ordinary epithelioma* and *rodent ulcer* may attack the nose, the latter being the more common of the two. *Lupus* and *syphilitic ulceration* frequently attack the nose, and may destroy the whole of the cartilaginous portion. In fact, lupus vulgaris begins more frequently on the ala of the nose than in any other situation.

Cases of congenital occlusion of one or both nostrils, or adhesion between the ala and septum may occur, and may require immediate operation, since the obstruction much interferes with sucking. Bony closure of the posterior nares may also occur.

To *examine the nasal cavities*, the head should be thrown back and the nose drawn upward, the parts being dilated by some form of speculum. They can also be examined with the little finger or a probe, and in this way foreign bodies detected. A still more extensive examination can be made by *Roux's operation*, which was introduced for the cure of *ozæna*. This operation enables the surgeon to remove any dead bone which may be present in this disease. The cartilaginous framework of the nose is lifted up by an incision made inside the mouth, through the junction

of the upper lip with the bone; the septum nasi and the lateral cartilages are divided with strong scissors till the anterior nares are completely exposed. The posterior nares can be explored by the aid of reflected light from the mouth, by which the posterior nares can be illuminated. The examination is very difficult to carry out, and, as a rule, sufficient information regarding the presence of foreign bodies or tumors in the naso-pharynx can be obtained by the introduction of the finger behind the soft palate through the mouth. The *septum of the nose* may be displaced or *deviate* from the middle line: this may be the result of an injury or from some congenital defect in its development; in the latter case the deviation usually occurs along the line of union of the vomer and mesethmoid, and rarely occurs before the seventh year. Sometimes the deviation may be so great that the septum may come in contact with the outer wall of the nasal fossa, and may even become adherent to it, thus producing complete obstruction. *Perforation of the septum* is not an uncommon affection and may arise from several causes: syphilitic or tuberculous ulceration, blood-tumor or abscess of the septum, and especially in workmen exposed to the vapor of bichromate of potash, from the irritating and corrosive action of fumes. When small, the perforation may cause a peculiar whistling sound during respiration. When large, it may lead to the falling in of the bridge of the nose.

Epistaxis is a very common affection in children. It is rarely of much consequence, and will almost always subside, but in the more violent hemorrhages of later life it may be necessary to plug the posterior nares. In performing this operation it is desirable to remember the size of the posterior nares. A ready method of regulating the size of the plug to fit the opening is to make it of the same size as the terminal phalanx of the thumb of the patient to be operated on.

Nasal polypus is a very common disease, and presents itself in three forms: the gelatinous, the fibrous, and the malignant. The first is by far the most common. It grows from the mucous membrane of the outer wall of the nasal fossa, where there is an abundant layer of highly vascular submucous tissue; rarely from the septum, where the mucous membrane is closely adherent to the cartilage and bone, without the intervention of much, if any, submucous tissue. The most common seat of gelatinous polyps is probably the middle turbinated bone. The fibrous polypus generally grows from the base of the skull behind the posterior nares or from the roof of the nasal fossæ. The malignant polypi, both sarcomatous and carcinomatous, may arise in the nasal cavities and the naso-pharynx; or they may originate in the antrum, and protrude through its inner wall into the nasal fossa.

Rhinoliths or nose-stones may sometimes be found in the nasal cavities. They arise from the deposition of phosphate of lime upon either a foreign body or a piece of inspissated secretion.

The nasal passages furnish a secretion of their own and receive secretion from other parts (tears and secretions of the accessory sinuses). The nasal cavities contain the ethmoidal labyrinths, the lateral masses of the ethmoid (which form the superior and middle turbinated bones), and the inferior turbinated bones. The nasal cavity is surrounded by three pairs of **pneumatic spaces**, the accessory sinuses. These are the maxillary sinuses, the frontal sinuses, and the cells of the ethmoidal labyrinth. The lachrymal duct opens into the inferior meatus. Inflammation of the air-cells may follow inflammation of the nasal mucous membrane or bone disease. One set of cells or many may suffer. Suppuration may occur. Pus may be blocked up and retained. Dead bone may form. The most serious conditions may follow (abscess of brain, sinus thrombosis, septicæmia), and an operation is necessary to obtain relief.

THE EYE.

The **eyeball** or **globe** (*bulbus oculi*) (Figs. 712 and 716) is contained in the anterior part of the cavity of the orbit. In this situation it is securely protected from injury, whilst its position is such as to ensure the most extensive range of sight. It is acted upon by numerous muscles, by which it is capable of being directed to different parts; it is supplied by vessels and nerves, and is additionally protected in front by the orbital margins, eyelids, etc.

The eyeball is embedded in the fat of the orbit, but is partly surrounded by a thin membranous sac, the **capsule of Ténon**, which isolates it, so as to allow of free movement.

The Fascia or Capsule of Ténon (*fascia bulbi* [*Tenoni*]) (Figs. 712 and 713).—The fascia or capsule of Ténon consists of a thin membrane which envelops the eyeball from the optic nerve to the ciliary region, separating it from the orbital fat and forming a socket in which it plays. Its inner surface is smooth, and is in contact with the outer surface of the sclerotic, the **perisclerotic** or **supra-**

scleral lymph-space only intervening. This lymph-space is continuous with the subdural and subarachnoid spaces, and is traversed by delicate bands of connective tissue which extend between the capsule and the sclerotic. This lymph-space forms a flexible pocket, in which the globe rotates. The capsule of Ténon, with the globe, forms a ball-and-socket joint (Deaver). The capsule is perforated behind by the **ciliary vessels** and **nerves** and by the **optic nerve**, being continuous with the sheath of the latter. In front it blends with the ocular conjunctiva, and with it is attached to the ciliary region of the eyeball. It is perforated by the muscles which move the eyeball and on to each muscle it sends a tubular sheath. The sheath of the Superior oblique is carried as far as the fibrous pulley of that muscle; that on the inferior oblique reaches as far as the floor of the orbit, to which it gives off a slip. The sheaths on the recti are gradually lost in the perimysium, but they give off important expansions. The expansion from the Superior rectus blends with the tendon of the Levator palpebrae; that of the

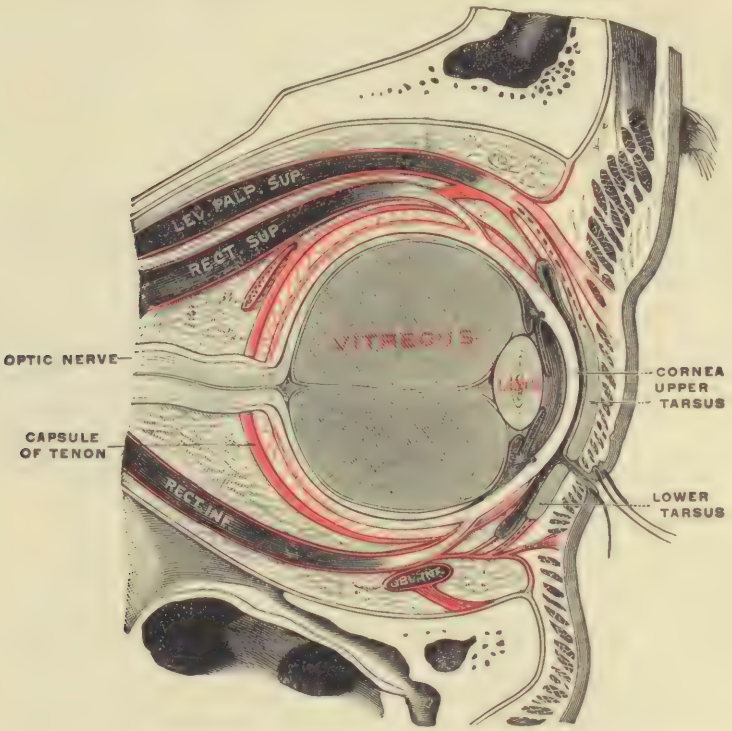

FIG. 712.—The right eye in sagittal section, showing the capsule of Ténon (semidiagrammatic). (Testut.)

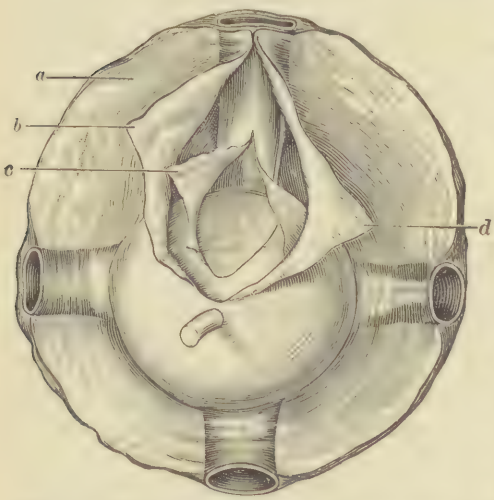

FIG. 713.—The capsule of Ténon. The aponeurosis is seen from behind forward on the posterior hemisphere of the globe: *a*, cellulo-fibrous intermuscular laminae; *b*, deep leaf of the sheath incised at the point where it leaves the muscle to fold itself on the posterior hemisphere when it forms the posterior capsule; *d*, partly incised; *c*, serous membrane. (Poirier and Charpy.)

Inferior rectus is attached to the inferior tarsal plate. These two recti, therefore, will exercise some influence on the movements of the eyelids. The expansions from the sheaths of the Internal and External recti are strong, especially the one from the latter muscle, and are attached to the lachrymal and malar bones respectively. As they probably check the action of these two recti, they have been named the **internal** and **external check ligaments.**

Lockwood has also described a thickening of the lower part of the capsule of Ténon, which he has named the **suspensory ligament of the eye.** It is slung like a hammock below the eyeball, being expanded in the centre and narrow at its extremities, which are attached to the malar and lachrymal bones respectively.[1]

The anterior one-third of the globe is covered by the **conjunctiva,** or mucous membrane, reflected from the inner surfaces of the lids (Fig. 715). A lateral view

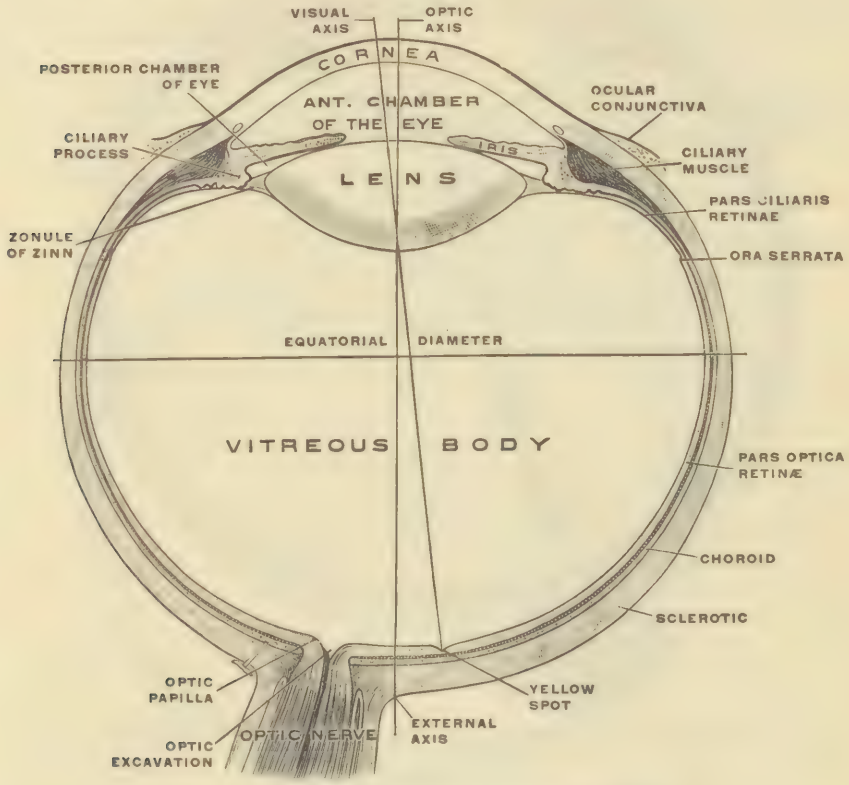

FIG. 714.—The right eye in horizontal section. (Toldt.)

of the globe shows that it is composed of **segments of two spheres** of different sizes (Figs. 712, 714, 715, and 716). The **anterior segment** is one of a small sphere, and forms about one-sixth of the eyeball. It is more prominent than the **posterior segment,** which is one of a much larger sphere, and forms about five-sixths of the globe. The segment of the larger sphere is opaque, and formed by the sclerotic, the tunic of protection to the eyeball; the smaller sphere is transparent, and formed by the cornea. Between the small, anterior or corneal segment, and the large, posterior or scleral segment, is a shallow and narrow groove, the **scleral sulcus** (*sulcus sclerae*). The **anterior pole** is the centre of the anterior portion of the cornea. The **posterior pole** is the centre of the posterior portion of the sclerotic. A straight line joining

[1] See a paper by C. B. Lockwood, Journal of Anatomy and Physiology, vol. xx., part i. p. 1.—ED. of 15th English edition.

these two poles is the **sagittal** or **optic axis** (*axis optica*) (Fig. 714). A line drawn around the eyeball equally distant at all points from the two poles is called the **equatorial diameter** or the **equator** (Fig. 714). The plane of the equator divides the globe in an **anterior** and a **posterior hemisphere.** Meridians may be drawn from one pole to the other at right angles to the equator. The **visual axis** (*linea visus*) (Fig. 714) passes in a straight line from the first nodal point on the cornea to the fovea centralis of the yellow spot on the retina. A **nodal point** is the point of intersection of convergent rays with the visual axis. The first nodal point is 6.9685 mm.

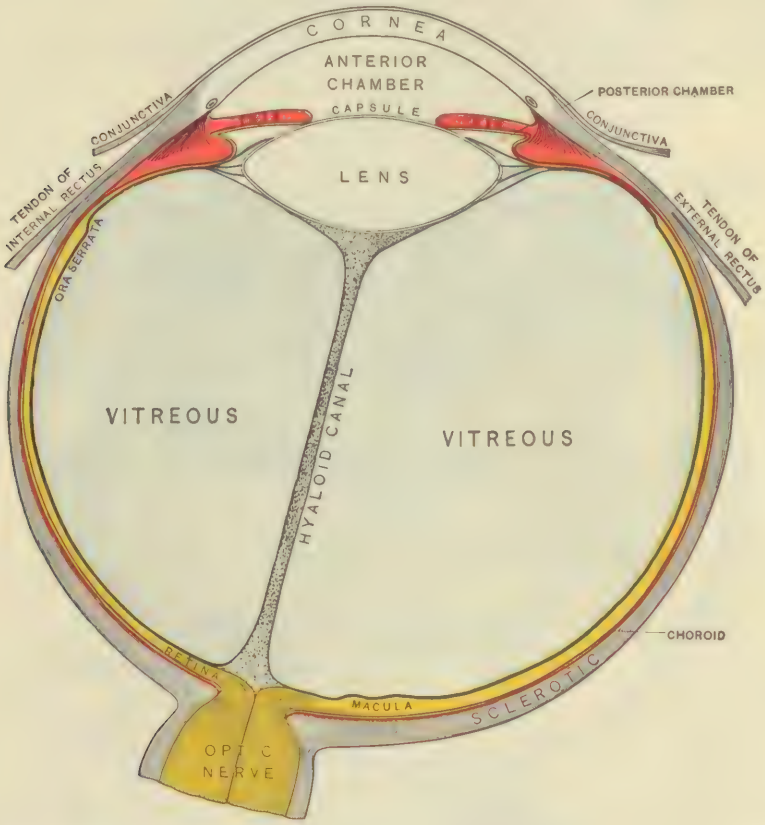

FIG. 715.—Diagram of a horizontal section of the right eye, showing the upper surface of the lower segment. (Testut.)

behind the summit of the cornea. The axes of the eyeballs are nearly parallel, and therefore do not correspond to the axes of the orbits, which are directed outward. The optic nerves follow the direction of the axes of the orbits, and are therefore not parallel; each nerve enters its eyeball about 1 mm. below and 3 mm. to the inner or nasal side of the posterior pole (Fig. 714). The eyeball measures rather more in its transverse and antero-posteror diameters than in its vertical diameter, the former amounting to nearly an inch, the latter to about nine-tenths of an inch. The diameters in the female are somewhat less than in the male.

The eyeball is composed of three **investing tunics** and of three **refracting media.**

THE TUNICS OF THE EYE.

From without inward the three tunics are:

I. Sclerotic Coat and Cornea.
II. Choroid, Ciliary Body, and Iris.
III. Retina.

I. The Fibrous or External Coat: The Sclerotic and Cornea (Tunica Fibrosa Oculi).

The sclerotic and cornea (Figs. 714, 715, and 716) form the external tunic of the eyeball; they are essentially fibrous in structure, the sclerotic being opaque, and forming the posterior five-sixths of the globe; the cornea, which forms the remaining sixth, being transparent.

The Sclera or Sclerotic Coat (*σκληρός*, hard).—The sclera or sclerotic coat has received its name from its extreme density and hardness; it is a firm, unyielding, opaque, fibrous membrane, forming the posterior five-sixths of the outer coat

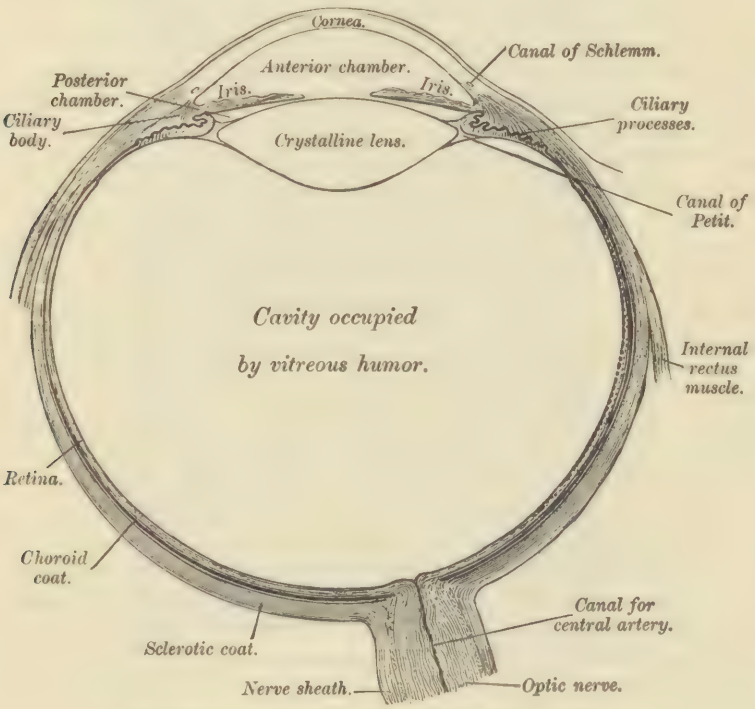

FIG. 716.—A horizontal section of the eyeball. (Allen.)

and serving to maintain the form of the globe. It is much thicker behind than in front. Its *external surface* is of a white color, and is in contact with the inner surface of the capsule of Ténon, a lymph-space intervening; it is quite smooth, except one-quarter of an inch back of the sclero-corneal junction, at the points where the Recti and Obliqui muscles are inserted into it, and its anterior part is covered by the **conjunctival membrane** (Fig. 744); hence the whiteness and brilliancy of the front of the eyeball. Its *inner surface* is stained a brown color, marked by grooves, in which are lodged the **ciliary nerves** and **vessels** (Figs. 719, 724, and 725); the inner surface of the sclera is loosely connected by three layers of exceed-

ingly fine cellular pigmented tissue (*lamina fusca*) with the outer surface of the choroid, an extensive lymph-space, the **perichoroidal space** (*spatium perichorioideale*) (Figs. 727 and 744) intervening between the sclerotic and choroid. Behind the sclera is pierced by the **optic nerve** (*n. opticus*), and is continuous with the fibrous sheath of the nerve, which is derived from the dura mater (Fig. 721). At the point where the optic nerve passes through the sclerotic, the lamina fusca is represented by an arrangement of the fibrous tissue which forms a thin network, the **cribriform lamina** (*lamina cribrosa sclerae*) (Fig. 731); the minute orifices in this network serve for the transmission of separate bundles of nervous filaments, and the fibrous septa dividing them from one another are continuous with the membranous processes which separate the bundles of nerve-fibres. One of these openings (*porus opticus*), larger than the rest, occupies the centre of the lamella; it transmits the **arteria centralis retinae** to the interior of the eyeball (Fig. 731). Around the cribriform lamella are numerous small apertures for the transmission of the **ciliary nerves** and the **short ciliary arteries**, and about midway between the margin of the cornea and the entrance of the optic nerve are four or five large apertures, for the transmission of **veins** (*venae vorticosae*) (Fig. 721). In front, the fibrous tissue of the sclerotic is continuous with the substantia proporia, the cornea by direct continuity of tissue (Fig. 744), but the opaque sclerotic slightly overlaps the outer surface of the transparent cornea. In the depths of the line of junction between the cornea and the sclera there is a circular canal, the **canal of Schlemm** (*sinus venosus sclerae*) (Figs. 716, 723, 727, and 744). This canal receives the sclera veins (Fig. 723) and communicates internally by numerous minute openings in the pectineal ligament of the iris (Fig. 744) with the anterior chamber of the eyeball. These openings are the spaces of Fontana (Fig. 727).

Structure.—The sclerotic is formed of white fibrous tissue intermixed with fine elastic fibres, and of flattened connective-tissue corpuscles, some of which are pigmented, contained in cell-spaces between the fibres (Figs. 720 and 731). These fibres are aggregated into bundles, some of which are arranged in layers having an equatorial direction, but most of which are arranged in layers lying in meridian lines. The sclera is joined to the choroid by three thin layers of loose connective tissue containing pigment cells, the **lamina fusca** (*lamina fasciae sclerae*) (Fig. 724). Where the optic nerve passes through the sclera there is very thin network to represent the lamina fusca. This network is the *lamina cribrosa* (Fig. 731). The muscles of the eyeball are attached to the sclera (Figs. 715, 716, and 744), and their tendons enter among the bundles of fibrous connective tissue. The conjunctiva covers the anterior portion of the sclera and is attached to it by submucous tissue (Figs. 715 and 727). The sclera yields gelatin on boiling. Its vessels (Figs. 721 and 723) are not numerous, the capillaries being of small size and uniting at long and wide intervals. It obtains arterial blood from the **short posterior ciliary** and the **anterior ciliary arteries.** The venous blood is removed by the **venae vorticosae** and the **anterior ciliary veins.** There are lymph-spaces between the cells which empty into the **perischeral** (Fig. 712 and p. 1104) and **perichoroidal lymph-spaces** (Fig. 727). Its nerves are derived from the **ciliary nerves** (Fig. 719). They lose their medullary sheaths and enter among the bundles of fibrous tissue, but it is not known how they terminate.

The Cornea (Figs. 712, 715, and 721).—The cornea is the projecting transparent part of the external tunic of the eyeball, and forms the anterior sixth of the globe. It is almost, but not quite, circular in shape, occasionally a little broader in the transverse than in the vertical direction. It is convex anteriorly, and projects forward from the sclerotic in the same manner that a watch-glass does from the case. Its degree of curvature varies in different individuals, and in the same individual at different periods of life, it being more prominent in youth than in advanced life, when it becomes flattened. Usually the curvature is slightly greater in the vertical plane than in the horizontal plane; at its centre than at its periphery, and at its temporal than at its nasal side. The cornea is dense and of uniform thickness throughout;

its *posterior surface* is perfectly circular in outline, and exceeds the anterior surface slightly in extent, from the latter being overlapped by the sclerotic. The *anterior surface* is covered with conjunctiva (Fig. 727).

Structure (Fig. 717).—The cornea consists of five layers—namely: (1) the anterior or epithelial layer; (2) the anterior elastic layer; (3) the substantia propria; (4) the posterior elastic layer; (5) the posterior or endothelial layer.

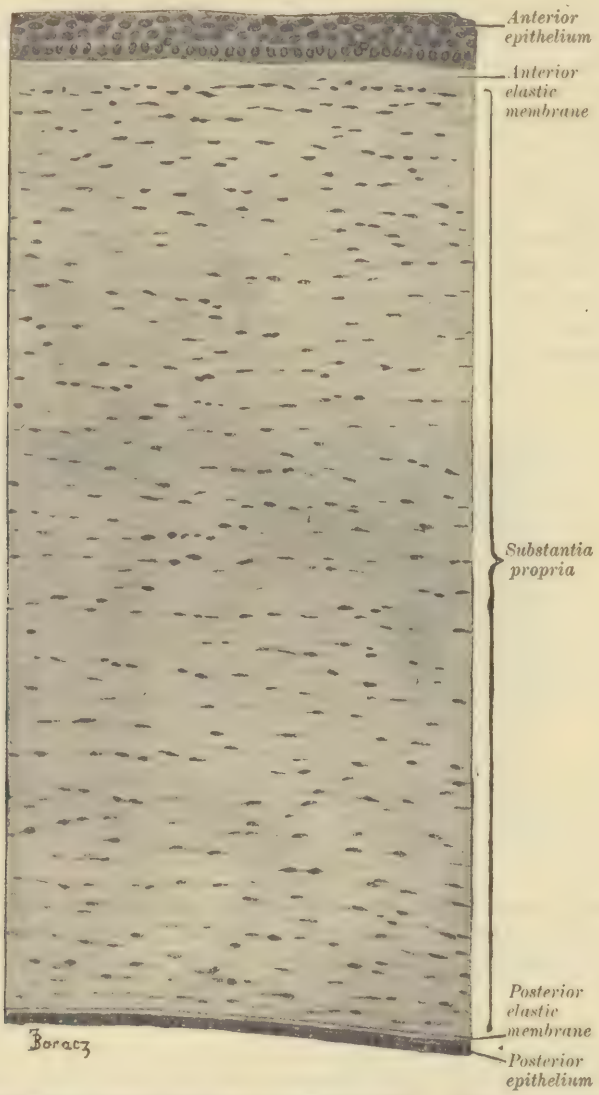

FIG. 717.—Vertical section through the cornea of a newborn child. × 200. (Szymonowicz.)

(1) The **Anterior Layer** (*epithelium corneae*) is composed of stratified epithelium and is continuous with the cells of the conjunctiva at the borders of the cornea. There are from five to eight strata of nucleated cells in the anterior layer. The deepest cells are columnar. Above the columnar cells are several layers of polygonal cells, most of which have finger-like processes and are called **prickle cells.** At the surface the cells and nuclei become flat. The anterior epithelial layer prevents the absorption of the fluid of the tears.

(2) The **Anterior Elastic** or **Anterior Limiting Layer** or **Bowman's Membrane** (*lamina elastica anterior*) is less than half the thickness of the layer of stratified epithelium.

It differs in some essential respects from true elastic tissue. It shows evidences of fibrillary structure, and does not have a tendency to curl inward or to undergo fracture when detached from the other layers of the cornea. It consists of extremely close interwoven fibrils, similar to those found in the rest of the cornea proper, but contains no corneal corpuscles. It ought, therefore, to be regarded as a part of the proper tissue of the cornea.

(3) The **Substantia Propria** or proper substance of the cornea forms the main thickness of that structure. It is fibrous, tough, unyielding, perfectly transparent, and continuous with the sclerotic. It is composed of about sixty flattened lamellae, superimposed one on another. These lamellae are made up of bundles of modified connective tissue, the fibres of which are directly continuous with the fibres of the sclerotic. The fibres of each lamella are for the most part parallel with each other; those of alternating lamellae at right angles to each other. Fibres, however, frequently pass obliquely from one lamella to the next (*fibrae arcuatae*).

The lamellae are connected with each other by an interstitial cement-substance, in which are spaces, the **corneal spaces, cell spaces** or **lacunae** (Fig. 718). The spaces are stellate in shape, and have numerous offsets or **canaliculi** (Fig. 718), by which they communicate with each other. Each space contains a cell, the **corneal corpuscle** (Fig. 718), which resembles in form the space in which it is

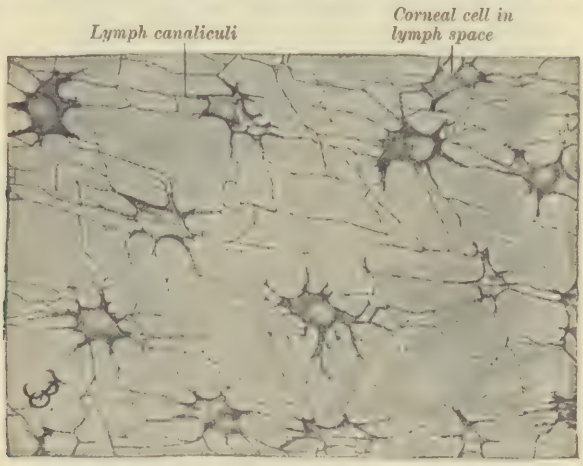

FIG. 718.—From a horizontal section of an ox's cornea. Positive picture of the canal system demonstrated by the gold chloride method. × 450. (Szymonowicz.)

lodged, but it does not entirely fill it, the remainder of the space containing lymph. In the aged the margin of the cornea becomes opaque gray. This rim is called the **arcus senilis**, and is due to fat deposit in the lamellae and corneal corpuscles.

(4) The **Posterior Elastic Lamina**, the **Membrane of Descemet**, or the **Membrane of Demours** (*lamina elastica posterior*), which covers the proper structure of the cornea behind, presents no structure recognizable under the microscope. It consists of an elastic, and perfectly transparent homogeneous membrane, of extreme thinness, which is not rendered opaque by either water, alcohol, or acids. It is very brittle, but its most remarkable property is its extreme elasticity, and the tendency which it presents to curl up, or roll upon itself, with the attached surface innermost, when separated from the proper substance of the cornea. Its use appears to be (as suggested by Dr. Jacob) "to preserve the requisite permanent correct curvature of the flaccid cornea proper."

At the margin of the cornea this posterior elastic membrane breaks up into fibres to form a reticular structure at the outer angle of the anterior chamber, the intervals between the fibres forming small cavernous spaces, the **spaces of Fontana** (*spatia*

anguli iridis) (Fig. 727). These little recesses communicate with a circular canal in the deeper parts of the corneo-scleral junction. This is the **canal of Schlemm** (*sinus venosus sclerae*) (Figs. 716, 723, and 727); it communicates internally with the anterior chamber through the spaces of Fontana, and externally with the scleral veins. Some of the fibres of this reticulated structure are continued into the front of the iris, forming the *ligamentum pectinatum iridis;* while others are connected with the forepart of the sclerotic and choroid.

(5) The **Posterior Layer** or the **Corneal Endothelium** (*endothelium camerae anterioris*) lines the aqueous chamber and prevents the absorption of the aqueous humor. It covers the posterior surface of the elastic lamina, is reflected on to the front of the iris, and also lines the spaces of Fontana. It consists of a single layer of polygonal flattened transparent nucleated cells, similar to those lining other serous cavities.

Arteries and Nerves.—The fœtal cornea contains blood-vessels which pass from the margin almost to the centre. The adult cornea contains no blood-vessels, except at its margin. The capillaries from the sclera and conjunctiva form loops at the corneal margin, and many of these loops enter the cornea for a distance of 1 mm. (Fig. 723). The balance of the cornea is non-vascular and obtains its nourishment from the lymph in the *lacunae* and *canaliculi*. Lymphatic vessels have not as yet been demonstrated in it, but are represented by the channels in which the bundles of nerves run; these channels are lined by endothelium and are continuous with the cell-spaces. The nerves are numerous, twenty-four to thirty-six in number (Kölliker), forty to forty-five (Waldeyer and Sümisch); they are derived from the ciliary nerves; they form the **annular plexus** (*plexus annularis*), at the corneal margin, and enter the laminated tissue of the cornea, lose their medullary sheaths, and ramify throughout the substantia propria as the **fundamental plexus** or the **plexus of the stroma**. From this deep plexus come **perforating fibres** (*fibrae perforantes*), which pass through the anterior elastic lamina and form the **subepithelial plexus**, and from it fibrils are given off which ramify between the epithelial cells, forming a network which is termed the **intra-epithelial plexus**. Nerve-fibres from the annular plexus and from the plexus of the stroma come into close relation with the corneal corpuscles.

Dissection.—In order to separate the sclerotic and cornea, so as to expose the second tunic, the eyeball should be immersed in a small vessel of water and held between the finger and thumb. The sclerotic is then carefully incised, in the equator of the globe, till the choroid is exposed. One blade of a pair of probe-pointed scissors is now introduced through the opening thus made, and the sclerotic divided around its entire circumference, and removed in separate portions. The front segment being then drawn forward, the handle of the scalpel should be pressed gently against it at its connection with the iris, and, these being separated, a quantity of perfectly transparent fluid will escape; this is the aqueous humor. In the course of the dissection the ciliary nerves (Fig. 719) may be seen lying in the loose cellular tissue between the choroid and sclerotic or continued in delicate grooves on the inner surface of the latter membrane.

II. The Choroid, Ciliary Body, and Iris, the Tunica Media, the Uveal Tract (Tunica Vasculosa Oculi) (Figs. 714, 716, 719, 724, 744).

The second or middle tunic of the eye is formed from behind forward by the choroid, the ciliary body, and the iris.

The choroid is the vascular and pigmentary tunic of the eyeball, investing the posterior five-sixths of the globe, and extending as far forward as the *ora serrata* of the retina; the ciliary body connects the choroid to the circumference of the iris. The iris is the circular muscular septum, which hangs vertically behind the cornea, presenting in its centre a large rounded aperture, the **pupil**.

The Choroid (*chorioidea*).—The choroid is a thin, highly vascular membrane, of a dark-brown or chocolate color, which invests the posterior five-sixths of the

globe, and is pierced behind by the optic nerve, and in this situation is firmly adherent to the sclerotic. It is thicker behind than in front. Externally, it is loosely connected by the **lamina fusca** with the inner surface of the sclerotic (p. 1108). Its inner surface is attached to the retina.

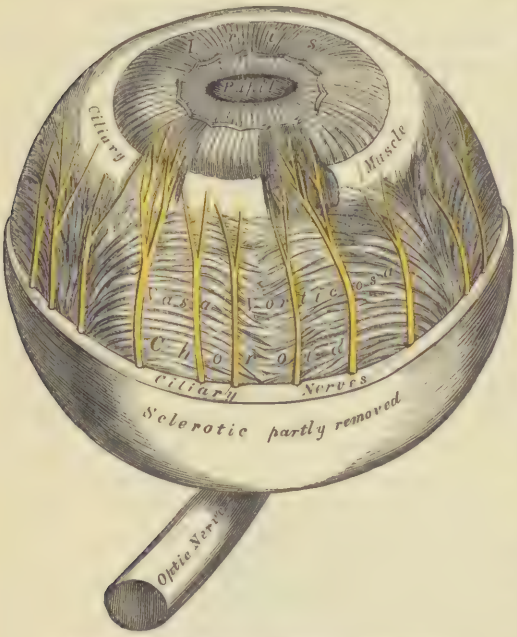

Fig. 719. The choroid and iris. (Enlarged.)

Structure (Fig. 720).—The choroid consists of a dense capillary plexus and of small arteries and veins, carrying the blood to and returning it from this plexus (Fig. 723), and of branched and pigmented cells which lie in connective tissue. There are three layers in the choroid. Named from without inward, they are the **lamina suprachorioidea,** the **choroid proper,** and **lamina basalis** (Fig. 720).

(1) The **Lamina Suprachorioidea** is on the external surface, that is, the surface next to the sclerotic.

It resembles the lamina fusca of the sclerotic. It is composed of delicate non-vascular lamellae, each lamella consisting of a network of fine elastic fibres, among which are branched pigment-cells. The spaces between the lamellae are lined by endothelium, and open freely into the perichoroidal lymph-space, which, in its turn, communicates with the perisclerał space by the perforations in the sclerotic through which the vessels and nerves are transmitted.

(2) The **Choroid Proper** is internal to the lamina suprachorioidea. In consequence of the small arteries and veins of the choroid proper being arranged on the outer surface of the capillary network, it is customary to describe this as consisting of two layers: the **outermost** (*lamina vasculosa*), composed of small arteries and

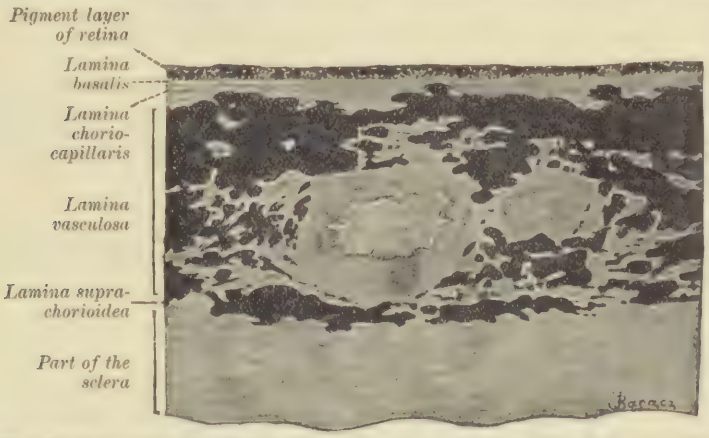

Fig. 720.—Vertical section through the chorioidea and a part of the sclera of an ape. × 440. (Szymonowicz.)

veins, with pigment-cells interspersed between them, and the **inner** (*lamina choriocapillaris*), consisting of a capillary plexus. The **external layer of the choroid proper** or the **lamina vasculosa** consists, in part, of the larger branches of the **short**

posterior ciliary arteries (Figs. 721, 723, and 725), which run forward between the veins, before they bend inward to terminate in the capillaries; but this layer is

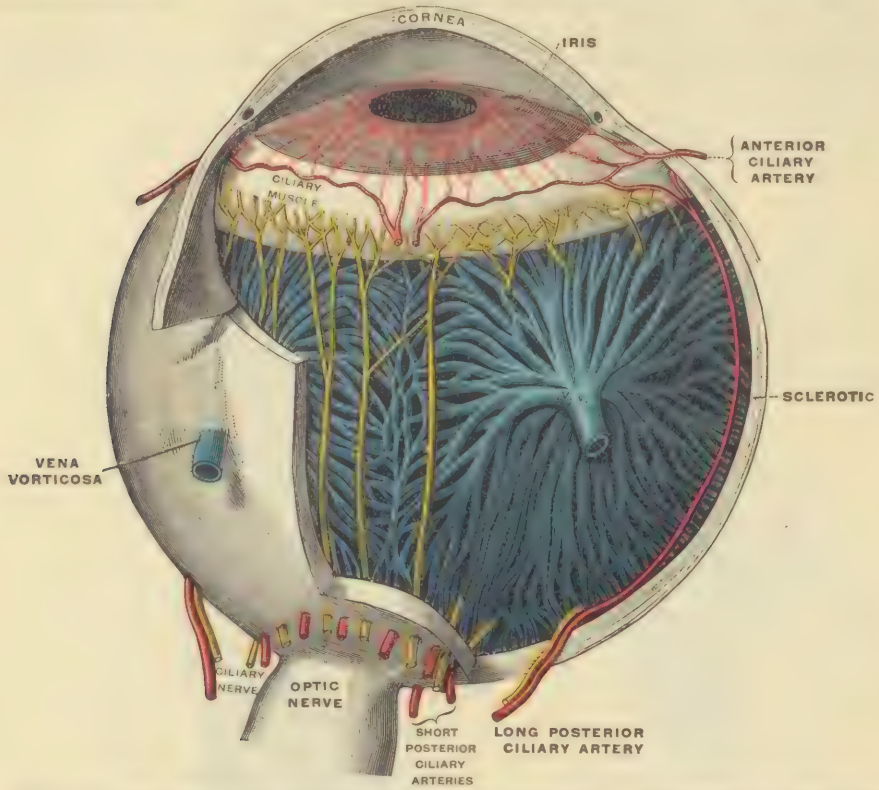

FIG. 721.—Vessels and nerves of the choroid and iris, seen from above. The sclerotic and cornea have been largely removed. (Testut.)

formed principally of veins, which have a whirl-like arrangement and empty into four or five large equidistant trunks, the **venae vorticosae** (Figs. 721, 722, and 723), which pierce the sclerotic midway between the margin of the cornea and the entrance of the optic nerve. Around the veins are **lymph-spaces.** Interspersed between the vessels are dark star-shaped pigment-cells, the offsets from which, communicating with similar branchings from neighboring cells, form a delicate network or stroma, which toward the inner surface of the choroid loses its pigmentary chraacter. The **internal layer of the choroid proper** consists of an exceedingly fine capillary plexus, formed by the short ciliary vessels (Fig. 723), and is known as the **tunic of Ruysch** (*lamina choriocapillaris*).

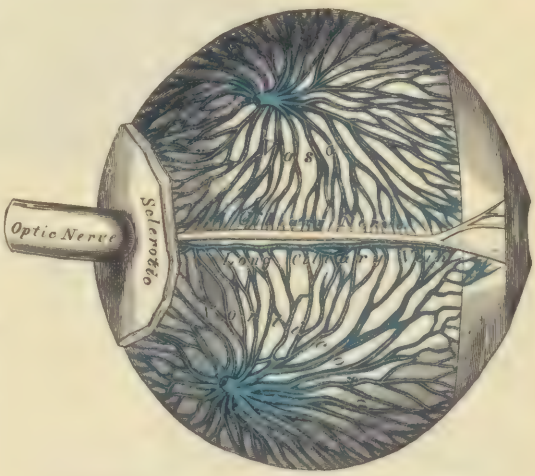

FIG. 722.—The veins of the choroid. (Enlarged.)

The network is close, and finer at the hinder part of the choroid than in front. About half an inch behind the cornea its meshes become larger, and are continuous

with those of the ciliary processes. These two laminae are connected by an **intermediate stratum**, which is destitute of pigment-cells and consists of fine elastic fibres.

On the inner surface of the lamina choriocapillaris is a very thin, structureless, or, according to Kölliker, faintly fibrous membrane, called the **lamina basalis** or **membrane of Bruch**; it is closely connected with the stroma of the choroid, and separates it from the pigmentary layer of the retina.

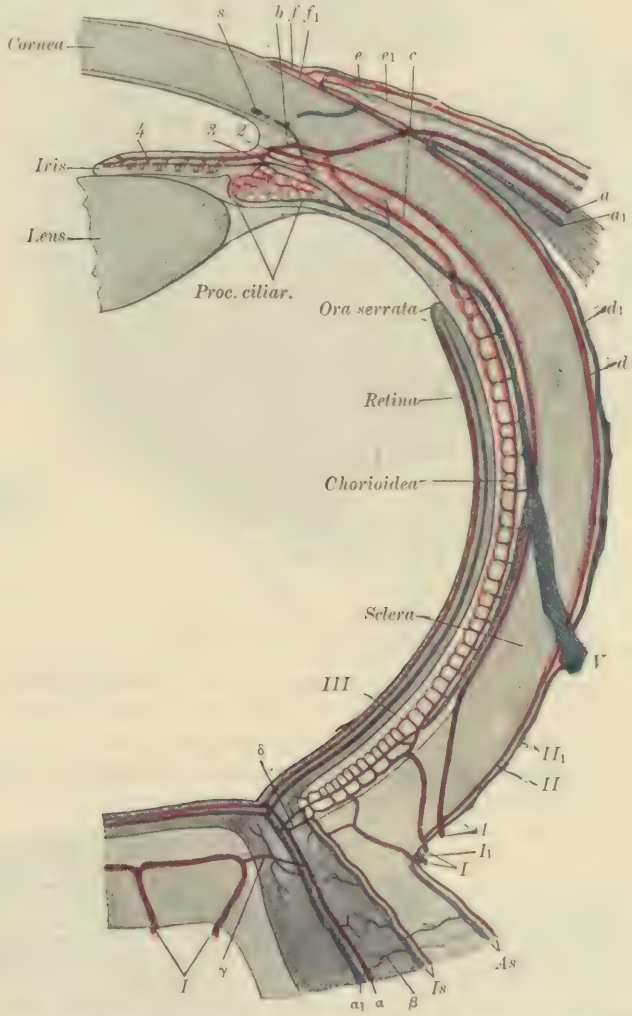

FIG. 723.—Diagram of the blood-vessels of the eye, as seen in a horizontal section. (Leber, after Stöhr.)

Course of vasa centralia retinae: α, arteria, α_1 vena centralis retinae; β, anastomosis with vessels of outer coats; γ, anastomosis with branches of short posterior ciliary arteries; δ, anastomosis with chorioideal vessels.

Course of vasa ciliar. postic. brev.: I, arteriae, and I_1, venae ciliar. postic. brev.; II, episcleral artery; II_1, episcleral vein; III, capillaries of lamina choriocapillaris.

Course of vasa ciliar. postic. long.: 1, a. ciliar. post. longa; 2, circulus iridis major cut across; 3, branches to ciliary body; 4, branches to iris.

Course of vasa ciliar. ant.: a, arteria, a_1, vena ciliar. ant.; b, junction with the circulus iridis major; c, junction with lamina choriocapill.; d, arterial, and d_1, venous episcleral branches; e, arterial, and e_1, venous branches to conjunctiva sclerae; f, arterial, and f_1, venous branches to corneal border; V, vena vorticosa; S, transverse section of sinus venosus sclerae.

Tapetum (*lucidum*).—This name is applied to the iridescent appearance which is seen in the outer and posterior parts of the choroid of many animals, but not in man.

The ciliary body should now be examined. It may be exposed, either by detaching the iris from its connection with the Ciliary muscle, or by making a transverse section of the globe, and examining it from behind.

The Ciliary Body (*corpus ciliare*) (Fig. 716).—The ciliary body or cyclon joins the choroid to the margin of the iris. It is in reality a process of the choroid or uveal tract and comprises the **orbiculus ciliaris**, the **ciliary processes**, and the **Ciliary muscle.**

The Orbiculus Ciliaris or Annulus Ciliaris (Figs. 724, 726, and 742).—The orbiculus ciliaris is a zone of about one-sixth of an inch in width, directly continuous with the anterior part of the choroid. The lamina basalis presents numerous ridges arranged in a radial manner. The depressions between the ridges are filled with retinal pigment epithelium (Szymonowicz). The orbiculus contains no lamina choriocapillaris.

The Ciliary Processes (*processus ciliares*) (Figs. 714, 716, 726, and 744).—The ciliary processes are formed by the plaiting and folding inward of the various layers of the choroid—*i. e.*, the choroid proper and the lamina basalis—at its anterior margin, and are received between corresponding foldings of the suspensory ligament of the lens, thus establishing a connection between the choroid and inner tunic of the eye. They are arranged in a circle, and form a sort of plaited frill, the **corona ciliaris**, behind the iris, round the margin of the lens (Figs. 726 and 744). They vary between sixty and eighty in number, lie side by side, and may be divided into large and small; the latter, consisting of about one-third of the entire number, are situated in the spaces between the former, but without regular alternation. The larger processes are each about one-tenth of an inch in length, and are attached by their periphery to three or four of the ridges of the orbiculus ciliaris, and are continuous with the layers of the choroid; the opposite margin is free, and rests upon the circumference of the lens. Their anterior surface is turned toward the back of the iris, with the circumference of which they are continuous. The posterior surface is connected with the suspensory ligament of the lens.

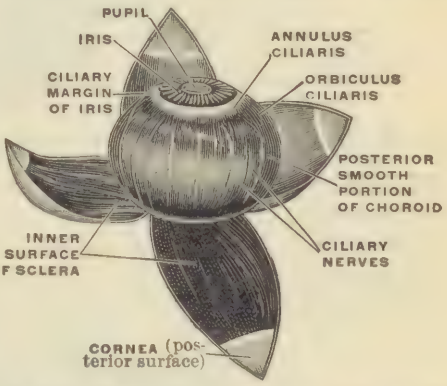

FIG. 724.—The middle or vascular coat of the eyeball exposed from without. Left eye, seen obliquely from above and before. (Toldt.)

Structure.—The ciliary processes are similar in structure to the choroid, but the vessels are larger, and have chiefly a longitudinal direction. They are the most vascular portion of the eyeball. The processes are covered on their inner surface by two strata of black pigment-cells, which are continued forward from the retina, and are named the **pars ciliaris retinae** (Figs. 720 and 727). In the stroma of the ciliary processes there are also stellate pigment-cells, which, however, are not so numerous as in the choroid itself.

The Ciliary Muscle or Bowman's Muscle (*m. ciliaris*) (Figs. 719, 721, 725, 727, 728, and 729).—The ciliary muscle consists of unstriped fibres; it forms a grayish, semitransparent, circular band, about one-eighth of an inch broad, on the outer surface of the forepart of the choroid, between the choroid and the iris and back of the sclero-corneal junction. It is thickest in front and gradually becomes thinner behind. It consists of two sets of fibres, **radiating** and **circular.**

The **Radiating Fibres** (*fibrae meridianales* [*Bruckei*]) (Figs. 727 and 744), much the more numerous, arise at the point of junction of the cornea and sclerotic, and partly also from the ligamentum pectinatum iridis, and, passing backward, are attached to the choroid opposite to the ciliary processes. One bundle, according to Waldeyer, is continued backward to be inserted into the sclerotic.

The **Circular Fibres** (*fibrae circulares* [*Mulleri*]) (Figs. 727 and 744) are internal to the radiating ones and to some extent unconnected with them, and have a circular course around the attachment of the iris. They are sometimes called the "**ring muscle**" **of Muller**, and were formerly described as the **ciliary ligament**. They are well developed in hypermetropic, but are rudimentary or absent in myopic eyes.

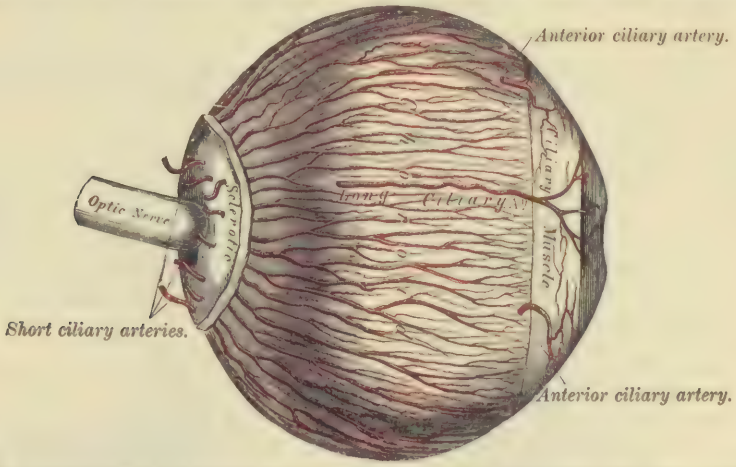

FIG. 725.—The arteries of the choroid and iris. The sclerotic has been mostly removed. (Enlarged.)

The Ciliary muscle is admitted to be the chief agent in accommodation—*i. e.*, in adjusting the eye to the vision of near objects. Bowman believed that this was effected by its compressing the vitreous body, and so causing the lens to advance. At the present time all agree that the chief element in accommodation is altered curvature of the lens, but there is diversity of opinion as to the manner in which

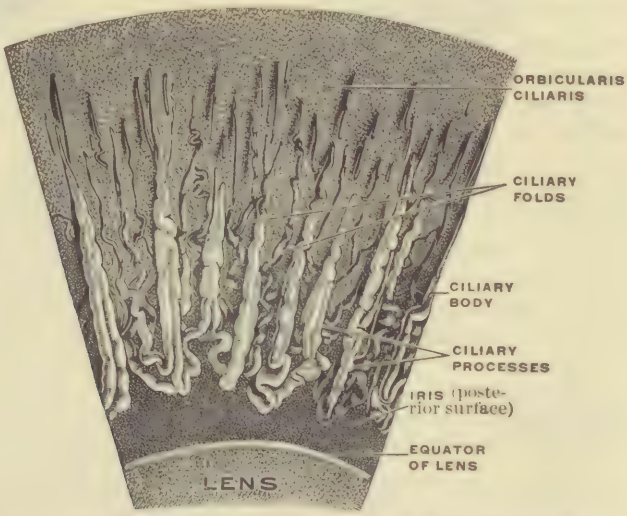

FIG. 726.—A portion of the corona ciliaris magnified. The ciliary processes and the ciliary folds. (Toldt.)

this is accomplished. The view which now prevails is that of Helmholtz. He maintained that in an unaccommodated eye the capsule and suspensory ligament of the lens are tense, and their pressure flattens the anterior surface of the lens, and parallel rays (and rays from objects far off are practically parallel) "are focused on the retina without any sense of effort."[1]

"In accommodation for a near object the meridional or antero-posterior fibres

[1] Stewart, Manual of Physiology.

of the ciliary muscle by their contraction pull forward the choroid and relax the suspensory ligament. The elasticity of the lens at once causes it to bulge forward till it is again checked by the tension of the capsule."[1] The pupil is at the same time slightly contracted.

The Iris (*iris*, a rainbow) (Figs. 716, 719, 721, 723, 724, 727, 728, 729, 730, and 744).—The iris has received its name from its various colors in different individuals. It is a thin, circular-shaped, contractile curtain, suspended in the aqueous humor behind the cornea, and in front of the lens, being perforated a little to the nasal side of its centre by a circular aperture, the **pupil** (*pupilla*) (Fig. 730), for the transmission of light. The pupil of a living person varies in size under the influence of light and in efforts at accommodation. In looking at a near object the pupil is small; in looking at a distant object it is large. In light the pupil contracts, in darkness it dilates; hence the pupil is a window which permits light to pass into the interior of the eye. The size of this window depends on the contraction or relaxation of the iris. The iris divides the **aqueous chamber** (the space between

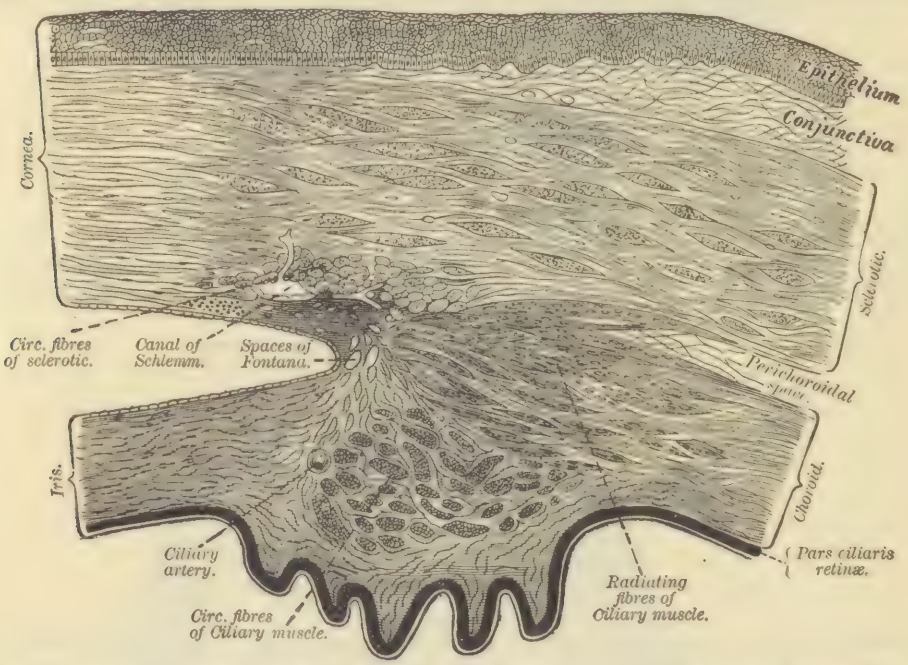

Fig. 727.—Section of the eye, showing the relations of the cornea, sclerotic, and iris, together with the Ciliary muscle and the cavernous spaces near the angle of the anterior chamber. (Waldeyer.)

the cornea and lens) into an **anterior chamber** and a **posterior chamber** which communicate through the pupil (Figs. 714 and 716). By its **circumference** or **ciliary margin** (*margo ciliaris*) (Figs. 727 and 728) the iris is continuous with the ciliary body, and it is also connected with the posterior elastic lamina of the cornea by means of the **pectinate ligament** (*ligamentum pectinatum iridis*) (Fig. 744). The pectinate ligament of the iris is derived from the posterior elastic layer of the cornea. This layer divides into numerous fibrillae and some of them reach the iris, and bridge the angle between the cornea and base of the iris (Deaver). The fibrillae which reach the iris constitute the ligament. In this ligament are numerous lymph-spaces, the **spaces of Fontana** (*spatia anguli iridis* [*Fontanae*]) (Fig. 727), and they join the canal of Schlemm to the anterior chamber of the eye. The inner or free edge of the iris forms the margin of the pupil, and is called the **pupillary margin** (*margo pupillaris*) (Fig. 728). The surfaces of the iris are flattened, and

[1] Stewart, Manual of Physiology.

look forward and backward, the anterior toward the cornea, the posterior toward the ciliary processes and lens. The iris is pigmented and the color of an individual's eyes depends upon this pigment. The **anterior surface** (*facies anterior*) (Figs. 728 and 744) of the iris is variously colored in different individuals, and is marked by lines which converge toward the pupil. The **posterior surface** (*facies posterior*) (Figs 726 and 744) is of a deep-purple tint, from being covered by two layers of pigmented, columnar epithelium, which layers are continuous posteriorly with the pars ciliaris retinae. This pigmented epithelium is termed the **pars iridica retinae,** though it is sometimes named **uvea,** from its resemblance in color to a ripe grape.

Structure.—The iris is composed of the following structures:

1. In front is a layer of flattened endothelial cells placed on a delicate hyaline basement-membrane. This layer is continuous with the endothelial layer covering the membrane of Descemet, and in men with dark-colored irides the cells contain pigment-granules.

2. **Stroma** (*stroma iridis*).—The stroma consists of fibres and cells. The former are made of fine, delicate bundles of fibrous tissue, of which some few fibres have

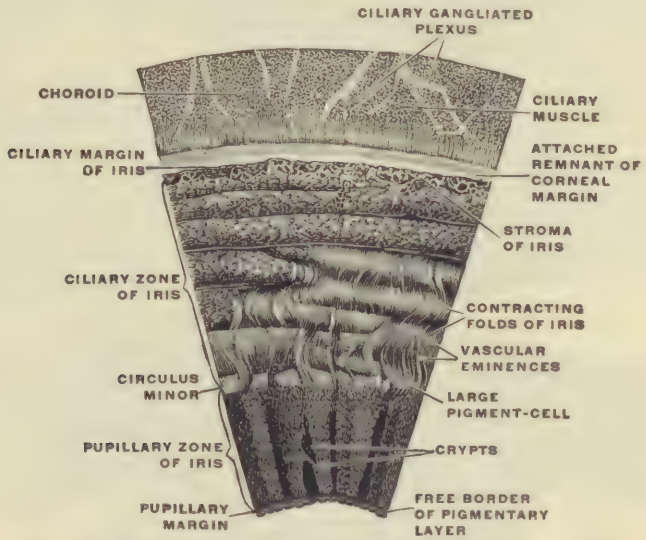

FIG. 728.—Section of the iris. Anterior surface magnified. (Toldt.)

a circular direction at the circumference of the iris, but the chief mass consists of fibres radiating toward the pupil. They form, by their interlacement, a delicate mesh, in which the vessels and nerves are contained. Interspersed between the bundles of connective tissue are numerous branched cells with fine processes. Many of them in dark eyes contain pigment-granules, but in blue eyes and the pink eyes of albinos they are unpigmented.

3. The **Muscular Fibre** is involuntary and consists of **circular** and **radiating fibres.** The **circular fibres** (*m. sphincter pupillae*) surround the margin of the pupil on the posterior surface of the iris, like a sphincter, forming a narrow band about one-thirtieth of an inch in width, those near the free margin being closely aggregated; those more external somewhat separated, and forming less complete circles. The **radiating fibres** (*m. dilator pupillae*) converge from the circumference toward the centre, and blend with the circular fibres near the margin of the pupil. These fibres are regarded by some as elastic, not muscular, but Grunnert positively demonstrated them.[1] The fibres are very small and are placed between the stroma and the posterior layer of endothelium.

[1] Von Graefe's Arch. f. Ophthal., Bd. xlvii.

4. **Pigment.**—The situation of the pigment-cells differs in different irides. In the various shades of blue eyes the only pigment-cells are several layers of small round or polyhedral cells filled with dark pigment, situated on the posterior surface

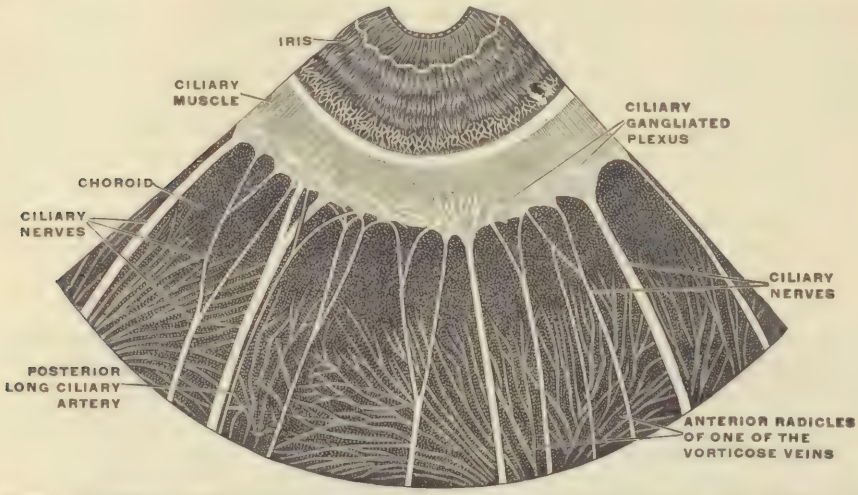

FIG. 729.—The ciliary gangliated plexus and the ciliary nerves entering the plexus. Outer surface of the middle or vascular coat of the eyeball. (Toldt.)

of the iris and continuous with the pigmentary lining of the ciliary processes. The color of the eye in these individuals is due to this coloring-matter showing more or less through the texture of the iris. In the albino even this pigment is absent.

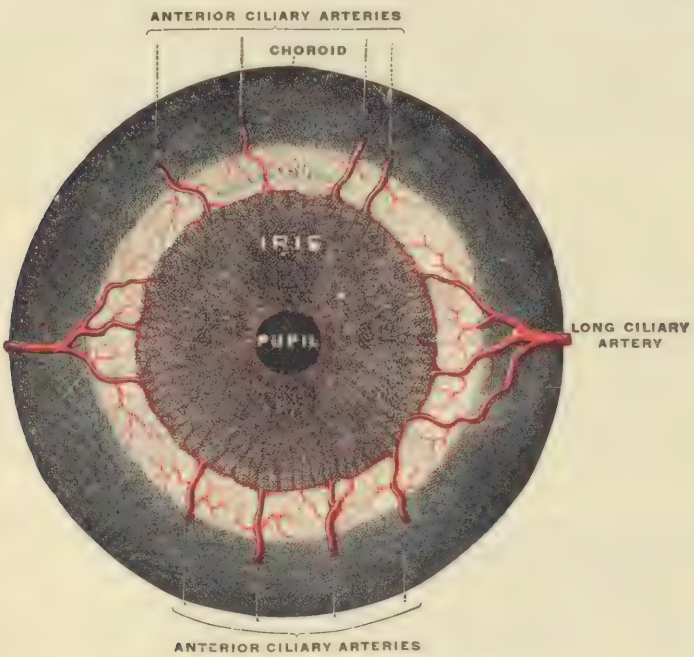

FIG. 730.—Iris, front view. (Testut.)

In the gray, brown, and black eye there are, as mentioned above, pigment-granules to be found in the cells of the stroma and in the endothelial layers on the front of the iris; to these the dark color of the eye is due.

The Arteries of the Iris (Figs. 723, 725, 727, and 730).—The arteries of the iris are derived from the *long posterior ciliary* and *anterior ciliary* and from the vessels of the ciliary processes (see p. 1115). The **long posterior ciliary arteries** (Figs. 721 and 723), two in number, pass through the sclera, one on the inner and one on the outer side of the optic nerve, and pass forward between the sclera and choroid, and, having reached the attached margin of the iris (Figs. 721 and 730), divide into an upper and a lower branch, and, encircling the iris, anastomose with corresponding branches from the opposite side; into this vascular zone (*circulus arteriosus major*) (Fig. 744) the **anterior ciliary arteries** (Fig. 744), from the **lachrymal** and **anterior ciliary** from the muscular branches of the **ophthalmic**, pour their blood. From this zone vessels converge to the free margin of the iris, and these communicate by branches from one to another and thus form a second zone (*circulus arteriosus minor*) in this situation. The *veins* pass toward the ciliary margin and communicate with the veins of the ciliary processes and of the canal of Schlemm (Figs. 721 and 723).

The Nerves of the Choroid and Iris (Figs. 719, 721, and 729).—The nerves of the choroid and iris are the **short ciliary**, the **ciliary branches of the lenticular ganglion**, and the **long ciliary** from the **nasal branch of the opthalmic division of the fifth.** They pierce the sclerotic around the entrance of the optic nerve, and run forward in the perichoroidal lymph-space in which they form a plexus, from which plexus filaments pass to supply the blood-vessels of the choroid. After reaching the iris they form a plexus around its attached margin; from this are derived non-medullated fibres which terminate in the circular and radiating muscular fibres. Their exact mode of termination has not been ascertained. Other fibres from the plexus terminate in a network on the anterior surface of the iris. The fibres derived from the motor root of the lenticular ganglion (third nerve) supply the circular fibres, while those derived from the sympathetic supply the radiating fibres.

Membrana Pupillaris.—In the fœtus the pupil is closed by a delicate transparent vascular membrane, the **membrana pupillaris**, which divides the space into which the iris is suspended into two distinct chambers. This membrane contains numerous minute vessels, continued from the margin of the iris to those on the front part of the capsule of the lens. These vessels have a looped arrangement, and converge toward each other without anastomosing. Between the seventh and eighth months the membrane begins to disappear, by gradual absorption from the centre toward the circumference, and at birth only a few fragments remain. It is said sometimes to remain permanent and produce blindness.

III. The Tunica Interna or Retina (Figs. 723, 731, 733).

The retina is a delicate nervous membrane, in which the fibres of the optic nerve are spread out and upon the surface of which the images of external objects are received. Its outer surface is in contact with the choroid; its inner with the vitreous body. Behind, it is continuous with the optic nerve; it gradually diminishes in thickness from behind forward; and, in front, extends nearly as far as the ciliary body, where it appears to terminate in a jagged margin, the **ora serrata** (Figs. 723, 742, and 744). Here the nervous tissues of the retina end, but a thin prolongation of the membrane extends forward over the back of the ciliary processes and iris, forming the **para ciliaris retinae** and **pars iridica retinae** already referred to (Figs. 727 and 744). This forward prolongation consists of the pigmentary layer of the retina, together with a stratum of columnar epithelium. The portion back of the ora serrata is called the **physiological retina** (*pars optica retinae*) (Fig. 744). The retina is soft, semitransparent, and of a purple tint in the fresh state, owing to the presence of a coloring-material named **rhodopsin** or **visual purple**; but it soon becomes clouded, opaque, and bleached when exposed to sunlight. Exactly in the centre of the front surface of the posterior part of the retina, corresponding to the visual axis, and at a point in which the sense of vision is most perfect, is an oval yellowish

spot, called, after its discoverer, the **yellow spot of Sömmerring** (*macula lutea*) (Figs. 714 and 733), having a central depression, the **fovea centralis.** The retina in the situation of the fovea centralis is exceedingly thin, and the dark color of the choroid is distinctly seen through it; so that it presents more the appearance of a foramen, and hence the name **foramen of Sömmerring** at first given to it. It exists only in man, the quadrumana, and some saurian reptiles. About one-eighth of an inch (3 mm.) to the nasal side of the yellow spot and one-twenty-fourth of an inch below it, is the point of entrance of the optic nerve, the **optic disk** (*porus opticus*) (Figs. 731 and 733). The circumference of the optic disk is slightly raised so as to form an eminence, the **optic papilla** (*colliculus nervi optici*); the central portion is depressed and is called the **optic cup** (*excavatio papillae nervi optici*). The arteria centralis retinae pierces its centre. This is the only part of the surface of the retina from which the power of vision is absent, and is termed the **blind spot.**

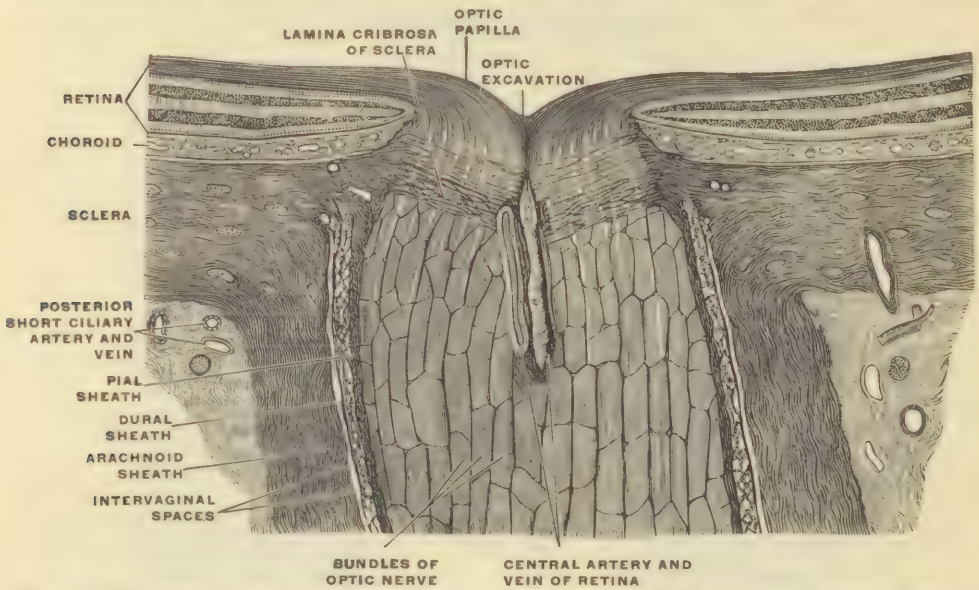

FIG. 731.—The terminal portion of the optic nerve and its entrance into the eyeball, in horizontal section. (Toldt.)

Structure.—The optical portion of the retina is an exceedingly complex structure, and, when examined microscopically by means of sections made perpendicularly to its surface, is found to consist of many layers of nervous structure. These nervous structures are bound together and supported by the **sustentacular fibres.** There are three layers: a **middle** or **neuro-epithelial layer,** an inner layer, and an **outer** or **pigmentary layer.** The neuro-epithelial layer is subdivided into four and the middle layer into six layers; hence the retina consists of eleven layers. The layers from within outward are as follows (Figs. 732, 734, 735, and 736):

1. Inner layer . . .	1. Membrana limitans interna.
	2. Layer of nerve-fibres (stratum opticum).
	3. Ganglionic layer, consisting of nerve-cells.
	4. Inner molecular, or plexiform, layer.
	5. Inner nuclear layer, or layer of inner granules.
	6. Outer molecular, or plexiform, layer.
2. Neuro-epithelial layer	7. Henle's fibre-layer.
	8. Outer nuclear layer, or layer of outer granules.
	9. Membrana limitans externa.
	10. Jacob's membrane (layer of rods and cones).
3. Outer layer	11. Pigmentary layer (tapetum nigrum).

1. The **Membrana Limitans Interna** (Figs. 732, 734, and 735), is the most internal layer of the retina, and is in contact with the hyaloid membrane of the vitreous

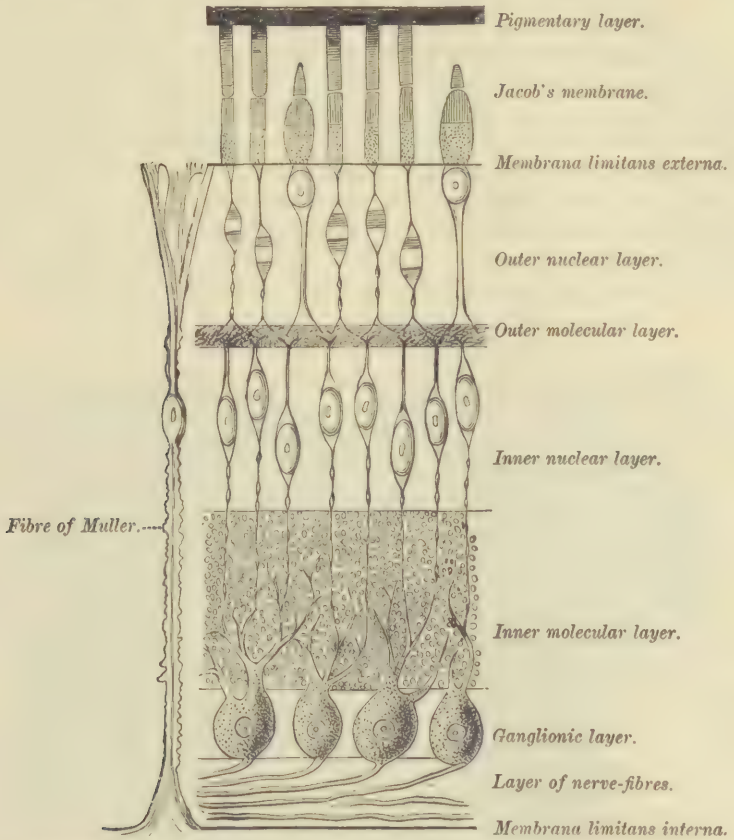

FIG. 732.—The layers of the retina with the exception of Henle's fibre-layer. (Diagrammatic.) (After Schultze.)

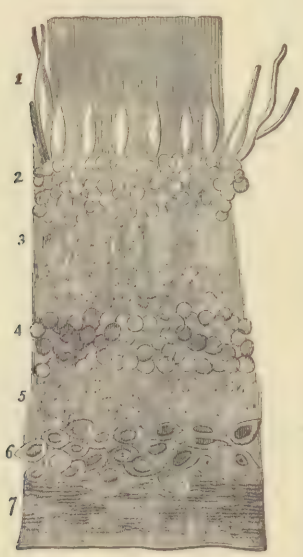
FIG. 733. The arteria centralis retinae, yellow spot, etc., the anterior half of the eyeball being removed. (Enlarged.)

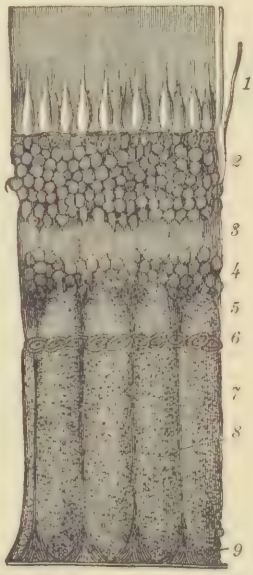
humor. It is derived from the *supporting framework* of the retina, with which tissue it will be described.

2. The **Layer of Nerve-fibres** (Figs. 732, 734, and 735) is formed by the expansion of the optic nerve. This nerve passes through all the other layers of the retina, except the membrana limitans interna, to reach its destination. As the nerve passes through the lamina cribrosa of the sclerotic coat, the fibres of which it is composed lose their medullary sheaths and are continued onward, through the choroid and retina, as simple axis-cylinders. When these non-medullated fibres reach the internal surface of the retina, they radiate from their point of entrance over the surface of the retina, become grouped in bundles, and in many places, according to Michel, arranged in plexuses. Most of the fibres in this layer are **centripetal,** and are the direct continuations of the

axis-cylinder processes of the cells of the next layer. A few of the fibres are **centrifugal**, which are axis-cylinders of ganglion-cells within the brain. The centrifugal fibres in the layer of nerve-fibres pass through it and the next succeeding layer to ramify in the inner molecular and inner nuclear layers, where they terminate in enlarged extremities. The layer is thickest at the optic nerve entrance, and gradually diminishes in thickness toward the ora serrata.

3. The **Ganglionic Layer** or the **Inner Ganglionic Layer** (Figs. 732, 734, and 735) consists of a single layer of large ganglion-cells; except in the macula lutea, where there are several strata. The cells are somewhat flask-shaped, the rounded internal margin of each cell resting on the preceding layer and sending off an axone which is prolonged as a nerve-fibre into the fibrous layer. From the opposite extremity numerous thicker processes (dendrites) extend into the inner molecular layer, where they branch out into flattened arborizations at different levels. The ganglion-cells vary much in size, and the dendrites of the smaller ones, as a rule,





FIGS. 734 and 735. — Vertical sections of the human retina. Fig. 734, half an inch from the entrance of the optic nerve. Fig. 735, close to the latter. 1. Layer of rods and cones, Jacob's membrane, bounded underneath by the membrana limitans externa. 2. Outer nuclear layer. 3. Outer molecular layer. 4. Inner nuclear layer. 5. Inner molecular layer. 6. arborize in the inner molecular layer as soon as they enter it; while the processes of the larger cells ramify close to the inner nuclear layer.

4. The **Inner Molecular**, the **Plexiform** or the **Inner Reticular Layer** (Fig. 732, 734, and 735) is made up of a dense reticulum of minute fibrils, formed by the interlacement of the dendrites of the ganglion-cells with those of the cells contained in the next layer, immediately to be described. Within the reticulum formed by these fibrils a few branched spongioblasts are sometimes embedded.

5. The **Inner Nuclear** or **Inner Granular Layer** (Figs. 732, 734, and 735) is made up of a number of closely packed cells, of which there are three different kinds. (1) A large number of oval cells, which are commonly regarded as **bipolar nerve-cells**, and are much more numerous than either of the other kind. They each consist of a large oval body placed vertically to the surface, and containing a distinct nucleus. The protoplasm is prolonged into two processes; one of these passes inward into the inner molecular layer, is varicose in appearance, and ends in a terminal ramification, which is often in close proximity to the ganglion-cells (Fig. 736, 1, *c*). The outer process passes outward into the outer molecular layer, and there breaks up into a

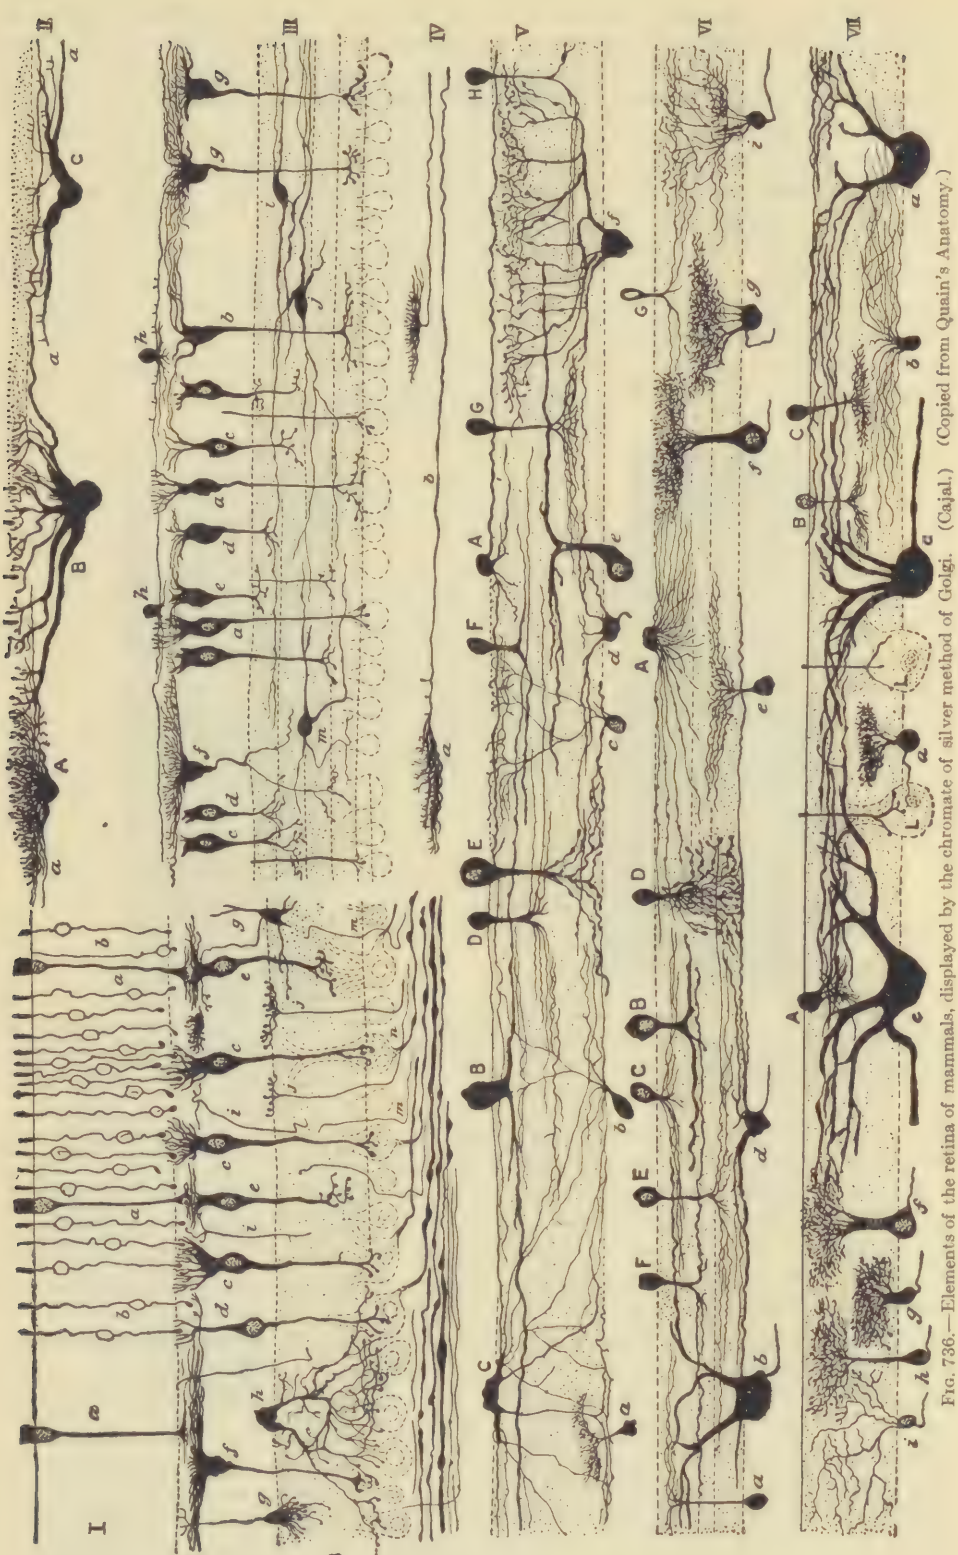

Fig. 736.—Elements of the retina of mammals, displayed by the chromate of silver method of Golgi. (Cajal.) (Copied from Quain's Anatomy.)

number of branches. According to Cajal, there are two varieties of these pipolar cells: one in which the outer process arborizes around the knobbed ends of the rod-fibres, and the inner around the cells of the ganglionic layer; these he calls **rod-bipolars** (Fig. 736, I); the others are those in which the outer process breaks up in a horizontal ramification, in contact with the end of a cone-fibre; these are the **cone-bipolars**, and their inner process breaks up into its terminal ramifications in the inner molecular layer (Fig. 736, I). (2) At the innermost part of this inner nuclear layer is a stratum of cells, which are named Cajal **amacrine cells**, from the fact that they have no axis-cylinder process, but they give a number of short protoplasmic processes which extend into the inner molecular layer and there ramify (Fig. 736, I). There are also at the outermost part of this layer some cells, the processes of which extend into and ramify in the outer molecular layer. These are the **horizontal cells of Cajal.** (3) Some few cells are also found in this layer, connected with the fibres of Müller and will be described with those structures.

6. The **Outer Molecular** or **Outer Reticular Layer** or the **Plexiform Layer** (Figs. 732, 734, and 735) is much thinner than the inner molecular layer; but, like it, consists of a dense network of minute fibrils, derived from the processes of the horizontal cells of the preceding layer and the outer processes of the bipolar cells, which ramify in it, forming arborizations around the ends of the rod-fibres and with the branched foot-plates of the cone-fibres.

7. **Henle's Fibre Layer** is a non-granular layer in the neighborhood of the macula lutea, and is produced by elongations from the inner segments of rod-fibres and cone-fibres.

8. The **Outer Nuclear** or **Outer Granular Layer** (Figs. 732, 734, and 735), like the inner nuclear layer, contains several strata of clear oval nuclear bodies; they are of two kinds, and on account of their being respectively connected with the rods and cones of Jacob's membrane (rod-fibres and cone-fibres) are named **rod-granules** and **cone-granules.**

The **rod-granules** are much the more numerous, and are placed at different levels throughout the layer. Their nuclei present a peculiar cross-striped appearance, and prolonged from either extremity of the granule is a fine process; the outer process is continuous with a single rod of Jacob's membrane; the inner passes inward toward the outer molecular layer and terminates in an enlarged extremity,

---

DESCRIPTION OF FIG. 736.

I. Section of the dog's retina. *a*. Cone-fibre. *b*. Rod-fibre and nucleus. *c, d*. Bipolar cells (inner granules) with vertical ramification of outer processes destined to receive the enlarged ends of rod-fibres. *e*. Bipolars with flattened ramification for ends of cone-fibres. *f*. Giant bipolar with flattened ramification. *g*. Cell sending a neurone or nerve-fibre process to the outer molecular layer. *h*. Amacrine cell with diffuse arborization in inner molecular layer. *i*. Nerve-fibrils passing to outer molecular layer. *j*. Centrifugal fibres passing from nerve-fibre layer to inner molecular layer. *m*. Nerve-fibril passing into inner molecular layer. *n*. Ganglionic cells.

II. Horizontal or basal cells of the outer molecular layer of the dog's retina. A. Small cell with dense arborization. B. Large cell, lying in inner nuclear layer, but with its processes branching in the outer molecular. *a*. Its horizontal neurone. C. Medium-sized cell of the same character.

III. Cells from the retina of the ox. *a*. Rod-bipolars with vertical arborizations. *b, c, d, e*. Cone-bipolars with horizontal ramification of outer process. *h*. Cell lying on the outer surface of the outer molecular layer, and ramifying within it. *i, j, m*. Amacrine cells within the substance of the inner molecular layer.

IV. Neurones or axis-cylinder processes belonging to horizontal cells of the outer molecular layer, one of them, *b*, ending in a close ramification at *a*.

V. Nervous elements connected with the inner molecular layer of the ox's retina. A. Amacrine cell, with long processes ramifying in the outermost stratum. B. Large amacrine with thick processes ramifying in second stratum. C. Flattened amacrine with long and fine processes ramifying mainly in the first and fifth strata. D. Amacrine with radiating tuft of fibrils destined for third stratum. E. Large amacrine, with processes ramifying in fifth stratum. F. Small amacrine, branching into second stratum. G, H. Other amacrines destined for fourth stratum. *a*. Small ganglion-cell sending its processes to fourth stratum. *b*. A small ganglion-cell with ramifications in three strata. *c*. A small cell ramifying ultimately in first stratum. *d*. A medium-sized ganglion-cell ramifying in fourth stratum. *e*. Giant-cell, branching in third stratum. *f*. A bistratified cell ramifying in second and fourth strata.

VI. Amacrines and ganglion-cells from the dog. A. Amacrine with radiating tuft. B. Large amacrine passing to third stratum. C and G. Small amacrines with radiations in second stratum. F. Small amacrine passing to third stratum. D. Amacrine with diffuse arborization. E. Amacrine belonging to fourth stratum. *a, d, e, g*. Small ganglion-cells ramifying in various strata. *b, f*. Large ganglion-cells showing two different characters of arborization. *i*. Bistratified cell.

VII. Amacrines and ganglion-cells from the dog. A, B, C. Small amacrines ramifying in middle of molecular layer. *b, d, g, h, i*. Small ganglion-cells showing various kinds of arborization. *f*. A larger cell, similar in character to *g*, but with longer branch. *a, c, e*. Giant-cells with thick branches ramifying in the first, second, and third layers. L, L. Ends of bipolars branching over ganglion-cells.

and is embedded in the tuft into which the outer process of the rod-bipolars break up. In its course it presents numerous varicosities.

The **cone-granules**, fewer in number than the rod-granules, are placed close to the membrana limitans externa, through which they are continuous with the cones of Jacob's membrane. They do not present any cross-striping, but contain a pyriform nucleus which almost completely fills the cell. From their inner extremity a thick process passes inward to the outer molecular layer, upon which it rests by a somewhat pyramidal enlargement, from which are given off numerous fine fibrils,

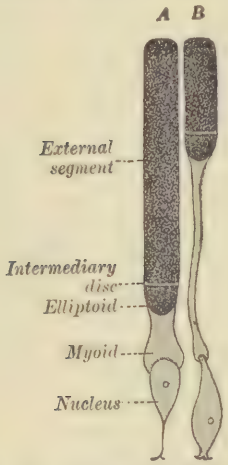

FIG. 737.—The cells of the rods of the retina in the frog. *A*, red rod; *B*, green rod. (Poirier and Charpy.)

which enter the outer molecular layer, where they come in contact with the outer processes of the cone-bipolars.

9. The **Membrana Limitans Externa** (Figs. 732, 734, and 735), like the membrana limitans interna, is derived from the fibres of Müller, with which structures it will be described.

10. **Jacob's Membrane** or the **Layer of Rods and Cones** (Figs. 732, 734, and 735) consists of **visual cells**, and the elements which compose it are of two kinds, **rod-cells** and **cone-cells**, the former being much more numerous than the latter.

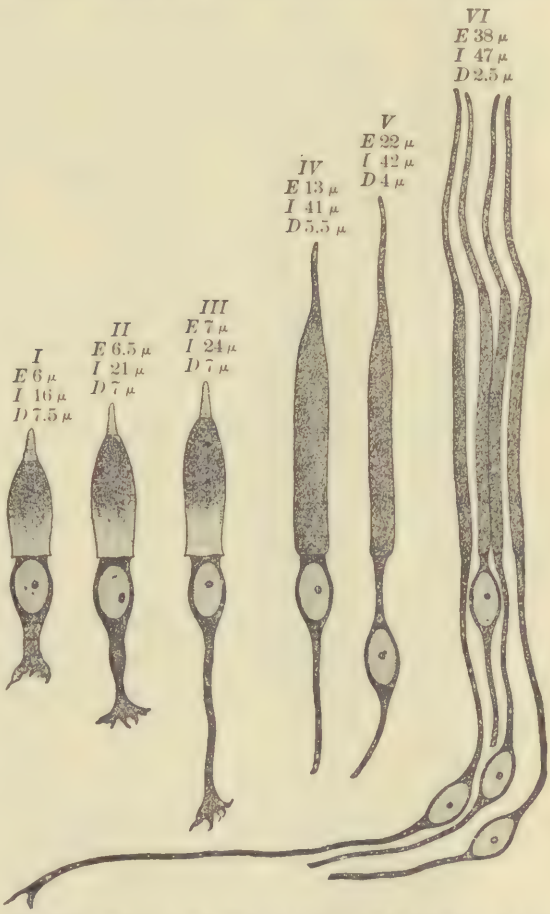

FIG. 738.—Cones in the different regions of the retina. *I*, near the ora serrata; *II*, at 3 mm. from the ora serrata; *III*, at an equal distance from the ora serrata and the papilla; *IV*, at the periphery of the fovea centralis; *V*, in the fovea centralis; *VI*, at the centre of the fovea centralis; *E*, length of the external segment; *I*, length of internal segment; *D*, diameter of the internal segment. (Poirier and Charpy.)

The **rod-cells** (Fig. 737) are of nearly uniform size, and arranged perpendicularly to the surface. A rod-cell consists of a **rod** and a **rod-fibre**, and the fibre contains the nucleus. The rods are cylindrical and each consists of two portions, an **outer segment** and an **inner segment**, which are of about equal length. The segments differ from each other as regards refraction and in their behavior with coloring reagents, the inner portion becoming stained by carmine, iodine, etc., the outer portion remaining unstained with these reagents, but staining yellowish-brown with osmic acid. The outer portion of each rod is marked by transverse striae, and is made up of a number of thin disks superimposed on one another. It also

exhibits faint longitudinal markings. The inner portion of each rod, at its deeper part where it is joined to the outer process of the rod-granule, is indistinctly granular; its more superficial part presents a longitudinal striation, being composed of fine, bright, highly refracting fibres. In most vertebrates the outer portion of the inner segment contains a fibrous body, the **ellipsoid of Krause.** The visual purple, or *rhodopsin*, is found only in the outer segments of the rods. At its inner end each rod is prolonged into a very fine fibre, the **rod-fibre,** which contains a nucleus, and which terminates in the outer nuclear layer, being somewhat enlarged at its termination.

The **cone-cells** (Fig. 738) are conical or flask-shaped, their broad ends resting upon the membrana limitans externa, the narrow pointed extremity being turned to the choroid. Each cone-cell consists of two parts, the **cone** and the **cone-fibre.**

The **cones** are shorter than the rods and exhibit an outer and an inner segment.

The **outer segment** is a short conical process, which, like the outer segment of a rod, presents transverse striae. The inner segment resembles the inner portion of the rods in structure, presenting a superficial striated and deeper granular part; but differs from it in size, being bulged out laterally and presenting a flask shape.

The **inner segment** of the cone, as does the rod, contains an ellipsoid of Krause. Each cone is prolonged into a **cone-fibre,** and at the junction of the cone with the fibre is the nucleus of the cone-cell. The cone-fibre passes to the outer nuclear layer, and terminates as an expansion from which very minute fibrils are given off. The chemical and optical characters of the rod-cells and cone-cells are identical.

11. The **Pigmentary Layer or Tapetum Nigrum** (Fig. 732).—The most external layer of the retina, formerly regarded as a part of the choroid, consists of a single layer of hexagonal epithelial cells, loaded with pigment-granules. Each cell contains a flattened nucleus in the outer portion of the cell which is free from pigment at this point. These cells are smooth externally, where they are in contact with the choroid, but internally they are prolonged into fine, straight processes, which extend between the rods, this being especially the case when the eye is exposed to light. The pigment changes its position under the influence of light, and is distributed through the entire cell. In the eyes of albinos, the cells of the pigmentary layer are present, but they contain no coloring-matter. In the eyes of many mammals also, as in the horse, and many of the carnivora, there is no pigment in the cells of this layer, and the choroid possesses a beautiful iridescent lustre, which is termed the **tapetum lucidum.**

Supporting Framework of the Retina.—Almost all these layers of the retina are connected together by a supporting framework, formed by the **supporting cells** or **supporting fibres of Müller** or **radiating fibres,** from which the *membrana limitans interna et externa* are derived. These fibres are found stretched between the two limiting layers (Fig. 732), "like columns between a floor and a roof," and they pass through all the nervous layers except Jacob's membrane. Each commences on the inner surface of the retina by a conical hollow base, which sometimes contains a spheroidal body which stains deeply with hæmatoxylin, the edges of the bases of adjoining fibres being united and thus forming a boundary line, which is the membrana limitans interna. As they pass through the nerve-fibre and ganglionic layers they give off few lateral branches; in the inner nuclear layer they give off numerous lateral processes for the support of the inner granules, while in the outer nuclear layer they form a network, the **fibre-baskets,** around the rod and cone-fibrils, and unite to form the external limiting membrane at the bases of the rods and cones. In the inner nuclear layer each fibre of Müller presents a clear oval nucleus, which is sometimes situated at the side of, sometimes altogether within, the fibre. The supporting framework of the retina contains neuroglia cells.

The Path of Light Stimuli.—The stimulus is first received by the rod and cone-cells (the visual cells), and is transmitted to the bipolar cells of the inner nuclear layer and then to the cells of the ganglionic layer, which send fibres by way of the optic nerve to the brain.

Macula Lutea and Fovea Centralis.—The structure of the retina at the yellow spot presents some modifications. In the macula lutea (1) the nerve-fibres are wanting as a continuous layer; (2) the ganglionic layer consists of several strata of cells, instead of a single layer; (3) in Jacob's membrane there are no rods, but only cones, and these are longer and narrower than in other parts; and (4) in the outer nuclear layer there are only cone-fibres, which are very long and arranged in curved lines. At the fovea centralis the only parts which exist are the cones of Jacob's membrane, the outer nuclear layer, the cone-fibres of which are almost horizontal in direction, and an exceedingly thin inner granular layer, the pigmentary layer, which is thicker and its pigment more pronounced than elsewhere. The color of the macula seems to imbue all the layers except Jacob's membrane; it is of a rich yellow, deepest toward the centre, and does not appear to consist of pigment-cells, but simply a staining of the constituent parts.

At the **Ora Serrata** (Fig. 723) the nervous layers of the retina terminate abruptly, and the retina is continued onward as a single layer of elongated columnar cells covered by the pigmentary layer. This prolongation is known as the **pars ciliaris retinae** (Fig. 727), and can be traced forward from the ciliary processes on to the back of the iris, where it is termed the **pars iridica retinae** or **uvea.**

From the description given of the nervous elements of the retina it will be seen that there is no direct continuity between the structures which form its different layers except between the ganglionic and nerve-fibre layers, the majority of the nerve-fibres being formed of the axones of the ganglionic cells. In the inner molecular layer the dendrites of the ganglionic layer interlace with those of the cells of the inner nuclear layer, while in the outer molecular layer a like synapsis occurs between the processes of the inner granules and the rod and cone elements.

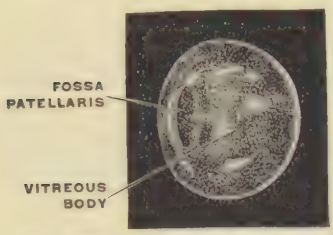

Fig. 739.—The vitreous body removed from the eye in the fresh state, with the saucer-shaped hollow in which the lens lies. Seen obliquely from the side and before. (Toldt.)

The **Arteria Centralis Retinae** (Figs. 723 and 731) and its accompanying vein, **vena centralis retinae,** pierce the optic nerve, and enter the globe of the eye through the porus opticus. It immediately bifurcates into an upper and a lower branch, and each of these again divides into an inner or nasal, and an outer or temporal, branch, which at first run between the hyaloid membrane and the nervous layer; but they soon enter the latter, and pass forward, dividing dichotomously. From these branches a minute capillary plexus is given off, which does not extend beyond the inner nuclear layer. The macula receives small twigs from the temporal branches and others directly from the central artery; these do not, however, reach as far as the fovea centralis, which has no blood-vessels. The branches of the arteria centralis retinae do not anastomose with each other—in other words, they are "terminal arteries." In the fœtus, a small vessel passes forward, through the **hyaloid canal** in the vitreous body, to the posterior surface of the capsule of the lens (Fig. 715).

THE REFRACTING MEDIA.

The Refracting media are three, viz.:

Aqueous humor. Vitreous body. Crystalline lens.

I. The Aqueous Humor (Humor Aqueus).

The aqueous humor completely fills the lymph space known as the **aqueous chamber,** the space which is bounded in front by the cornea and behind by the lens and its suspensory ligament and the ciliary body (Fig. 744). The aqueous chamber

is partly divided by the iris into two communicating parts, the **anterior** and **posterior chambers** (Figs. 714, 715, and 744.) The **posterior chamber** (*cumera oculi posterior*) is only a narrow chink between the peripheral part of the iris, the suspensory ligament of the lens, and the ciliary processes. The **anterior chamber** (*cumera oculi anterior* is bounded in front by the cornea and behind by the iris. The external angle of the anterior chamber is bounded by the periphery of the cornea and of the iris. It is called the **angle** or **sinus of the anterior chamber** or the **filtration angle** (*angulus iridis*). It is by way of the filtration angle that any excess of aqueous humor passes by way of the spaces of Fontana and the canal of Schlemm (Fig. 727) to the anterior ciliary veins and relieves tension. The aqueous humor is small in quantity (scarcely exceeding, according to Petit, four or five grains in weight), has an alkaline reaction, in composition is little more than water, less than one-fiftieth of its weight being solid matter, chiefly chloride of sodium.

In the adult, these two chambers communicate through the pupil; but in the fœtus of the seventh month, when the pupil is closed by the membrana pupillaris, the two chambers are quite separate.

II. The Vitreous Body (Corpus Vitreum) (Figs. 712, 715, 739).

The vitreous body forms about four-fifths of the entire globe. It is composed of a jelly-like tissue containing 98 per cent. water, some salts, and a little albumin, and called the **vitreous humor** (*humor vitreus*), connective-tissue fibres, and connective-tissue cells. It fills the concavity of the retina, and is hollowed in front, forming a deep concavity, the **fossa patellaris** (*fossa hyaloidea*) (Fig. 739), for the reception of the lens. It is perfectly transparent, of the consistence of thin jelly, and is composed of an albuminous fluid enclosed in a delicate transparent membrane, the **hyaloid membrane** (*membrana hyaloidea*), the outside of which is in contact with the membrana limitans interna of the retina. It has been supposed by Hannover, that from its inner surface numerous thin **lamellae** (*stroma vitreum*) are prolonged inward in a radiating manner, forming spaces in which the fluid is contained. In the adult, these lamellae cannot be detected even after careful microscopic examination in the fresh state, but in preparations hardened in weak chromic acid it is possible to make out a distinct lamellation at the periphery of the body; and in the fœtus a peculiar fibrous texture pervades the mass, the fibres joining at the numerous points, and presenting minute nuclear granules at their point of junction. In the centre of the vitreous humor, running from the entrance of the optic nerve to the posterior surface of the lens, is a canal, filled with fluid and lined by a prolongation of the hyaloid membrane. This is the **canal of Stilling**, the **hyaloid canal**, or the **canal of Cloquet** (*canalis hyaloideus*) (Fig. 715), which in the embryonic vitreous humor conveyed the minute vessel from the central artery of the retina to the back of the lens.

The hyaloid membrane encloses the whole of the vitreous humor. In front of the ora serrata it is thickened by the accession of radial fibres and is termed the **zonule of Zinn** (*zonula ciliaris*) (Figs. 742 and 744). It presents a series of radially arranged furrows, in which the ciliary processes are accommodated and to which they are adherent, as evidenced by the fact that when removed some of their pigment remains attached to the zonule. The zonule of Zinn splits into two layers, one of which is thin and lines the fossa patellaris; the other is named the **suspensory ligament of the lens**; it is thicker, and passes over the ciliary body to be attached to the capsule of the lens a short distance in front of its equator. Scattered and delicate fibres are also attached to the region of the equator itself. This ligament retains the lens in position, and is relaxed by the contraction of the radial fibres of the Ciliary muscle, so that the lens is allowed to become more convex. Behind

the suspensory ligament there is a sacculated canal, the **canal of Petit** (*spatia zonularia*); which encircles the margin of the lens and which can be easily inflated through a fine blow-pipe inserted through the suspensory ligament. It is bounded in front by the anterior layer of the suspensory ligament of the lens, behind by the hyaloidea membrana, and internally by the capsule of the lens. The canal of Petit is a lymph-space. All the spaces of the canal of Petit communicate with the posterior chamber of the eye.

In the fœtus, the centre of the vitreous humor presents the hyaloid canal or canal of Stilling, already referred to, which transmits a minute artery, *the hyaloid artery*, to the capsule of the lens. *In the adult*, no vessels penetrate its substance, although a lymph channel remains; so that its nutrition must be carried on by the vessels of the retina and ciliary processes, situated upon its exterior.

III. The Crystalline Lens (Lens Crystallina) (Figs. 716, 723, 740, 741, 742, 743, 744).

The **crystalline lens**, enclosed in its *capsule*, is situated immediately behind the pupil, in front of the vitreous body, and is encircled by the ciliary processes, which slightly overlap its margin.

The **capsule of the lens** (*capsula lentis*) (Fig. 744) is a transparent, highly elastic, and brittle membrane, which closely surrounds the lens, and is composed in part of

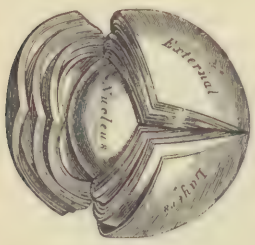

Fig. 740.—The crystalline lens, hardened and divided. (Enlarged.)

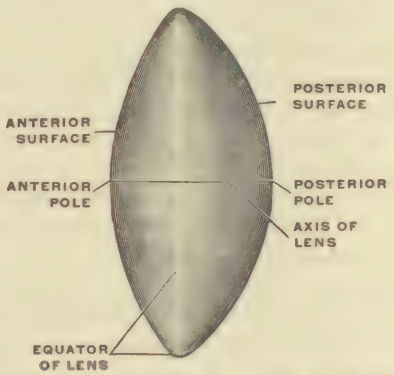

Fig. 741.—The terms used in the orientation of the lens. (Toldt.)

cuticular and in part of connective tissue. It is not white fibrous tissue, and is not true elastic tissue (Szymonowicz). Its outer surface is composed of lamella and possesses transverse striations. It rests, *behind*, in the fossa patellaris in the forepart of the vitreous body (Fig. 739); in *front*, it is in contact with the free border of the iris, this latter receding from it at the circumference, thus forming the **posterior chamber of the eye** (Fig. 744); and it is retained in its position chiefly by the suspensory ligament of the lens, already described (Fig. 744). The capsule is much thicker in front than behind, and when ruptured the edges roll up with the outer surface innermost, like the elastic lamina of the cornea.

The **substance of the lens** (*substantia lentis*) is an epithelial structure and takes origin from the ectoderm. It consists early in development of transparent cylindrical cells, which at a later period become higher at the posterior surface of the lens. Eventually very long cells form; they are known as **lens-fibres** (*fibræ lentis*), and are joined by a cement substance. The adult lens consists of lens-fibres, the anterior surface being covered by one layer of cubical epithelial cells, known as **lens epithelium** (*epithelium lentis*). This layer extends to the margin of the lens, at which point the cells gain in height and form lens-fibres. The lens-fibres at the margin are nucleated, the others are not. The lens-fibres run as meridians from the anterior surface backward. There is no epithelium on the posterior surface.

In the fœtus, a small branch from the arteria centralis retinae runs forward, as already mentioned, through the vitreous humor to the posterior part of the capsule of the lens, where its branches radiate and form a plexiform network, which covers its surface, and they are continuous around the margin of the capsule with the vessels of the pupillary membrane and with those of the iris. In the adult no vessels enter its substance.

Structure.—The lens is a transparent, biconvex body, the convexity being greater on the posterior than on the anterior surface (Fig. 741). The central points of its

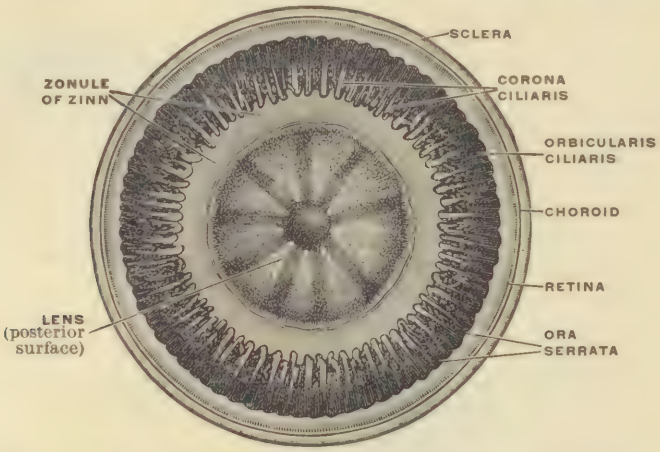

FIG. 742.—The zonule of Zinn or the suspensory ligament of the lens viewed from behind in connection with the lens and the ciliary body. (Toldt.)

anterior and posterior surfaces are known as its **anterior** and **posterior poles** (*polus anterior lentis et polus posterior lentis*) (Fig. 741). It measures from 9 to 10 mm. in the transverse diameter, and about 4 mm. in the antero-posterior. It consists of concentric layers (Fig. 740) of which the external in the fresh state are soft and easily detached (*substantia corticalis*) (Fig. 744); those beneath are firmer, the central ones forming a hardened nucleus (*nucleus lentis*) (Fig. 740). These laminae are best demonstrated by boiling or immersion in alcohol, and consist of minute parallel fibres, which are hexagonal prisms, the edges being dentated, and the

FIG. 743.—Diagram to show the direction and arrangement of the radiating lines on the front and back of the fœtal lens. A, from the front; B, from the back.

dentations fitting accurately into each other; their breadth is about $\frac{1}{5000}$ of an inch. Faint lines radiate from the anterior and posterior poles to the circumference of the lens. In the adult there may be six or more of these, but in the fœtus they are only three in number and diverge from each other at angles of 120° (Fig. 743). On the anterior surface one line ascends vertically and the other two diverge downward and outward. On the posterior surface one ray descends vertically and the other two diverge upward. They correspond with the free edges of an equal number of septa in the lens, along which the ends of the lens-fibres come into

apposition and are joined together by transparent amorphous substance. The fibres run in a curved manner from the septa on the anterior surface to those on the posterior surface. No fibres pass from pole to pole, but they are arranged in such a way that fibres which commence near the pole on the one aspect of the lens terminate near the peripheral extremity of the plane on the other, and *vice versa*. Each fibre of the outer layers of the lens contains a nucleus, and these nuclei form a layer, the **nuclear layer** on the surface of the lens. The nuclear layer is most distinct toward the circumference of the lens.

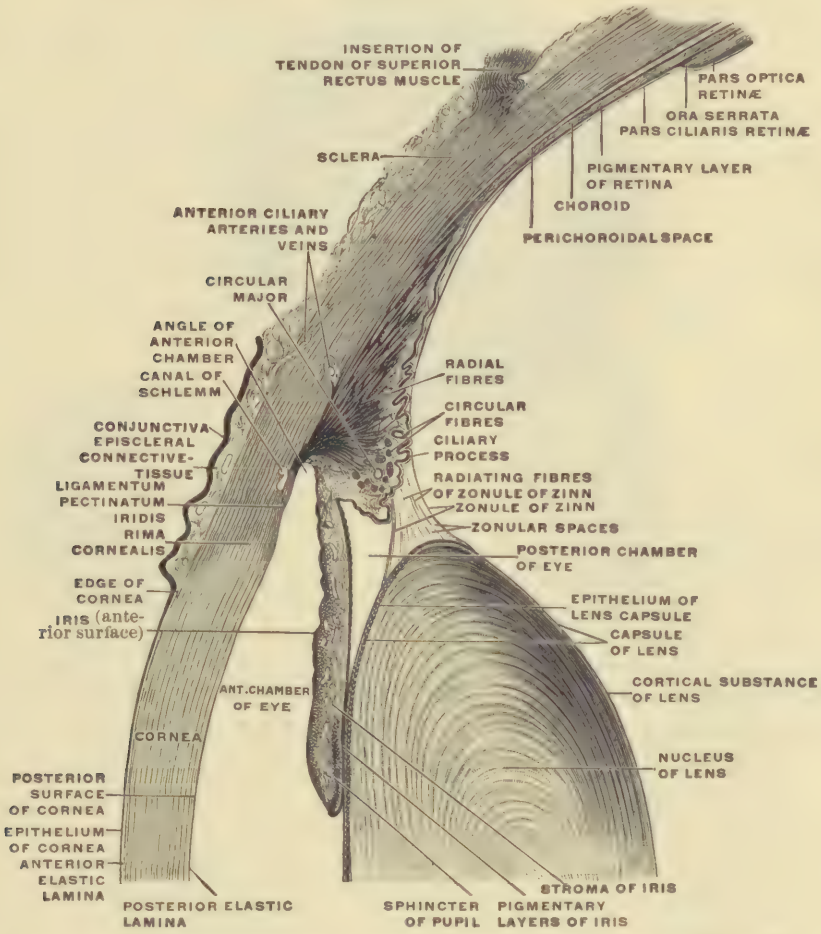

FIG. 744.—The upper half of a sagittal section through the front of the eyeball. (Toldt.)

The *changes produced in the lens by age* are the following:

In the **fœtus** its form is nearly spherical, its color of a slightly reddish tint, it is not perfectly transparent, and is so soft as to break down readily on the slightest pressure.

In the **adult** the posterior surface is more convex than the anterior; it is colorless, transparent, and firm in texture.

In **old age** it becomes flattened on both surfaces, slightly opaque, of an amber tint, and increases in density.

Arteries of the Globe of the Eye.—The arteries of the globe of the eye are the short posterior ciliary, long posterior ciliary, and anterior ciliary arteries, and the arteria centralis retinae.

The **short posterior ciliary arteries** (*aa. ciliares posteriores breves*) (Figs. 721, 723, and 725) are from eight to sixteen in number. They arise from the ophthalmic branch of the internal carotid, pass through the sclerotic coat near the optic nerve, and are distributed to the choroid.

There are two **long posterior ciliary arteries** (*aa. ciliares posteriores longae*) (Figs. 721, 723, and 730), one on each side of the optic nerve. They are branches of the ophthalmic. They pass through the sclerotic external to the short ciliary arteries, and extend forward in the choroid. In the ciliary body they form an anastomosis with the anterior ciliary arteries. The anastomosis is known as the **circulum iridis major** (Figs. 723 and 744). Branches from this circle pass to the iris, and at the periphery of the sphincter of the iris form the **circulum iridis minor.** The muscular branches and the lachrymal branch of the ophthalmic give off the **anterior ciliary arteries** (*aa. ciliares anteriores*), six or eight in number. They pass along tendons of the muscles of the eyeball, reach the sclera, and pass upon the sclera to the corneal margin (Fig. 730). Branches are given off which pass backward to supply the anterior half of the sclera, and which are known as **episcleral arteries** (*aa. episclerales*) (Fig. 723). Two branches are given off which pass forward to the conjunctiva bulbi, which are known as the **anterior conjunctival arteries** (*aa. conjunctivales anteriores*), which anastomose with the posterior conjunctival branches from the palpebral arteries, and which give branches to the delicate vascular network of the corneal margin which is in the annulus conjunctivae (Spalteholz). Eight or even more branches form the anterior ciliary arteries. They pass through the sclerotic near the sclero-corneal junction, and participate in the formation of the circulum iridis major.

The Veins of the Globe of the Eye (Figs. 721, 722, and 723).—The veins are seen on the outer surface of the choroid. They have a whorl-like formation and empty into four or five large veins, the **venae vorticosae.** These four, five, or six equidistant venae vorticosae pierce the sclerotic midway between the margin of the cornea and the entrance of the optic nerve, and empty into the ophthalmic vein. Another set of veins accompany the anterior ciliary arteries, and are known as the **anterior ciliary veins** (*vv. ciliares anteriores*). They are derivatives of the venous sinus of the sclera in the canal of Schlemm. They form a circular plexus. They receive vessels, the ciliary muscle, and pass through the sclera close to the corneal margin. **Posterior ciliary veins** (*vv. ciliares posteriores*) receive vessels which gather venous blood from the outer surface of the sclera near the optic nerve. The posterior ciliary veins join anteriorly with the venae vorticosae. After emerging from the sclera they receive anterior conjunctival branches, and by means of episcleral veins communicate with the venae vorticosae.

The Lymphatic Passages of the Eyeball.—The conjunctiva contains lymph-vessels. The eyeball contains lymph-spaces, but no lymph-vessels

There are two sets of lymph-spaces in the eyeball, the anterior and posterior.

The **anterior lymph-spaces** are the spaces of the cornea, of the iris, of the anterior chamber, and of the posterior chamber.

The lymph from the intralamellar lymph-spaces of the cornea enters the conjunctival lymphatics at the margin of the cornea.

The lymph-spaces of the iris open into the anterior chamber by the crypts of the iris and at the margin of the iris join the spaces of Fontana.

The aqueous humor fills the anterior and posterior chambers, but is furnished by the vessels in the posterior chamber; in part by the vessels of the ciliary body, and in part by the vessels of the posterior surface of the iris. The lymph thus secreted passes by way of the pupil into the anterior chamber, and then is taken up by the spaces of Fontana, the canal of Schlemm, and the anterior ciliary veins.[1]

[1] Deaver's Anatomy.

The **posterior lymph-spaces** are the hyaloid canal, the perichoroidal lymph-space, the space of Ténon, the intervaginal space of the optic nerve, and the supravaginal space (Deaver).

The **hyaloid canal** (Figs. 712 and 715) passes between the posterior surface of the lens and the optic disk. In the embryo the canal holds an artery, the hyaloid artery. During development the artery disappears, but a lymph channel remains. The hyaloid canal opens into the intervaginal space of the optic nerve. Between the sclerotic and the choroid is the **perichoroidal lymph-space** (Fig. 744). It is around the choroid vessels and the venae vorticosae, and empties into Ténon's space by means of openings through the sclera about the venae vorticosae.

Ténon's space (Figs. 712 and 713) is between the sclera and the capsule of Ténon. It receives lymph from the perichoroidal space, and empties into the supravaginal space.

The optic nerve (Fig. 731) has a sheath of dura and a sheath of pia, and between these sheaths is the **intervaginal lymph-space**. It is divided by a prolongation of the cerebral arachnoid into a **subdural space** and a **subarachnoid space**, which empty into the corresponding spaces of the membranes of the brain.

The **supravaginal space** is between the dural portion of the sheath of the optic nerve and a posterior prolongation of Ténon's capsule.[1]

The Nerves of the Globe of the Eye.—The **long ciliary nerves** (*nn. ciliaris longi*), two in number, are derived from the nasal branch of the ophthalmic and the **short ciliary nerves** (*nn. ciliares breves*), twelve to fifteen in number, are derived from the ciliary or ophthalmic ganglion. Both the long and short ciliary nerves perforate the sclera in the neighborhood of the optic nerve (Fig. 721). They pass along the perichoroidal lymph-space, forming a plexus, and send filaments to the choroid vessels. In front of the Ciliary muscle they form a second plexus, and from it come branches which go to the Ciliary muscle and the muscular fibres and vessels of the iris, sclera, choroid, ciliary body, and iris (Fig. 729). The ciliary nerves supply the cornea. The circular fibres of the iris are innervated by the third nerve and the radiating fibres by the sympathetic.

Surgical Anatomy.—From a surgical point of view the cornea may be regarded as consisting of three layers: (1) of an external epithelial layer, developed from the epiblast, and continuous with the external epithelial covering of the rest of the body, and therefore in its lesions resembling those of the epidermis; (2) of the cornea proper, derived from the mesoblast, and associated in its diseases with the fibro-vascular structures of the body; and (3) the posterior elastic layer with its endothelium, also derived from the mesoblast and having the characters of a serous membrane, so that inflammation of it resembles inflammation of the other serous and synovial membranes of the body.

The *cornea* contains no blood-vessels, except at its periphery, where numerous delicate loops, derived from the anterior ciliary arteries, may be demonstrated on the anterior surface of the cornea. The rest of the cornea is nourished by lymph, which gains access to the proper substance of the cornea and the posterior layer through the spaces of Fontana. This lack of a direct blood-supply renders the cornea very apt to inflame in the cachectic and ill-nourished. In spite of the absence of blood-vessels, wounds of the cornea usually heal rapidly. A wound which penetrates the cornea opens the anterior chamber, and aqueous humor escapes. An *ulcer* may also open the anterior chamber. Through a wound or a perforated ulcer the pupillary margin of the iris may prolapse. A trivial injury of the cornea is repaired by transparent tissue. A severe injury is repaired by fibrous tissue, and *opacity* results. A slight opacity resembling a cloud of gray smoke is called *nebula;* a more marked white opacity is called *leucoma.*

In *abscess of the cornea* pus gravitates between the layers to the lower part of the cornea and the purulent collection assumes a crescentic shape (*onyx*).

The *arcus senilis*, seen in the aged, is a condition of haziness or opacity at the corneal margin due to fatty degeneration of the tissue of the cornea. It signifies interference with the blood-supply, because of senile degeneration of adjacent vessels. In cases of *granular lids* there is a peculiar affection of the cornea, called *pannus*, in which the anterior layers of the cornea become vascularized, and a rich network of blood-vessels may be seen on the cornea; and in *interstitial keratitis* new vessels extend into the cornea, giving it a pinkish hue, to which the term *salmon patch* is applied. The cornea is richly supplied with nerves, derived from the ciliary nerves, which

[1] For the lymphatic channels of the eyeball see Deaver's Surgical Anatomy, vol. ii. p. 392.

enter the cornea through the forepart of the sclerotic and form plexuses in the stroma, terminating between the epithelial cells by free ends or in corpuscles. In cases of *glaucoma* the ciliary nerves may be pressed upon as they course between the choroid and sclerotic (Fig. 719), and in consequence of the pressure upon them, the cornea, to which they are distributed, becomes anæsthetic. When a scar forms on the cornea and the iris becomes adherent, the scar and the iris, and sometimes even the lens, may bulge forward from intraocular tension. This condition is *staphyloma of the cornea*. In conditions of impaired nutrition the cornea may be bulged forward by intraocular pressure. The line of least resistance is a little below the centre of the cornea, and it is bulged forward and strongly curved. This condition is known as *conical cornea*. The sclerotic has very few blood-vessels and nerves. The blood-vessels are derived from the anterior ciliary, and form an open plexus in its substance. As they approach the corneal margin this arrangement is peculiar. Some branches pass through the sclerotic to the ciliary body; others become superficial and lie in the episcleral tissue, and form arches, by anastomosing with each other, some little distance behind the corneal margin. From these arches numerous straight vessels are given off, which run forward to the cornea, forming its marginal plexus. In *inflammation of the sclerotic* and *episcleral tissue* these vessels become conspicuous, and form a pinkish zone of straight vessels radiating from the corneal margin, commonly known as the *zone of ciliary injection*. In *inflammation of the iris and ciliary body* this zone is present, since the sclerotic speedily becomes involved when these structures are inflamed. But in *inflammation of the cornea* the sclerotic is seldom much affected, though the cornea and sclerotic are structurally continuous. This would appear to be due to the fact that the nutrition of the cornea is derived from a different source from that of the sclerotic. The *sclerotic* may be *ruptured subcutaneously* without any laceration of the conjunctiva, and the rupture usually occurs near the corneal margin, where the tunic is thinnest. It may be complicated with lesions of adjacent parts—laceration of the choroid, retina, iris, or suspensory ligament of the lens—and is then often attended with hemorrhage into the anterior chamber, which masks the nature of the injury. In some cases the lens has escaped through the rent in the sclerotic, and has been found under the conjunctiva. *Wounds of the sclerotic*, if they do not perforate, usually heal readily. If they extend through the sclerotic they cause diminished tension, are always dangerous, and are often followed by inflammation, suppuration, and by sympathetic ophthalmia. The sclerotic may be weakened by injury, inflammation, etc., and the weakened portion may bulge from intraocular pressure, and even a healthy sclera may bulge from excessive intraocular pressure. According to its situation the lesion is known as *ciliary staphyloma, equatorial staphyloma,* or *posterior staphyloma.*

One of the functions of the *choroid* is to provide nutrition for the retina and to convey vessels and nerves to the ciliary body and iris. *Inflammation of the choroid* is therefore followed by grave disturbance in the nutrition of the retina, and is attended with early interference with vision. *Purulent choroiditis* is not confined to the choroid; the retina, the vitreous, and the entire uveal tract become involved, and even other structures may suffer. In its diseases it bears a considerable analogy to those which affect the skin, and, like it, is one of the places from which *melanotic sarcomata* may grow. These tumors contain a large amount of pigment in their cells, and grow only from those parts where pigment is naturally present. The *choroid* may be *ruptured* without injury to the other tunics, as well as participating in general injuries of the eyeball. In cases of uncomplicated rupture the injury is usually at its posterior part, and is the result of a blow on the front of the eye. It is attended by considerable hemorrhage, which for a time may obscure vision, but in most cases this is restored as soon as the blood is absorbed.

The *iris* is the seat of a malformation, termed *coloboma*, which consists in a deficiency or cleft, which in a great number of cases is clearly due to an arrest in development. In these cases it is found at the lower aspect, extending directly downward from the pupil, and the gap frequently extends through the choroid to the entrance of the optic nerve. In some rarer cases the gap is found in other parts of the iris, and is then not associated with any deficiency of the choroid. The *iris* is abundantly supplied with blood-vessels and nerves, and is therefore very prone to become *inflamed*. And when inflamed, in consequence of the fact that the iris and ciliary body are continuous, and that their vessels communicate, *iritis* is usually associated with *cyclitis*, the disease being called *irido-cyclitis*. And, in addition, inflammation of adjacent structures, the cornea and sclerotic, is apt to spread into the iris. The iris is covered with endothelium, and partakes of the character of a serous membrane, and, like these structures, is liable to pour out a plastic exudation when inflamed, and contract adhesions, either to the cornea in front (*synechia anterior*), or to the capsule of the lens behind (*synechia posterior*). In iritis the lens may become involved, and the condition known as *secondary cataract* may be set up. *Tumors* occasionally commence in the iris; of these, *cysts*, which are usually congenital and *sarcomatous tumors*, are the most common and require removal. *Gummata* are not unfrequently found in this situation. In some forms of injury of the eyeball, as the impact of a spent shot, the rebound of a twig, or a blow with a whip, the iris may be *detached* from the Ciliary muscle, the amount of detachment varying from the slightest degree to the separation of the whole iris from its ciliary connection.

The *Argyll-Robertson pupil* shows no reaction to light, but retains reaction to accommodation and vision remains good.

The *retina*, with the exception of its pigment-layer and its vessels, is perfectly transparent, and is invisible when examined by the ophthalmoscope, so that its diseased conditions are recognized by its loss of transparency. In *retinitis*, for instance, there is more or less dense and extensive opacity of its structure, and not unfrequently extravasations of blood into its substance. Hemorrhages may also take place into the retina from rupture of a blood-vessel without inflammation.

In *optic neuritis*, *papillitis*, or *choked disk*, the ophthalmoscope shows increase in vascularity, and swelling and opacity of the nerve, which extend beyond the disk margins. Optic atrophy is apt to follow. (Fig. 745 shows a normal optic disk.)

The *retina* may become *displaced* from effusion of serum between it and the choroid or by blows on the eyeball, or may occur without apparent cause in *progressive myopia*, and in this case the ophthalmoscope shows an opaque, tremulous cloud. *Glioma*, a form of sarcoma, and essentially a disease of early life, is occasionally met with in connection with the retina.

The *lens* has no blood-vessels, nerves, or connective tissue in its structure, and therefore is not subject to those morbid changes to which tissues containing these structures are liable. It does, however, present certain morbid or abnormal conditions of various kinds. Thus, variations in shape, absence of the whole or a part of the lens, and displacements are amongst its *congenital defects*. *Opacities* may occur from injury, senile changes, malnutrition, or errors in growth or development. An opacity of the capsule, of the lens, or of both, is known as a *cataract*. *Senile changes* may take place in the lens, impairing its elasticity and rendering it harder than in youth,

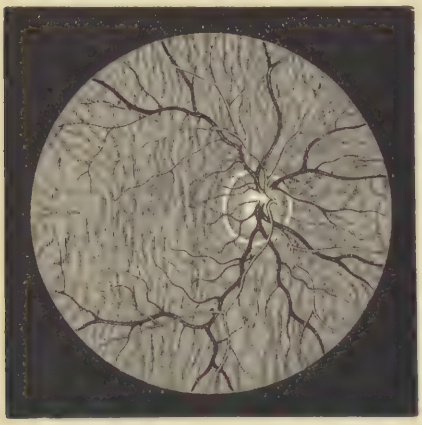

FIG. 745.—Ophthalmoscopic appearances of healthy fundus in a person of very fair complexion. Scleral ring well marked. Left eye, inverted image. (Wecker and Jaeger.)

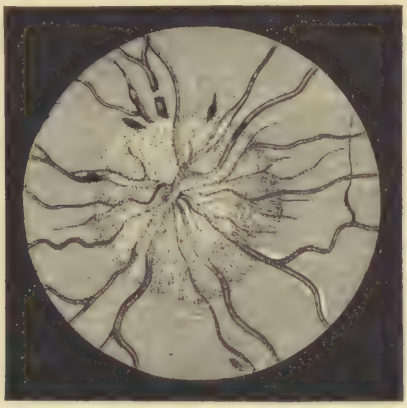

FIG. 746.—Ophthalmoscopic appearance of severe recent papillitis. Several elongated patches of blood near border of disk. (After Hughlings Jackson.)

so that its curvature can only be altered to a limited extent by the Ciliary muscle. And, finally, the lens may be *dislocated* or displaced by blows upon the eyeball, and its relations to surrounding structures altered by adhesions or the pressure of new growths.

There are two particular regions of the eye which require special notice: one of these is known as the "filtration area," and the other as the "dangerous area." The *filtration area* is the circumcorneal zone immediately in front of the iris. Here are situated the cavernous spaces of Fontana, which communicate with the canal of Schlemm, through which the chief transudation of fluid from the eye is now believed to take place. The *dangerous area of the eye* is the region in the neighborhood of the ciliary body, and wounds or injuries in this situation are peculiarly dangerous; for inflammation of the ciliary body is liable to spread to many of the other structures of the eye, especially to the iris and choroid, which are intimately connected by nervous and vascular supplies. Moreover, wounds which involve the ciliary region are especially liable to be followed by sympathetic ophthalmia, in which destructive inflammation of one eye is excited by some irritation in the other.

Emmetropia is normal vision. In normal vision the practically parallel light rays from distant objects focus on the retina without effort; divergent rays from near objects are focused on the retina by an effort of accommodation.

Hyperopia or *hypermetropia* is far-sightedness. In this condition the retina is in front of the principal focus when the eye is at rest. The patient endeavors to correct the failure by constant and tiresome efforts at accommodation. The condition is usually due to inordinate shortness of the axis of the eye, but may be due to loss of the lens, decreased convexity of the refractive surfaces, or lessened refractive power in the refractive media of the eye. It is corrected by the use of convex glasses.

Myopia is near-sightedness. In this condition the rays of light come to a focus in front of the retina, and the patient is subjected to continued eye-strain. It is usually due to too great length of the axis of the eye, but may result from increase in refractive power of refractive media. It is corrected by concave glasses. Sometimes, as a person with hyperopia begins to age, an increased refractive power of the lens causes myopia. The occurrence of myopia in a hyperopic eye is called *second sight*, and it enables the individual to cease wearing convex glasses.

Exenteration of the contents of the orbit means removal of all the contents except those at the orbital apex. Even the periosteum is taken away. It is performed for malignant disease.

Evisceration of the eyeball is performed by making a circular incision at the corneal margin and removing the internal and middle coats and the contents of the globe. The sclera is not removed. A glass ball is inserted into the scleral sheath, and the sclera is closed over the ball by vertical stitches, and the conjunctiva is closed over it by transverse stitches. The operation is performed for leucoma or staphyloma of the cornea. An artificial eye (a shell) is placed over the stump when healing is complete.

Enucleation, or *excision of the eyeball*, differs from exenteration of the *orbital contents* in the fact that only the eyeball is removed. A circular incision through the ocular conjunctiva is carried around and near to the corneal margin. The conjunctiva and capsule of Ténon are pushed back and the Rectus muscles are clamped and divided back of the clamp. Traction is made upon the globe in a forward and inward direction, and the optic nerve and adjacent structures are cut with scissors from the outer aspect of the globe. The eye is then pulled out of the orbit, and all structures which tend to retain it are divided. The stumps of the Recti muscles are sewed together.

THE APPENDAGES OF THE EYE (TUTAMINA OCULI).

The appendages of the eye include the **eyebrows**, the **eyelids**, the **conjunctiva**, and the **lachrymal apparatus**—viz., the **lachrymal gland**, the **lachrymal sac**, and the **nasal duct**.

The Eyebrow (Supercilium).

The eyebrows are two arched eminences of integument which surmount the upper circumference of the orbit on each side, and support numerous short, thick hairs, directed obliquely on the surface. The hairs may entangle foreign bodies and lessen somewhat the force of blows. In structure the eyebrows consist of thickened integument, connected beneath with the Orbicularis palpebrarum, Corrugator supercilii, and Occipito-frontalis muscles. These muscles serve, by their action on this part, to control to a certain extent the amount of light admitted into the eye.

The Eyelid (Palpebra) (Figs. 747, 748).

The eyelids are two thin, movable folds placed in front of the eye, and by closure protecting the eye from injury. The eyelids are composed of skin, superficial fascia, and alveolar tissue, fibres of the Orbicularis palpebrarum muscle, palpebral and orbito-tarsal ligaments, tarsal cartilages, and conjunctiva. The upper lid also contains the Levator labii superioris muscle. In the lids are blood-vessels, lymph-vessels, nerves, and Meibomian glands. There are two lids, the **upper** (*palpebra superior*) and the **lower** (*palpebra inferior*). The upper lid is the larger and the more movable of the two, and is furnished with a separate elevator muscle, the **Levator palpebrae superioris**. Each lid consists of two portions. The part near the orbital margin, "whose groundwork is formed merely by the **thin palpebral fascia** (*septum orbitale*),"[1] is called the **orbital portion** (*pars orbitalis*). The part in which the tarsus lies is called the **tarsal portion** (*pars tarsalis*). Between the two portions in each lid is a sulcus, called, in the upper lid, the **superior orbito-palpebral sulcus** (*sulcus orbitopalpebralis superior*), and, in the lower lid, the **inferior orbito-palpebral sulcus** (*sulcus orbitopalpebralis inferior*). When the eyelids are

[1] An Atlas of Human Anatomy. By Carl Toldt, assisted by A. D. Rosa. Translated by M. Eden Paul.

opened an elliptical space, the **interpalpebral slit** (*fissura palpebrarum*), is left between their margins, the angles of which correspond to the junction of the upper and lower lids, and are called **canthi**.

The Canthi.—The **outer canthus** (*angulus oculi lateralis*) is more acute than the inner, and the lids here lie in close contact with the globe; but the **inner canthus** (*angulus oculi medialis*) is prolonged for a short distance inward toward the nose. The two lids are separated at the inner canthus by a triangular space, the **lacus lacrimalis**. At the commencement of the lacus lacrimalis, on the margin of each eyelid, is a small conical elevation, the **lachrymal papilla**, the apex of which is pierced by a small orifice, the **punctum lacrimale** (Fig. 751), the commencement of the lachrymal canal (Fig. 750). When the lids are closed a space remains between them and the globe to permit of the flow of tears inward (*rivus lacrimalis*).

The Eyelashes (*cilia*) (Fig. 748).—The eyelashes are attached to the free edges of the eyelids; they are short, thick, curved hairs, arranged in a double or triple row at the margin of the lids; those of the upper lid, more numerous and longer than the lower, curve upward; those of the lower lid curve downward. Because of this arrangement the two sets do not interlace in closing the lids. Near the attachment of the eyelashes are the openings of **sebaceous glands** (*glandulae sebaceae*) (Fig. 748) and of a number of glands, **glands of Moll** (*glandulae ciliares* [*Molli*]) (Fig. 748), arranged in several rows close to the free margin of the lid. They are regarded as enlarged and modified sweat-glands. On the inner surface are the **Meibomian glands** (*glandulae tarsales* [*Meibomi*]) (Fig. 750). Internal to the openings of the lachrymal canaliculi there are neither lashes nor Meibomian glands.

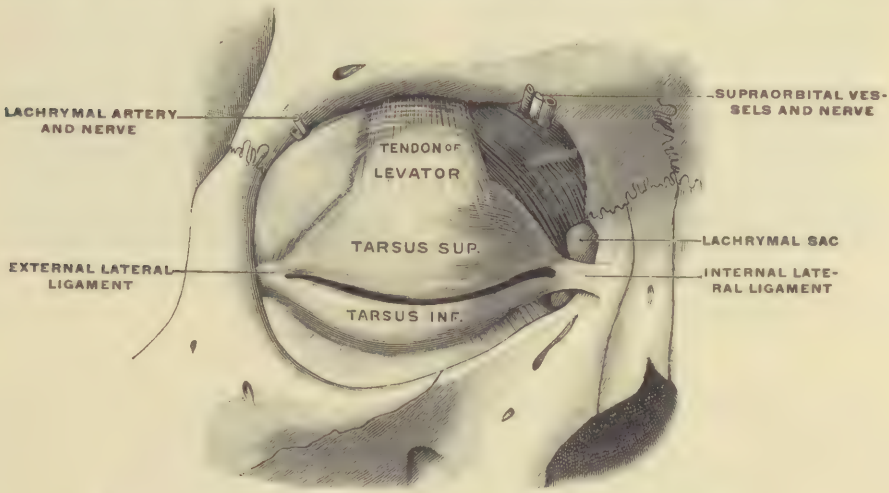

FIG. 747.—The tarsi and their ligaments. Right eye, front view. (Testut.)

Structure of the Eyelids (Fig. 748).—The eyelids are composed of the following structures, taken in their order from without inward:

Integument, areolar tissue, fibres of the Orbicularis muscle, tarsal plate, and its ligament, Meibomian glands, and conjunctiva. The upper lid has, in addition, the aponeurosis of the Levator palpebræ.

The **integument** is extremely thin, and continuous at the margin of the lids with the conjunctiva.

The **subcutaneous areolar tissue** is very lax and delicate, seldom contains any fat, and is extremely liable to serous infiltration.

The **fibres of the Orbicularis muscle**, where they cover the palpebrae (*m. ciliaris* [*Riolani*]), are thin, pale in color, and possess an involuntary action.

The **tarsal plates** are two thin elongated plates of dense connective tissue about an inch in length. They are placed one in each lid, contributing to their form and support.

The **superior tarsal plate, superior tarsus** or **superior tarsal body** (*tarsus superior*) (Fig. 747), the larger, is of a semilunar form, about one-third of an inch in breadth at the centre, and becoming gradually narrowed at each extremity. To the anterior surface of this plate the aponeurosis of the Levator palpebrae is attached.

The **inferior tarsal plate, inferior tarsus** or **inferior tarsal body** (*tarsus inferior*) (Fig. 747), the smaller of the two, is thinner and of an elliptical form.

The **free** or **ciliary margin** of these plates is thick, and presents a perfectly straight edge. The **attached** or **orbital margin** is connected to the circumference of the orbit by the fibrous membrane of the lids, with which it is continuous. The outer angle of each plate is attached to the malar bone by the **external tarsal** or **external lateral ligament**, or the **external palpebral ligament** or **raphé** (*ligamentum palpebralis lateralis*)(Fig. 747). The inner angles of the two plates terminate at the commencement of the lacus lacrimalis; they are attached to the nasal process of the superior maxilla by the **internal tarsal** or **internal lateral** or **internal palpebral ligament** or the **tendo oculi** (*ligamentum palpebrale mediale*) (Fig. 747).

The fibrous membrane of the lids constitutes the **orbito-tarsal ligaments** or the **palpebral fasciae.** In reality these so-called ligaments are fascial expansions situated one in each lid, and are attached marginally to the edge of the orbit, where they are continuous with the periosteum. The superior ligament blends with the tendon of the Levator palpebrae, the inferior with the inferior tarsal plate. Externally the superior and inferior ligaments fuse to form the **external tarsal ligament** or **raphé** just referred to; internally they are much thinner, and, becoming separated from the internal tarsal ligament, are fixed to the lachrymal bone immediately behind the lachrymal sac. Together the ligaments form an incomplete septum, the **orbital septum** (*septum orbitale*), which is perforated by the vessels and nerves which pass from the orbital cavity to the face and scalp.

FIG. 748.—Vertical section through the upper eyelid. *a*, Skin. *b*, Orbicularis palpebrarum. *b'*, Marginal fasciculus of orbicularis (ciliary bundle). *c*, Levator palpebrae. *d*, Conjunctiva. *e*, Tarsal plate. *f*, Meibomian gland. *g*, Sebaceous gland. *h*, Eyelashes. *i*, Small hairs of skin. *j*, Sweat-glands. *k*, Posterior tarsal glands. (After Waldeyer.)

The Meibomian or Tarsal Glands (*glandulae tarsales* [*Meibomi*]) (Figs. 748 and 750).—The Meibomian or tarsal glands are situated upon the inner surface of the eyelids between the tarsal plates and conjunctiva, and may be distinctly seen through the mucous membrane on everting the eyelids, presenting the appearance of parallel strings of pearls. They are about thirty in number in the upper eyelid, and somewhat fewer in the lower. They are embedded in grooves in the inner

surface of the tarsal plates, and correspond in length with the breadth of each plate; they are, consequently, longer in the upper than in the lower eyelid. Their ducts open on the free margin of the lids by minute foramina, which correspond in number to the follicles. The use of their secretion is to prevent adhesions of the lids.

Structure of the Meibomian Glands.—These glands are a variety of the cutaneous sebaceous glands, each consisting of a single straight tube or follicle, having a cæcal termination, and with numerous small secondary follicles opening into it. The tubes consist of basement-membrane, lined at the mouths of the tubes by stratified epithelium; the deeper parts of the tubes and the secondary follicles are lined by a layer of polyhedral cells. They are thus identical in structure with the sebaceous glands.

The Conjunctiva (Figs. 714, 715, 727, 749).

The conjunctiva is the mucous membrane of the eye. It lines the inner surface of the eyelids, is reflected over the forepart of the sclerotic and cornea, and joins the lids to the eyeball. In each of these situations its structure presents some peculiarities.

The Palpebral Portion (*tunica conjunctiva palpebrarum*) (Fig. 750).—The palpebral portion of the conjunctiva lines the posterior surface of the lids. It is thick, opaque, highly vascular, and covered with numerous papillae, its deeper parts presenting a considerable amount of lymphoid tissue. At the margin of the lids it becomes continuous with the lining membrane of the ducts of the Meibomian glands, and, through the lachrymal canals, with the lining membrane of the lachrymal sac and nasal duct. At the outer angle of the upper lid the lachrymal ducts open on its free surface; and at the inner angle of the eye it forms a semilunar fold, the **plica semilunaris** (*plica semilunaris conjunctivæ*) (Fig. 751). The folds formed by the reflection of the conjunctiva from the lids on to the eye are called the **superior** and **inferior palpebral folds**, the former being the deeper of the two. These folds form the **superior** and **inferior conjunctival fornix** (Fig. 749).

The Bulbar Portion (*tunica conjunctiva bulbi*).—Upon the *sclerotic* the conjunctiva is loosely connected to the globe; it becomes thinner, loses its papillary structure, is transparent, and only slightly vascular in health. Upon the *cornea* the conjunctiva consists only of epithelium, constituting the anterior layer of the cornea (conjunctival epithelium) already described (p. 1109). Lymphatics arise in the conjunctiva in a delicate zone around the cornea, from which the vessels run to the ocular conjunctiva.

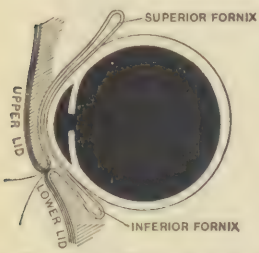

Fig. 749. Sagittal section of eye, showing superior and inferior fornices of the conjunctiva. (Testut.)

Fornix of Conjunctiva.—At the point of reflection of each fold of the conjunctiva from the lid on to the globe of the eye a pocket or arch is formed. These arches are termed the **fornix conjunctivae** (Fig. 749).

Glands of Conjunctiva.—In the conjunctiva there are a number of mucous glands which are much convoluted. They are chiefly found in the upper lid. Other glands, analogous to lymphoid follicles, and called by Henle **trachoma glands**, are found in the conjunctiva, and, according to Stromeyer, are chiefly situated near the inner canthus of the eye. They were first described by Brush, in his description of Peyer's patches of the small intestines, as "identical structures existing in the under eyelid of the ox."

The Nerves of the Conjunctiva.—The nerves in the conjunctiva are numerous and form rich plexuses. According to Krause, they terminate in a peculiar form of tactile corpuscle, which he terms the **terminal bulb.**

The Caruncula Lacrimalis.—The caruncula lacrimalis is a small, reddish, conical-shaped body, situated at the inner canthus of the eye, and filling up the small

triangular space in this situation, the **lacus lacrimalis**. It consists of an island of skin containing sebaceous and sweat-glands, and is the source of the whitish secretion which constantly collects at the inner angle of the eye. A few slender hairs are attached to its surface. On the outer side of the caruncula is a slight semilunar fold of conjunctiva, the concavity of which is directed toward the cornea; it is called the **plica semilunaris** (Fig. 751). Müller found smooth muscular fibres in this fold, and in some of the domesticated animals a thin plate of cartilage has been discovered. This structure is considered to be the rudiment of the third eyelid in birds, the **membrana nictitans.**

The Lachrymal Apparatus (Apparatus Lacrimalis) (Figs. 750, 751).

The lachrymal apparatus consists of the lachrymal gland, which secretes the tears, and its excretory ducts, which convey the fluid to the surface of the eye. This fluid is carried away by the lachrymal canals into the lachrymal sac, and along the nasal duct into the cavity of the nose.

The Lachrymal Glands (*glandula lacrimalis*).—The lachrymal gland is lodged in a depression at the outer angle of the orbit, on the inner side of the external

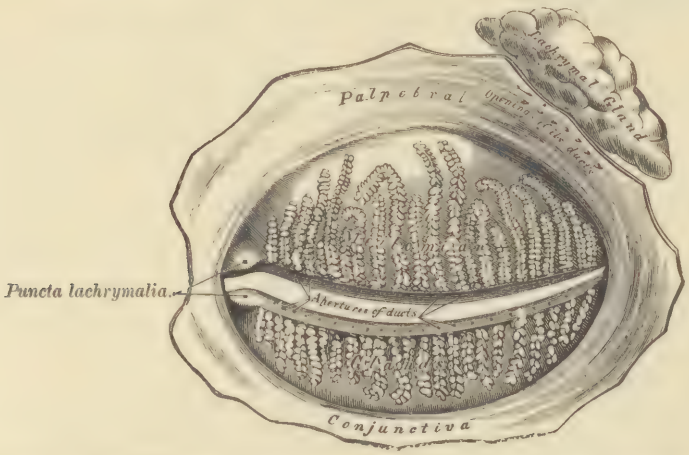

FIG. 750.—The Meibomian glands, etc., seen from the inner surface of the eyelids.

angular process of the frontal bone. It is of an oval form, about the size and shape of an almond. Its upper convex surface is in contact with the periosteum of the orbit, to which it is connected by a few fibrous bands. Its under concave surface rests upon the convexity of the eyeball and upon the Superior and External recti muscles. Its vessels and nerves enter its posterior border, whilst its anterior margin is closely adherent to the back part of the upper eyelid, where it is covered to a slight extent by the reflection of the conjunctiva. The forepart of the gland is separated from the rest by a fibrous septum; hence it is sometimes described as a separate lobe, called the **inferior lachrymal gland, palpebral portion of the gland,** or the **accessory gland of Rosenmuller** (*glandula lacrimalis inferior*), the back part of the gland then being called the **superior lachrymal gland** (*glandula lacrimalis superior*). The ducts of the lachrymal gland, from six to twelve in number, run obliquely beneath the mucous membrane for a short distance, and, separating from each other, open by a series of minute orifices on the upper and outer half of the conjunctiva near its reflection on to the globe. These orifices are arranged in a row, so as to disperse the secretion over the surface of the membrane.

Structure of the Lachrymal Gland.—In structure and general appearance the lachrymal resembles the serous salivary glands. In the recent state the cells are so

crowded with granules that their limits can hardly be defined. Each cell contains an oval nucleus, and the cell-protoplasm is finely fibrillated.

The **Lachrymal Canaliculi** or **Canals** (Fig. 751) commence at the minute orifices, **puncta lacrimalia,** on the summit of a small conical elevation, the **lachrymal papilla** or **caruncle** (*caruncula lacrimalis*), seen on the margin of the lids at the outer extremity of the lacus lacrimalis. The **superior canal** (*ductus lacrimalis superior*), the smaller and shorter of the two, at first ascends, and then bends at an acute angle, and passes inward and downward to the ampulla. The **inferior canal** (*ductus lacrimalis inferior*) at first descends, and then, abruptly changing its course, passes almost horizontally inward to the ampulla. These canals are dense and elastic in structure and somewhat dilated at their angle. The mucous membrane is covered with scaly epithelium. The two canals join in a dilatation, the **ampulla** (*ampulla ductus lacrimalis*), which empties into the lachrymal sac.

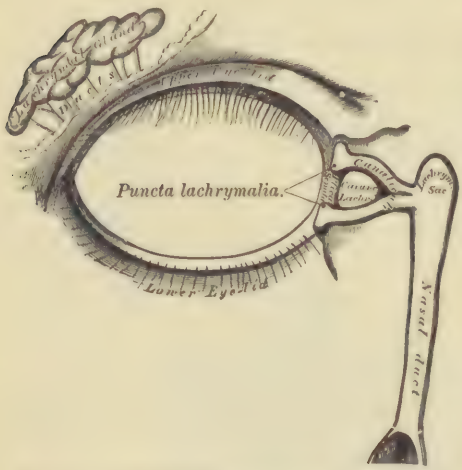

Fig. 751.—The lachrymal apparatus. Right side.

The Lachrymal Sac (*saccus lacrimalis*) (Fig. 751).—The lachrymal sac is the upper dilated extremity of the **nasal duct,** and is lodged in a deep groove formed by the lachrymal bone and the nasal process of the superior maxillary bone. It is oval in form, its upper extremity being closed in and rounded, whilst below it is continued into the nasal duct. It is covered by a fibrous expansion derived from the tendo oculi, and on its deep surface it is crossed by the Tensor tarsi muscle (Horner's muscle, p. 371), which is attached to the ridge on the lachrymal bone.

Structure.—It consists of a fibrous elastic coat, lined internally by mucous membrane, the latter being continuous, through the ampulla and lachrymal canals, with the mucous lining of the conjunctiva, and, through the nasal duct, with the pituitary membrane of the nose.

The Nasal Duct (*ductus nasolacrimalis*) (Fig. 751).—The nasal duct is a membranous canal, about three-quarters of an inch in length, which extends from the lower part of the lachrymal sac to the inferior meatus of the nose, where it terminates by a somewhat expanded orifice, provided with an imperfect valve, the **valve of Hasner** (*plica lacrimalis* [*Hasneri*]), formed by the mucous membrane. It is contained in an osseous canal formed by the superior maxillary, the lachrymal, and the inferior turbinated bones, is narrower in the middle than at each extremity, and takes a direction downward, backward, and a little outward. It is lined by mucous membrane, which is continuous below with the pituitary lining of the nose. The membrane in the lachrymal sac and nasal duct is covered with columnar epithelium, as in the nose. This epithelium is in places ciliated.

Surface Form.—The *palpebral fissure,* or opening between the eyelids, is elliptical in shape, and differs in size in different individuals and in different races of mankind. In the Mongolian races, for instance, the opening is very small, merely a narrow fissure, and this makes the eyeball appear small in these races, whereas the size of the eye is relatively very constant. The normal direction of the fissure is slightly oblique, in a direction upward and outward, so that the outer angle is on a slightly higher level than the inner. This is especially noticeable in the Mongolian races, in whom, owing to the upward projection of the malar bone and the shortness of the external angular process of the frontal bone, the tarsal plate of the upper lid is raised at its outer part and gives an oblique direction to the palpebral fissure.

When the eyes are directed forward, as in ordinary vision, the upper part of the cornea is covered by the upper lid, and the lower margin of the cornea corresponds to the level of the lower lid, so that about the lower three-fourths of the cornea is exposed under ordinary circumstances. On the margins of the lids, about a quarter of an inch from the inner canthus, are two small openings, the *puncta lacrimalia*, the commencement of the lachrymal canals. They are best seen by everting the eyelids. In the natural condition they are in contact with the conjunctiva of the eyeball, and are maintained in this position by the *Tensor tarsi muscle*, so that the tears running over the surface of the globe easily find their way into the lachrymal canals. The position of the *lachrymal sac* into which the canals open is indicated by a little tubercle, which is plainly to be felt on the lower margin of the orbit. The lachrymal sac lies immediately above and to the inner side of this tubercle, and a knife passed through the skin in this situation would open the cavity. The position of the lachrymal sac may also be indicated by the *tendo oculi* or *internal tarsal ligament*. If both lids be drawn outward, so as to tense the skin at the inner angle, a prominent cord will be seen beneath the tightened skin. This is the *tendo oculi*, which lies immediately over the lachrymal sac, bisecting it, and thus forming a useful guide to its situation. A knife entered immediately beneath the tense cord would open the lower part of the sac. A probe introduced through this opening can be readily passed downward through the duct into the inferior meatus of the nose. The direction of the duct is downward, outward, and backward, and this course should be borne in mind in passing the probe, otherwise the point may be driven through the thin bony walls of the canal. A convenient plan is to direct the probe in such a manner that if it were pushed onward it would strike the first molar tooth of the lower jaw on the same side of the body. In other words, the surgeon standing in front of his patient should carry in his mind the position of the first molar tooth, and should push his probe onward in such a way as if he desired to reach this structure.

Beneath the internal angular process of the frontal bone the pulley of the *Superior oblique muscle* of the eye can be plainly felt by pushing the finger backward between the upper and inner angle of the eye and the roof of the orbit; passing backward and outward from this pulley, the tendon can be felt for a short distance.

Surgical Anatomy.—The eyelids are composed of various tissues, and consequently are liable to a variety of diseases. The skin which covers them is exceedingly thin and delicate, and is supported on a quantity of loose and lax subcutaneous tissue which contains no fat. In consequence of this it is very freely movable, and is liable to be drawn down by the contraction of neighboring cicatrices. Such contractions may produce an eversion of the lid known as *ectropion*. Inversion of the lids (*entropion*) from spasm of the Orbicularis palpebrarum or from chronic inflammation of the palpebral conjunctiva may also occur. In some individuals there is an extra row of eyelashes on the inner margin of the lid, directed toward the cornea (*distichiasis*). *Trichiasis* is a condition in which the lashes are directed toward the eye, but there is not inversion of the lid. The eyelids are richly supplied with blood, and are often the seat of vascular growths, such as *nævi*. *Rodent ulcer* also frequently commences in this situation. The loose cellular tissue beneath the skin is liable to become extensively infiltrated either with blood or inflammatory products, producing very great swelling. Even from very slight injuries to this tissue the extravasation of blood may be so great as to produce considerable swelling of the lids and complete closure of the eye, and the same is the case when inflammatory products are poured out. The follicles are liable to become inflamed, constituting the disease known as *marginal blepharitis*, *blepharitis ciliaris*, or "*blear-eye*." Irregular or disorderly growth of the eyelashes not unfrequently occurs, some of them being turned toward the eyeball and producing inflammation and follicles of the eyelashes or the sebaceous glands associated with these follicles may be the seat of inflammation, constituting the ordinary *hordeolum* or "*sty*." The Meibomian glands are affected in the so-called "*tarsal tumor*;" the tumor, according to some, being caused by the retained secretion of these glands; by others it is believed to be a neoplasm connected with the gland. The Orbicularis palpebrarum may be the seat of *spasm* (*blepharospasm*), either in the form of slight quivering of the lids or repeated twitchings, most commonly due to errors of refraction in children, or more continuous spasm, due to some irritation of the fifth or seventh cranial nerves. The Orbicularis may be *paralyzed*, generally associated with paralysis of the other facial muscles. Under these circumstances the patient is unable to close the lids, and if he attempts to do so, rolls the eyeball upward under the upper lid. The tears overflow from displacement of the lower lid, and the conjunctiva and cornea, being constantly exposed and the patient being unable to wink, become irritated from dust and foreign bodies. As a result there may be ulceration of the cornea, and possibly eventually complete destruction of the eye. In *paralysis of the Levator palpebræ superioris* there is drooping of the upper eyelid (*ptosis*) and other symptoms of implication of the third nerve. The eyelids may be the seat of *bruises*, *wounds*, or *burns*. After wounds or burns adhesions of the margins of the lids to each other or adhesion of the lids to the globe may take place. The eyelids are sometimes the seat of *emphysema* after fracture of some of the thin bones forming the inner wall of the orbit. If shortly after such an injury the patient blows his nose, air is forced from the nostrils through the lacerated structure into the

connective tissue of the eyelids, which suddenly swell up and present the peculiar crackling on pressure which is characteristic of this affection.

Foreign bodies frequently get into the *conjunctival sac* and cause great pain, especially if they come in contact with the corneal surface, during the movements of the lid and the eye on each other. The conjunctiva is frequently involved in severe injuries of the eyeball, but is seldom ruptured alone; the most common form of injury to the conjunctiva alone is from a *burn*, either from fire, strong acids, or lime. In these cases union is liable to take place between the eyelid and the eyeball. The conjunctiva is often the seat of *inflammation* arising from many different causes, and the arrangement of the conjunctival vessels should be remembered as affording a means of diagnosis between this condition and injection of the sclerotic, which is present in inflammation of the deeper structures of the globe. The inflamed conjunctiva is bright red; the vessels are large and tortuous, and greatest at the circumference, shading off toward the corneal margin; they anastomose freely and form a dense network, and they can be emptied by gentle pressure.

The *lachrymal gland* is occasionally, though rarely, the seat of *inflammation* (*dacryoadenitis*), either acute or chronic; it is also sometimes the seat of *tumors*, benign or malignant, and for these may require removal. This may be done by an incision through the skin just below the eyebrow; and the gland, being invested with a special capsule of its own, may be isolated and removed without opening the general cavity of the orbit. The *canaliculi may be obstructed*, either as a congenital defect or by some foreign body, as an eyelash or a dacryolith, causing the tears to run over the cheek. The canaliculi may also become occluded as the result of *burns* or *injury;* overflow of tears may in addition result from *deviation of the puncta* or from chronic inflammation of the lachrymal sac. When there is failure of the lachrymal tubes to drain off the tears and the fluid gathers beneath and flows over the lids, the condition is known as *epiphora* or *stillicidium*. This latter condition is set up by some *obstruction to the nasal duct* frequently occurring in tuberculous subjects. In consequence of this the tears and mucus accumulate in the lachrymal sac, distending it. *Suppuration in the lachrymal sac* (*dacryocystitis*) is sometimes met with; this may be the sequel of a chronic inflammation; or may occur after some of the eruptive fevers in cases where the lachrymal passages were previously quite healthy. It may lead to *lachrymal fistula*.

THE EAR (ORGANON AUDITUS).

The organ of hearing is divisible into three parts—the **external ear**, the **middle ear** or **tympanum**, and the **internal ear** or **labyrinth**.

THE EXTERNAL EAR (AURIS EXTERNA).

The external ear consists of an expanded portion named **pinna** or **auricle**, and the **auditory canal** or **meatus**. The former serves to collect the vibrations of the air by which sound is produced; the latter conducts those vibrations to the tympanum.

The Pinna or Auricle (Auricula) (Fig. 752).

The pinna or auricle is attached to the side of the head midway between the forehead and occiput. "Its level is indicated by horizontal lines extending backward from the eyebrows above and from the tip of the nose below."[1] It is of an ovoid form, with its larger end directed upward. Its *outer surface* is irregularly concave, directed slightly forward. The angle which it bears to the head is called the **cephalo-auricular angle**. In some cases this angle is almost absent. In others it is nearly a right angle. The pinna of one side may vary in size, shape, and angle from the pinna of the other side. The pinna of a woman is apt to be smaller than that of a man, and is less often deformed. The outer surface of the pinna presents numerous eminences and depressions which result from the foldings of its fibro-cartilaginous element. To each of these, names have been assigned. Thus the external prominent rim of the auricle is called the **helix**. Another curved prominence, parallel with and in front of the helix, is called the **antihelix**; this bifurcates above and forms the *crura*, which encloses a triangular depression, the **fossa of the antihelix** (*fossae triangularis* [*auriculae*]). The narrow curved depression between

[1] Arthur Hensman in Henry Morris' Human Anatomy.

the helix and antihelix is called the **fossa of the helix** or the **scaphoid fossa** (*scapha*); the antihelix describes a curve around a deep, capacious cavity, the **concha auriculae,**

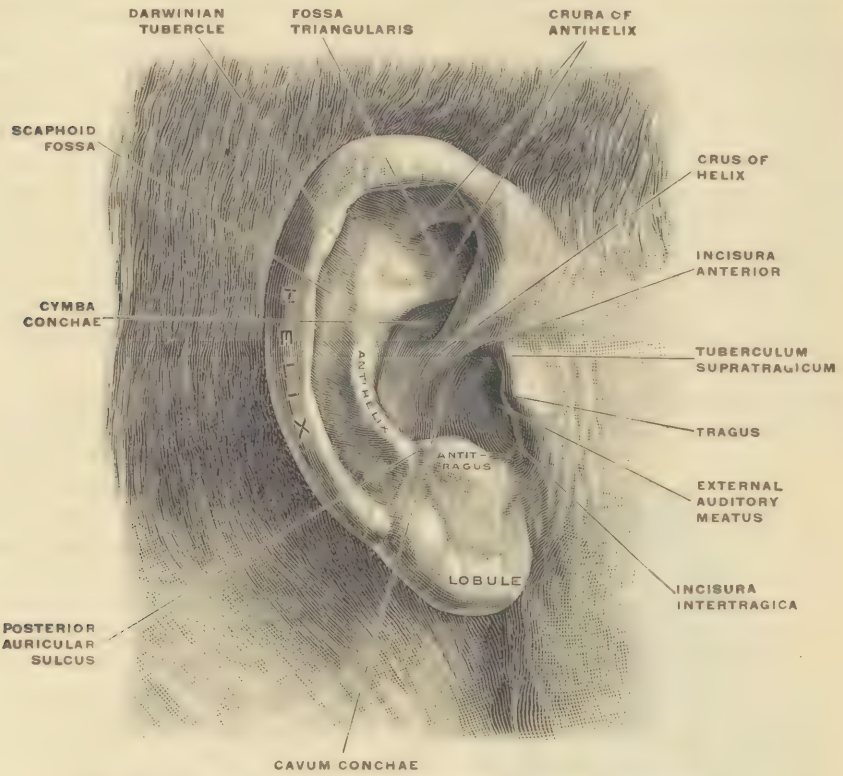

FIG. 752.—The right pinna or auricle, viewed from without. (Spalteholz.)

which is partially divided into two parts by the **crus of the helix**, or the commencement of the helix; the upper part is termed the **cymba conchae**, the lower part the **cavum conchae.** In front of the concha, and projecting backward over the meatus, is a small pointed eminence, the **tragus**, so called from its being generally covered on its under surface with a tuft of hair resembling a goat's beard. Opposite the tragus, and separated from it by a deep notch (*incisuria intertragica*) is a small tubercle, the **antitragus.** Below this is the **lobule** (*lobulus auriculae*), composed of tough areolar and adipose tissue, wanting the firmness and elasticity of the rest of the pinna. Sometimes the lobule does not hang freely, but is adherent. Where the helix turns downward a small tubercle, the **tubercle of Darwin** (*tuberculum auriculae* [*Darwini*]), is frequently seen. This tubercle is very evident about the sixth month of fœtal life; at this stage the human pinna has a close resemblance to that of some of the adult monkeys.

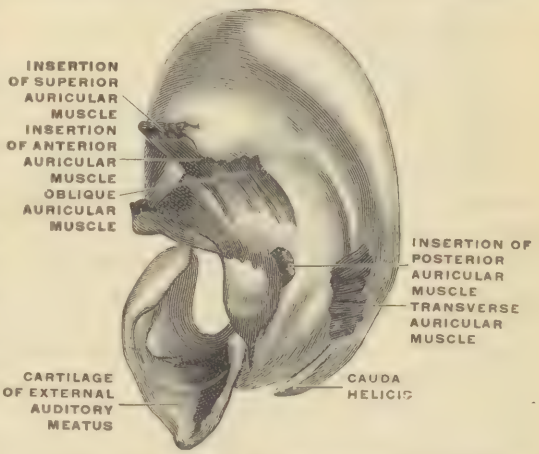

FIG. 753.—The cartilages of the right auricle, isolated, with the muscles, viewed from the inside. (Spalteholz.)

The *cranial surface* of the pinna presents elevations which correspond to the depressions on its outer surface and after which they are named, *e. g.*, **eminentia conchae, eminentia fossae triangularis,** etc.

The eminentia conchae and the fossae triangularis are separated by a furrow (*sulcus antihelicis transversus*), which corresponds to the inferior crus of the antihelix, or groove (*sulcus cruris helicis*), and upon the eminence there is a vertical ridge, the **pons**culus, which indicates the point of insertion of the Retrahens auriculam muscle.

Structure of the Pinna.—The pinna is composed of a thin plate of yellow fibro-cartilage, covered with integument, and connected to the surrounding parts by the extrinsic ligaments and muscles, and to the commencement of the external auditory canal by fibrous tissue.

The Integument.—The integument is thin, closely adherent to the cartilage, and covered with hairs furnished with sebaceous glands, which are most numerous in the concha and scaphoid fossa. The hairs are most numerous and largest on the tragus and antitragus.

The Cartilage of the Pinna (*cartilago auriculae*) (Fig. 754).—The cartilage of the pinna consists of one single piece; it gives form to this part of the ear, and upon its surface are found all the eminences and depressions above described. It does not enter into the construction of all parts of the auricle; thus it does not form a constituent part of the lobule; it is deficient also between the lamina of the tragus and beginning of the crus helix, the notch between (*incisura terminalis auris*)them being filled up by dense fibrous tissue. At the front part of the pinna,where the helix bends upward, is a small projection of cartilage, called the **spine of the helix** (*spina helicis*), while the lower part of the helix is prolonged downward as a tail-like process, the **cauda helicis**; this is separated from the antihelix by a fissure, the **fissura antitragohelicina.** The **fissures of Santorini** are usually two in number: one in the substance of the tragus, which partially separates the different parts, and one in the cartilage of the meatus. The fissure of the helix is a short vertical slit, situated at the forepart of the pinna. Another fissure, the **fissure of the tragus,** is seen upon the anterior surface of the tragus. Anteriorly and inferiorly the cartilage of the pinna is continuous with the cartilage of the external auditory meatus by a **cartilaginous isthmus** (*isthmus cartilaginis auris*). Some authors regard the tragus as part of the cartilage of the meatus. The cartilage of the pinna is very pliable, elastic, of a yellowish color and belongs to that form of cartilage which is known under the name of yellow fibro-cartilage.

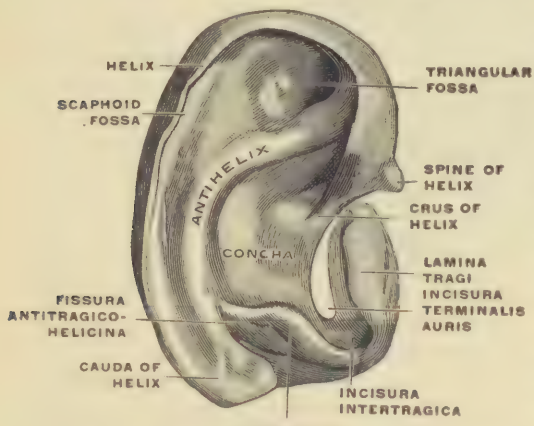

FIG. 754.—The right ear cartilages, isolated, viewed from without. (Spaltholz.)

The Ligaments of the Pinna (*ligamenti auricularia* [*Valsalvae*]).—The ligaments of the pinna consist of two sets: 1. The extrinsic set, or those connecting it to the side of the head. 2. The intrinsic set, or those connecting the various parts of its cartilage together.

The **Extrinsic Ligaments,** the most important, are three in number: **superior, anterior,** and **posterior.** The **superior ligament** (*ligamentum auriculare superius*) extends from the suprameatal spine to the spine of the helix. The **anterior ligament** (*ligamentum auriculare anterius*) extends from the spina helicis and tragus to the

root of the zygoma. The **posterior ligament** (*ligamentum auriculare posterius*) passes from the posterior surface of the concha to the outer surface of the mastoid process of the temporal bone.

The chief **Intrinsic Ligaments** are: (1) a strong fibrous band, stretching across from the tragus to the commencement of the helix, completing the meatus in front, and partly encircling the boundary of the concha; and (2) a band which extends between the antihelix and the cauda helicis. Other less important bands are found on the cranial surface of the pinna.

The Muscles of the Pinna (Figs. 753 and 755).—The muscles of the pinna consist of two sets: 1. The **extrinsic**, which connect it with the side of the head, moving the pinna as a whole—viz., the Attollens, Attrahens, and Retrahens auriculam (p. 369). 2. The **intrinsic**, which extend from one part of the auricle to another, viz.:

Helicis major.	Antitragicus.
Helicis minor.	Transversus auriculae.
Tragicus.	Obliquus auriculae.

The **Helicis Major** (*m. helicis major*) is a narrow vertical band of muscular fibres, situated upon the anterior margin of the helix. It arises, below, from the cauda helicis, and is inserted into the anterior border of the helix, just where it is about to curve backward. It is pretty constant in its existence.

The **Helicis Minor** (*m. helicis minor*) is an oblique fasciculus which covers the crus helicis.

The **Tragicus** (*m. tragicus*) is a short, flattened band of muscular fibres situated upon the outer surface of the tragus, the direction of its fibres being vertical.

The **Antitragicus** (*m. antitragicus*) arises from the outer part of the antitragus; its fibres are inserted into the cauda helicis and antihelix. This muscle is usually very distinct.

The **Transversus Auriculae** (*m. transversus auriculae*) is placed on the cranial surface of the pinna. It consists of scattered fibres, partly tendinous and partly muscular, extending from the convexity of the concha to the prominence corresponding with the groove of the helix.

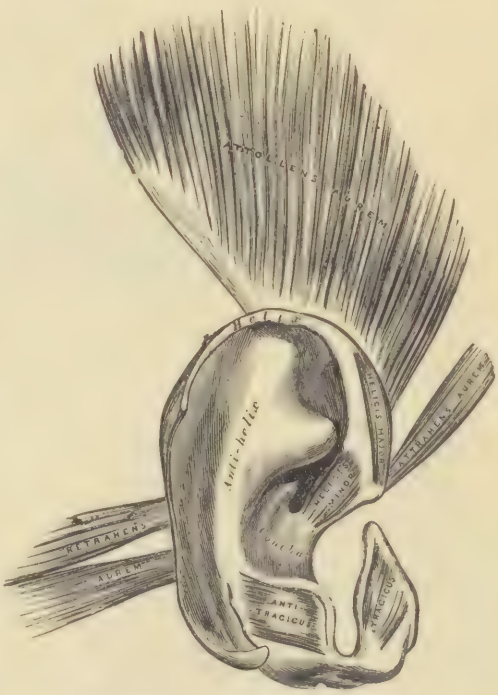

FIG. 755.—The muscles of the pinna.

The **Obliquus Auriculae** (Tod) (*m. obliquus auriculae*) consists of a few fibres extending from the upper and back part of the concha to the convexity immediately above it.

The Arteries of the Pinna.—The arteries of the pinna are the posterior auricular from the external carotid, the anterior auricular from the temporal and an auricular branch from the occipital artery.

The Veins of the Pinna.—The veins of the pinna accompany the corresponding arteries.

The Lymphatics of the Pinna.—The lymphatics enter into the pre-auricular glands and the glands upon the Sterno-mastoid muscle at its insertion.

The Nerves of the Pinna.—The nerves of the pinna are: the auricularis magnus, from the cervical plexus; the auricular branch of the pneumogastric; the auriculo-temporal branch of the inferior maxillary nerve; the occipitalis minor from the cervical plexus, and the occipitalis major or internal branch of the posterior division of the second cervical nerve. The muscles of the pinna are supplied by the facial nerve.

The External Auditory or External Acoustic Canal or External Auditory Meatus (Meatus Acusticus Externus or Meatus Auditorius Externus).

The external auditory or acoustic canal or meatus extends from the bottom of the concha to the membrana tympani (Figs. 752, 756, and 757). It is about an inch and a half in length if measured from the tragus; from the bottom of the concha its length is about an inch. It forms a sort of S-shaped curve, and is directed at first inward, forward, and slightly upward (*pars externa*); it then passes inward and backward (*pars media*), and lastly is carried inward, forward, and slightly downward (*pars interna*). It forms an oval cylindrical canal, the greatest diameter being in the vertical direction at the external orifice, but in the

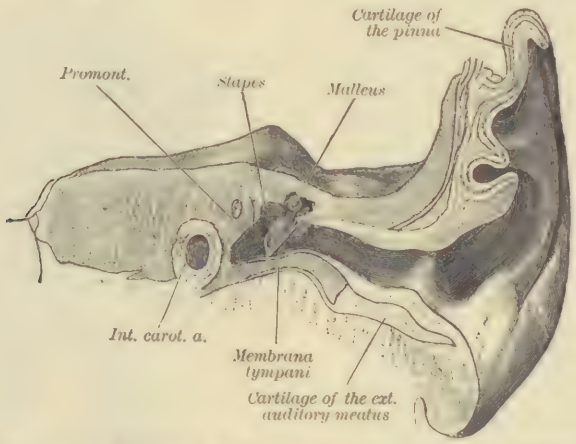

FIG. 756.—Transverse section of external auditory meatus and tympanum. Left side. (Gegenbauer.)

transverse direction at the tympanic end. It presents two constrictions, one near the inner end of the cartilaginous portion, and another, the **isthmus**, in the osseous portion, about three-quarters of an inch from the bottom of the concha. The **membrana tympani** (Figs. 756 and 757), which occupies the termination of the meatus, is directed obliquely, in consequence of which the floor of the canal is longer than the roof, and the anterior wall longer than the posterior. The auditory canal is formed partly by cartilage and membrane, partly by bone, and is lined by perichondrium and periosteum, which is covered with skin.

The Cartilaginous Portion (*meatus acusticus externus cartilagineus*).—The cartilaginous portion is about one-third of an inch (8 mm.) in length; it is formed by the cartilage of the pinna, prolonged inward, and firmly attached to a greater portion of the circumference of the auditory process of the temporal bone. The cartilage is deficient at its upper and back part, its place being supplied by fibrous membrane. This part of the canal is rendered extremely movable by two or three deep fissures, the **fissures of Santorini** (*incisurae cartilaginis meatus acustici externi* [*Santorini*]), which extend through the cartilage in a vertical direction. It is firmly attached at its lower and front part to the posterior root of the zygoma and to the lateral edge of the tympanic portion of the temporal bone.

The Osseous Portion (*meatus acusticus externus osseus*).—The osseous portion is about two-thirds of an inch (16 mm.) in length, and narrower than the cartilaginous portion. It is directed inward and a little forward, forming a slight curve in its course, the convexity of which is upward and backward. Its inner end, which communicates, in the dry bone, with the cavity of the tympanum, is smaller than the outer and sloped, the anterior wall projecting beyond the posterior about two lines; it is marked, except at its upper part, by a narrow groove, the **tympanic sulcus** (*sulcus tympanicus*), for the insertion of the membrana tympani. Its outer edge is dilated and rough in the greater part of its circumference, for the attachment of the cartilage of the pinna. Its vertical transverse section is oval, the greatest diameter being from above downward. The front and lower parts of this canal are formed by a curved plate of bone, which, in the fœtus, exists as a separate ring (*annulus tympanicus*), incomplete at its upper part. (See Section on Osteology.)

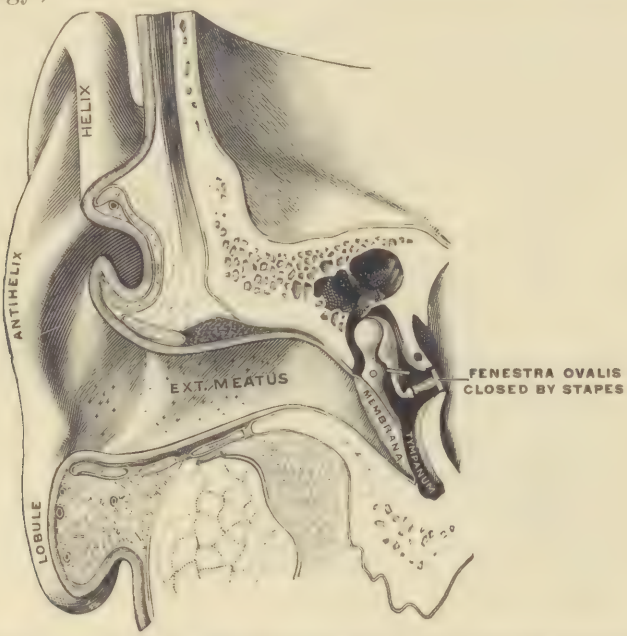

FIG. 757.—Vertical section through the external auditory meatus and tympanum, passing in front of the fenestra ovalis. (Testut.)

The Skin of the Meatus.—The skin lining the meatus is a prolongation of the external skin; it is thin, adheres closely to the cartilaginous and osseous portions of the tube, and covers the surface of the membrana tympani, forming a very thin outer layer. After maceration the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus are numerous **ceruminous glands** (*glandulæ ceruminosæ*) which secrete the *ear-wax*. They resemble in structure sweat-glands, and their ducts open on the surface of the skin.

Relations of the Meatus.—In front of the osseous part is the **glenoid fossa,** which receives the **condyle of the mandible** (Fig. 759), which, however, is separated from the cartilaginous part by the retromandibular part of the *parotid gland*. The movements of the jaw influence to some extent the lumen of the cartilaginous portion. Behind the osseous part are the *mastoid air-cells*, separated from it by a thin layer of bone (Fig. 46).

The Arteries of the External Meatus.—The arteries supplying the external meatus are branches from the posterior auricular, internal maxillary, and superficial temporal.

The Veins of the External Meatus.—Veins accompany the corresponding arteries and pass to the internal maxillary, temporal, and posterior auricular veins.

The Lymphatics of the External Meatus.—The lymphatics accompany the veins and enter the parotid and posterior auricular lymph-glands.

The Nerves of the External Meatus.—The nerves are derived from the auriculo-temporal branch of the inferior maxillary nerve, the auricularis magnus, and the auricular branch of the pneumogastric.

Surface Form.—The point of junction of the osseous and cartilaginous portions of the tube is an obtuse angle, which projects into the canal at its antero-inferior wall. This produces a sort of constriction in this situation, and renders it the narrowest portion of the canal—an important point to be borne in mind in connection with the presence of foreign bodies in the ear. The cartilaginous is connected to the bony part by fibrous tissue, which renders the outer part of the tube very movable, and therefore by drawing the pinna upward and backward the canal is rendered almost straight. At the external orifice are a few short, crisp hairs which serve to prevent the entrance of small particles of dust, flies or other insects. In the external auditory meatus the secretion of the ceruminous glands serves to catch any small particles which may find their way into the canal, and prevent their reaching the membrana tympani, where their presence might excite irritation. In young children the meatus is short, the osseous part being very deficient, and consisting merely of a bony ring (*annulus tympanicus*), which supports the membrana tympani. In the fœtus the osseous part is entirely absent. The shortness of the canal in children should be borne in mind in introducing the aural speculum, so that it shall not be pushed in too far, at the risk of injuring the membrana tympani; indeed, even in the adult the speculum should never be introduced beyond the constriction which marks the junction of the osseous and cartilaginous portions. In using this instrument it is advisable that the pinna should be drawn upward, backward, and a little outward, so as to render the canal as straight as possible, and thus assist the operator in obtaining, by the aid of reflected light, a good view of the membrana tympani. Just in front of the membrane is a well-marked depression, situated on the floor of the canal and bounded by a somewhat prominent ridge; in this foreign bodies may become lodged. By aid of the speculum, combined with traction of the auricle upward and backward, the whole of the membrana tympani is rendered visible. It is a pearly-gray membrane, slightly glistening in the adult, placed obliquely, so as to form with the floor of the meatus a very acute angle (about 55 degrees), while with the roof it forms an obtuse angle. At birth it is more horizontal—being situated in almost the same plane as the base of the skull. About midway between the anterior and posterior margins of the membrane, and extending from the centre obliquely upward, is a reddish-yellow streak; this is the handle of the malleus, which is inserted into the membrane (Fig. 760). At the upper part of this streak, close to the roof of the meatus, a little white rounded prominence is plainly to be seen; this is the processus brevis of the malleus, projecting against the membrane. The membrana tympani does not present a plane surface; on the contrary, its centre is drawn inward, on account of its connection with the handle of the malleus, and thus the external surface is rendered concave.

THE MIDDLE EAR, DRUM OR TYMPANUM (AURIS MEDIA) (Figs. 756, 757, 758, 762).

The middle ear or tympanum is an irregular cavity, compressed from without inward, and is situated within the petrous portion of the temporal bone. It is placed above the jugular fossa; the carotid canal lying in front, the mastoid cells behind, the external auditory meatus externally, and the labyrinth internally. It is lined with mucous membrane, is filled with air, and communicates with the mastoid cells, and with the naso-pharynx by the Eustachian tube. The tympanum is traversed by a chain of movable bones, which connect the membrana tympani with the labyrinth, and serve to convey the vibrations communicated to the membrana tympani across the cavity of the tympanum to the external ear. In shape it is roughly biconcave, the concave surfaces being placed vertically and forming the external and internal walls. The cavity forms an angle of 45 degrees with the median plane (Spalteholz).

The Tympanic Cavity (*cavum tympani*) (Figs. 762 and 763).—The tympanic cavity consists of two parts: the **atrium** or **tympanic cavity proper** (Fig. 763), opposite the tympanic membrane, and the **attic** or **epitympanic recess** or **aditus ad antrum** (*recessus epitympanicus*) (Figs. 761 and 762), above the level of the

upper part of the membrane; the latter contains the upper half of the malleus and the greater part of the incus. The diameter of the tympanic cavity, including the attic, measures about $\frac{3}{5}$ inch (15 mm.) vertically and transversely. From without inward it measures about $\frac{1}{4}$ inch (6 mm.) above and $\frac{1}{6}$ inch (4 mm.) below; opposite the centre of the tympanic membrane it is only about $\frac{1}{12}$ inch (2 mm.). It is bounded externally by the membrana tympani and meatus; internally, by the outer surface of the internal ear; and communicates behind with the mastoid antrum and through it with the mastoid cells; and in front with the Eustachian tube and canal for the Tensor tympani. Its roof and floor are formed by thin osseous laminae, the one forming the roof being a thin plate situated on the anterior surface of the petrous portion of the temporal bone, close to its angle of junction with the squamous portion of the same bone.

The Roof of the Tympanum (*paries tegmentalis*).—The roof of the tympanum is broad, flattened, and formed of a thin plate of bone (*tegmen tympani*) (Fig. 762), which separates the cranial and tympanic cavities. It is prolonged backward so as to roof in the mastoid antrum; it is also carried forward to cover in the canal for the Tensor tympani muscle.

The Floor (*paries jugularis*) (Fig. 762).—The floor is narrow, and is separated by a thin plate of bone (*fundus tympani*) from the jugular fossa. It frequently

FIG. 758.—View of the inner wall of the tympanum (enlarged).

presents numerous small notches in the bone (*cellulae tympanicae*). There is one small aperture in the floor. It is near the inner wall and is the opening of the **canaliculus tympanicus**, for the transmission of Jacobson's nerve (*n. tympanicus*). On the floor near the posterior wall there is often to be found a slight bony projection (*prominentia styloideae*).

The Outer Wall (Fig. 757).—The outer wall is formed mainly by the membrana tympani, partly by the ring of bone into which this membrane is inserted. The part formed by the membrana tympanum is called the *paries membranaceus*. This ring of bone is incomplete at its upper part, forming a notch, the **notch of Rivinus** (*incisura tympanica* [*Rivini*]) (Fig. 760). The anterior edge of the notch is known as the **spina tympanica major**, the posterior edge as the **spina tympanica minor**. The groove for the reception of the membrana tympani is the **sulcus tympanicus**. Close to the notch are three small apertures: the **iter chordae posterius**, the **Glaserian fissure**, and the **iter chordae anterius**.

The **iter chordae posterius** or the **tympanic aperture** (*canaliculus chordae tympani*) (Fig. 761) is in the angle of junction between the posterior and external walls of the tympanum, immediately behind the membrana tympani and on a level with the upper end of the handle of the malleus; it leads into a minute canal, which descends

in front of the aquaeductus Fallopii, and terminates in the aqueduct near the stylomastoid foramen. Through it the chorda tympani nerve enters the tympanum.

The **Glaserian** or **petro-tympanic fissure** (*fissura petrotympanica* [*Glaseri*]) (Fig. 761) opens just above and in front of the ring of bone into which the membrana tympani is inserted; in this situation it is a mere slit about a line in length. It lodges the long process and anterior ligament of the malleus, and gives passage to the tympanic branch of the internal maxillary artery.

The **iter chordae anterius** (Fig. 761) is seen at the inner end of the preceding fissure; it leads into a canal, the **canal of Huguier**, which runs parallel with the Glaserian fissure. Through it the chorda tympani nerve leaves the tympanum.

The outer wall bounds the epitympanic recess externally.

The Internal Wall of the Tympanum (*paries labyrinthica*) (Figs. 758 and 762).—The internal wall of the tympanum is adjacent to the labyrinth, is vertical in direction, and looks directly outward. It presents for examination the following parts:

Fenestra ovalis.	Promontory.
Fenestra rotunda.	Ridge of the aquaeductus Fallopii.

Prominence of the external semicircular canal.

The **Fenestra Ovalis**, the **Oval** or the **Vestibular Window** (*fenestra vestibuli*) (Fig. 758) is a reniform opening leading from the tympanum into the vestibule. It is situated in the depths of a fossa (*fossula fenestrae vestibuli*). Its long diameter is directed horizontally, and its convex border is upward. The opening in the recent state is occupied by the base of the stapes (Figs. 757 and 763), which is connected to the margin of the foramen by an annular ligament.

The **Fenestra Rotunda**, the **Round** or **Cochlear Window** (*fenestra cochleae*) (Fig. 758) is an aperture placed at the bottom of a **funnel-shaped depression** (*fossula fenestrae cochleae*) leading into the cochlea. It is situated below and rather behind the fenestra ovalis, from which it is separated by a rounded elevation, the **promontory**; at its border is a narrow ridge of bone (*crista fenestrae cochleae*), and it is closed in the recent state by a membrane, the **membrane of Scarpa** or the **secondary ear-drum membrane** (*membrana tympani secundaria*). This membrane is concave toward the tympanum, convex toward the cochlea. It consists of three layers: the external or mucous, derived from the mucous lining of the tympanum; the internal, from the lining membrane of the cochlea; and an intermediate or fibrous layer.

The **Promontory** (*promontorium*) (Fig. 762) is a rounded hollow prominence, formed by the projection outward of the first turn of the cochlea; it is placed between the fenestrae, and is **furrowed** on its surface (*sulcus promontorii*) for the lodgement of the **tympanic plexus**. A minute spicule of bone frequently connects the promontory to the pyramid.

The Rounded Eminence of the Aquaeductus Fallopii (*prominentia canalis facialis*) (Fig. 762), the prominence of the bony canal in which the facial nerve is contained, traverses the inner wall of the tympanum above the fenestra ovalis, and behind that opening curves nearly vertically downward along the posterior wall.

Just above the eminence of the aquaeductus Fallopii the wall is bulged by the **external semicircular canal** (*prominentia canalis semicircularis lateralis*).

The Posterior Wall of the Tympanum (*paries mastoidea*) (Fig. 762).—The posterior wall of the tympanum is wider above than below, and the lower portion of the posterior wall contains many *tympanic cells*. The posterior wall presents for examination the—

Opening of the antrum.	Prominentia styloideae.
Fossa incudis.	Pyramid.

Apertura tympanica canaliculi chordae.

The **Opening of the Antrum** is a large irregular aperture, which extends backward from the epitympanic recess and leads into a considerable air space, the **mastoid antrum** (*antrum tympanicum*), which is the entrance to the mastoid cells (p. 87). The antrum communicates with large irregular cavities contained in the interior of the mastoid process, the **mastoid air-cells.** These cavities vary considerably in number, size, and form; they are lined by mucous membrane continuous with that lining the cavity of the tympanum.

The **Fossa Incudis** (Fig. 762) is placed in the posterior and inferior part of the epitympanic recess. It lodges the short process of the incus.

The **Prominentia Styloideae** is sometimes seen below the apertura tympanica canaliculi chordae. It is a prominence produced by a prolongation of the styloid process.

The **Pyramid** (*eminentia pyramidalis*)(Fig. 758) is a conical eminence situated immediately behind the fenestra ovalis, and in front of the vertical portion of the eminence above described; it is hollow in the interior, and contains the Stapedius muscle; its summit projects forward toward the fenestra ovalis, and presents a small aperture which transmits the tendon of the muscle. The cavity in the pyramid is prolonged into a minute canal, which communicates with the aquaeductus Fallopii and transmits the nerve which supplies the Stapedius.

The **Apertura Tympanica Canaliculi Chordae** is just back of the posterior edge of the tympanic membrane, nearly level with the superior end of the manubrium mallei.

The Anterior Wall of the Tympanum (*paries carotica*).—The anterior wall of the tympanum is bony on its lower portion. Its upper part is the tympanic opening of the Eustachian tube. The long anterior wall contains tympanic cells. The anterior wall is wider above than below; it corresponds with the carotid canal, from which it is separated by a thin plate of bone (Fig. 762), perforated by the **canaliculi caroticotympanici,** which transmit the tympanic branch of the internal carotid artery and the carotico-tympanic nerves. It presents for examination the—

Canal for the Tensor tympani. Orifice of the Eustachian tube.
The processus cochleariformis.

The orifice of the canal for the Tensor tympani and the orifice of the Eustachian tube are situated at the upper part of the anterior wall, being incompletely separated from each other by a thin, delicate, horizontal plate of bone, the **processus cochleariformis** (*septum canalis musculotubarii*) (Figs. 49 and 758). The canalis musculotubarius is divided by this long process into the canal for the Tensor tympani and the canal for the Eustachian tube. These canals run from the tympanum forward, inward, and a little downward, to the retiring angle between the squamous and petrous portions of the temporal bone.

The **Canal for the Tensor Tympani** (*semicanalis m. tensoris tympani*) (Figs. 49, 758, and 762) is the superior and the smaller of the two; it is rounded and lies beneath the forward prolongation of the tegmen tympani. It extends on to the inner wall of the tympanum and ends immediately above the fenestra ovalis. The processus cochleariformis passes backward below this part of the canal, forming its outer wall and floor; it expands above the anterior extremity of the fenestra ovalis and terminates by curving outward so as to form a pulley over which the tendon passes. The bony wall of this canal is incomplete, and the osseous vacancy is filled by tough connective tissue.

The **Eustachian Tube** or **Ear Trumpet** (*tuba auditiva* [*Eustachii*]) (Figs. 49, 758, and 759) is the channel through which the tympanum communicates with the pharynx. Its length is an inch and a half (36 mm.), and its direction downward, inward, and forward, forming an angle of about 45 degrees with the sagittal plane and one of from 30 to 40 degrees with the horizontal plane.

The **canal for the Eustachian tube** (*semicanalis tubae auditivae*) (Fig. 759) is formed partly of bone, partly of cartilage and fibrous tissue.

The **Osseous Portion** (*pars ossea tubae auditivae* or *semicanalis tubae auditivae*) is about half an inch in length. It is the outer portion of the tube. It commences in the anterior wall of the tympanum, below the processus cochleariformis (*ostium tympanicum tubae auditivae*), and, gradually narrowing, terminates at the angle of junction of the petrous and squamous portions of the temporal bone, its extremity presenting a jagged margin which serves for the attachment of the cartilaginous portion. The roof of the osseous portion is the tegmen tympani. The inner wall is formed in part by the inner wall of the tympanum and in part by the canal for the Tensor tympani muscle. The outer wall is the tympanic portion of the temporal bone. The floor is a groove which near the tympanum contains the openings of **air-cells** (*cellulae pneumatici tubarii*).

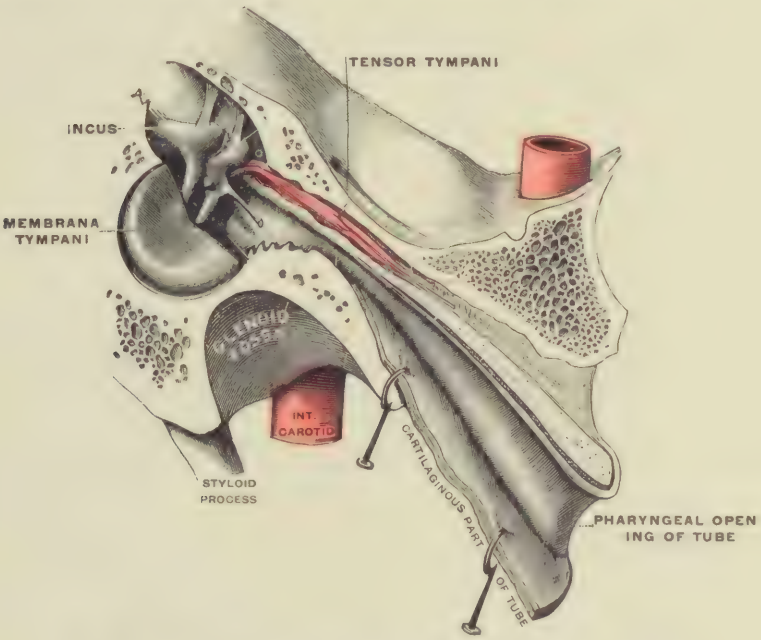

FIG. 759.—Eustachian tube, laid open by a cut in its long axis. (Testut.)

The **Cartilaginous Portion** (*pars cartilaginea tubae auditivae*), about an inch in length, is formed of a triangular plate of elastic fibro-cartilage (*cartilago tubae auditivae*), the apex of which is attached to the margin of the inner extremity of the osseous canal, while its base lies directly under the mucous membrane of the naso-pharynx, where it forms an elevation or cushion above and behind the pharyngeal orifice of the tube. The upper edge of the cartilage is curled upon itself, being bent outward so as to present on transverse section the appearance of a hook (*lamina lateralis*); a groove or furrow is thus produced, which opens below and externally, and this part of the canal is completed by fibrous membrane. On transverse section the cartilage exhibits the laminae which above are continuous with each other: the hard, thick lamina medialis and the thin and hooked lamina lateralis. The cartilage of the Eustachian tube, with a hood plate of cartilage, forms the posterior portion of the inner wall (the *lamina medialis*). The cartilage is fixed to the base of the skull, and lies in a groove (*sulcus tubae auditivae*) between the petrous-temporal and the greater wing of the sphenoid; this groove ends opposite the middle of the internal pterygoid plate, in a projection, the

processus tubarius. At the pharyngeal orifice the entire wall of the tube is cartilaginous, but the breadth of the cartilage progressively lessens as the isthmus is approached. Here and there the cartilage is deficient or pieces lie separate from the rest, the spaces between the islands being occupied by fibrous tissue. The Tensor palati muscle is placed to the outer side of the tube. The fibres of the muscle which take origin from the lamina lateralis are known as the **dilator tubae muscle of Rudinger.** The Tensor palati muscle and the mucous membrane of the pharynx lie to the inner side of the tube. The under and outer portion of the canal is completed by the **membranous part** (*lamina membranacea*), which is a strong fibrous membrane, passing between the two margins of the cartilage. It is thin above, but thick below, and the thick portion is called the **fascia salpingopharyngea of Tröltsch,** and from it arise some fibres of the **Tensor palati** (*m. salpingopharyngeus*). The cartilaginous and bony portions of the tube are not in the same plane, the former

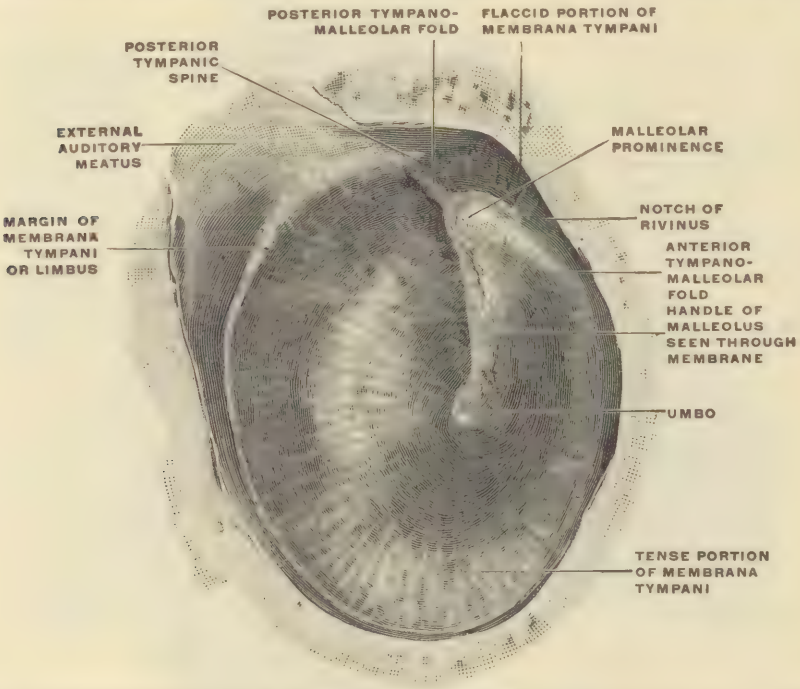

FIG. 760.—The right membrana tympani, viewed from the outside, from in front, and from below. (Spalteholz.)

inclining downward a little more than the latter. They join each other at a large obtuse angle, open below. The diameter of the canal is not uniform throughout, being greatest at the pharyngeal orifice and least at the junction of the bony and cartilaginous portions, where it is named the **isthmus** (*isthmus tubae auditivae*); it again expands somewhat as it approaches the tympanic cavity. The position and relations of the pharyngeal orifice (*ostium pharyngeum tubae auditivae*) are described with the anatomy of the naso-pharynx. Through this canal the mucous membrane of the pharynx is continuous with that which lines the tympanum. The mucous membrane is covered with ciliated epithelium and is thin in the osseous portion, while in the cartilaginous portion it contains many mucous glands and near the pharyngeal orifice a considerable amount of adenoid tissue, which has been named by Gerlach the **tube-tonsil.** The tube is opened during deglutition by the Salpingo-pharyngeus and Dilator tubae muscles.

The Drumhead or Membrana Tympani (Figs. 757, 759, 760, and 761).—The membrana tympani or drumhead separates the cavity of the tympanum from

the bottom of the external meatus. It is a thin, semi-transparent membrane, nearly oval in form, somewhat broader above than below, and directed very obliquely downward and inward, so as to form an angle of about 55 degrees with the floor of the meatus (Fig. 757). The antero-inferior portion is, therefore, placed at the greatest distance from the external orifice of the meatus. It is asserted that in musicians the membrana tympani is placed more nearly perpendicular, and that in deaf-mutes and cretins it is placed more obliquely than the usual 55 degrees. In a newborn child the membrana tympani is almost horizontal. The greatest diameter of the membrana tympani is from 9 to 10 mm.; its least diameter is from 8 to 9 mm.[1] The greater part of its circumference (*limbus membranae tympanae*) is thickened to form an **annular ring** (*annulus fibrocartilagineus*), which is fixed in a groove, the **sulcus tympanicus**, at the inner extremity

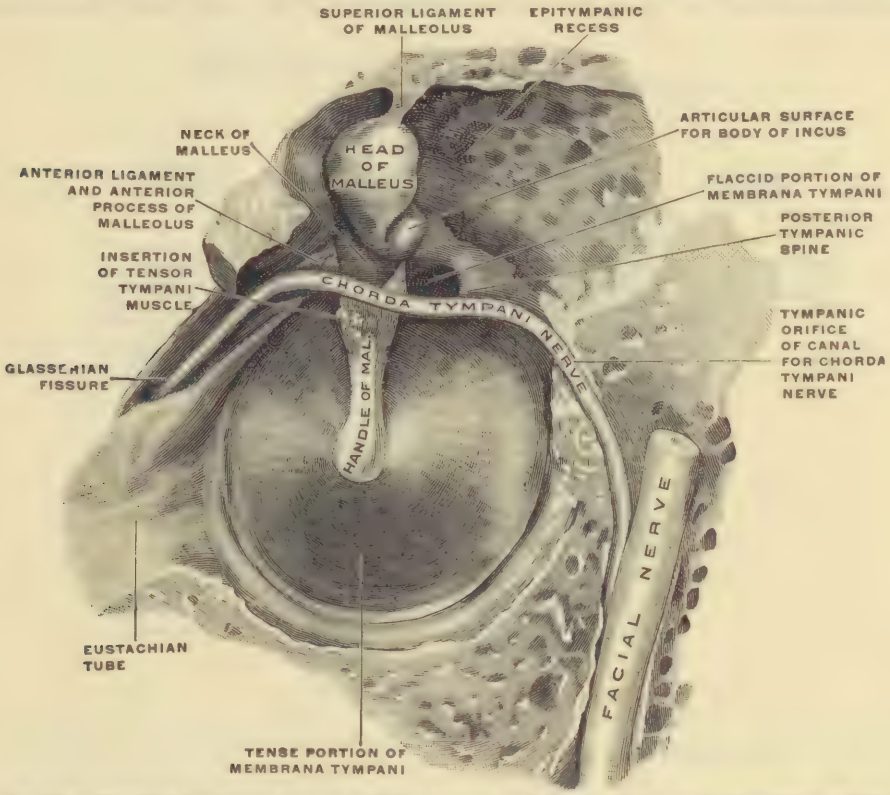

FIG. 761.—The right membrana tympani with the hammer and the chorda tympani, viewed from within, from behind, and from above. (Spalteholz.)

of the external meatus. This sulcus is deficient superiorly at the incisure or **notch of Rivinus** (*incisura tympanica* [*Rivini*]) (Fig. 760). From the extremities of the notch (*spinae tympanicae*) two folds pass and converge to the short process of the malleus (Fig. 760). One is known as the **anterior tympanomalleolar fold** or **ligament** (*plica membrana tympani anterior*). The other is known as the **posterior tympanomalleolar fold** or **ligament** (*plica membrana tympani posterior*). These are not to be confused with the anterior and posterior malleolar folds (p. 1162). The small, somewhat triangular part of the membrane situated above these folds is lax and thin, and is named the **flaccid portion** or the **membrana flaccida of Shrapnell** (Figs. 760 and 761). In it a small orifice is sometimes seen, which is of artificial and pathological formation. The larger lower portion of the drum membrane is stretched tightly, and is called the **tense portion** or **pars tensa** (Figs. 760 and 761).

[1] Prof. Cunningham's Text-book of Anatomy.

The handle of the malleus is firmly attached to the inner aspect of the membrana tympani as far as its centre (Fig. 761). It draws the central part of the membrane inward and makes its outer aspect concave. The most depressed part of the concavity is called the **umbo** or **navel** (*umbo membranae tympanae*)(Fig. 760). The walls of the umbo are convex outward.

On the outer surface of the drum membrane a light stripe (*stria malleolaris*) is seen. It runs from in front and above downward and backward, and is produced by the handle of the malleus, showing through the membrane (Fig. 760).

Structure.—This membrane is composed of three layers: an **external** (*cuticular*), a **middle** (*fibrous*), and an **internal** (*mucous*). The **cuticular lining** (*stratum cutaneum*) is derived from the integument lining the meatus. The **fibrous** or **middle layer** (*membrana propria*) consists of two strata: an external, of **radiating fibres** (*stratum radiatum*), which diverge from the handle of the malleus, and an

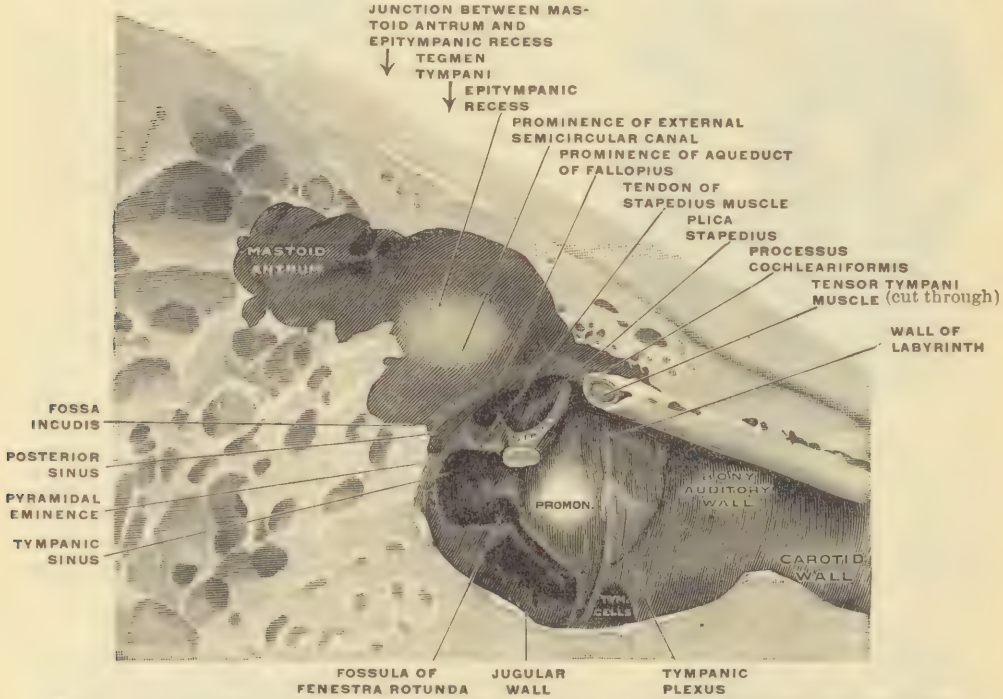

FIG. 762.—The medial wall and part of the posterior and anterior walls of the right tympanic cavity, lateral view. (Spalteholz.)

internal, of **circular fibres** (*stratum circulare*), which are plentiful around the circumference, but sparse and scattered near the centre of the membrane. **Branched** or **dendritic fibres,** as pointed out by Grüber, are also present, especially in the posterior half of the membrane. Both muscular layers are connected to the annulus fibrocartilagineus, and both are absent in the pars flaccida. The **inner** or **epithelial layer** is mucous membrane (*stratum mucosum*), which is a portion of the mucous membrane of the drum cavity.

The **Arteries** are derived from the deep auricular branch of the internal maxillary, which ramifies beneath the cuticular layer and from the stylo-mastoid branch of the posterior auricular and tympanic branch of the internal maxillary, which are distributed on the mucous surface. The arteries of the cutaneous set anastomose with the arteries of the mucous set by minute branches which penetrate the drum membrane near its margin. The **superficial veins** open into the external jugular; those on the mucous surface drain themselves partly into the lateral sinus and veins of the dura mater and partly into a plexus on the Eustachian tube.

The outer surface of the drum membrane receives its **nervous supply** from the auriculo-temporal branch of the inferior maxillary and the auricular branch of the vagus. The inner surface is supplied by the tympanic branch of the glossopharyngeal.

There are two sets of **lymphatics**, the cutaneous and mucous, which freely communicate. The spaces between the dendritic fibres of Grüber are lymph-spaces (Kessel).

The Ossicles of the Tympanum (Ossicula Auditus) (Fig. 763).

The tympanum contains in its upper part a chain of movable bones, three in number, the **malleus, incus,** and **stapes**. The first is attached to the membrana tympani, the last to the fenestra ovalis. The incus is placed between the two, and is connected to both by delicate articulations.

Fig. 763.—Chain of ossicles and their ligaments, seen from the front in a vertical, transverse section of the tympanum. (Testut.)

The Malleus or Hammer (Fig. 764).—The malleus or hammer, so named from its fancied resemblance to a hammer, is placed farthest in front and outward. It consists of a **head, neck,** and three processes—the **handle** or **manubrium,** the **processus gracilis,** and the **processus brevis.**

The Head (*capitulum mallei*).—The head is the large upper extremity of the bone, and is situated in the epitympanic recess (Fig. 761). It is oval in shape, and articulates posteriorly with the incus, being free in the rest of its extent. The facet for articulation with the incus is covered with cartilage, is constricted near the middle, and is divided by a ridge into an upper, larger, and a lower, lesser part, which form nearly a right angle with each other. Opposite the constriction the lower margin of the facet projects in the form of a process, the **cog-tooth** or **spur of the malleus.** On the back of the head below the spur is a crest (*crista mallei*), to which the posterior ligament of the malleus is attached.

The Neck (*collum mallei*).—The neck is the narrow contracted part just beneath the head; and below this is a prominence, to which the various processes are attached. The outer surface of the neck faces the membrana flaccida. The chorda tympani nerve crosses the inner surface (Fig. 761).

The Handle or Manubrium (*manubrium mallei*).—The manubrium is a vertical process of bone, which is connected by its outer margin with the fibrous layer of the membrana tympani, its entire length being fastened to the fibrous layer of the drum membrane by its own periosteum and by a layer of cartilage (Grüber) (Figs. 761 and 763). It is directed downward, inward, and backward; it decreases in size toward its extremity, where it is curved slightly forward, and is flattened from within outward. The handle forms a variable angle with the head of the hammer. It averages about 130 degrees, but is always greater in the right ear than in the left. It forms an angle with the horizontal, averaging on the right side 50 degrees and on the left side 45 degrees (Spaltcholz). Internally the handle is covered by the mucous membrane of the tympanum. On the inner side, near its upper end, is a slight projection, into which the tendon of the Tensor tympani is inserted (Fig. 761).

The **Processus Gracilis or Long Process** (*processus anterior* [*Folii*]).—The processus gracilis is a long and very delicate process, which passes from the front of

the neck forward and outward to the Glaserian fissure, to which it is connected by ligamentous fibres. In the fœtus this is the longest process of the malleus, and is in direct continuity with the cartilage of Meckel.

The Processus Brevis (*processus lateralis*).—The processus brevis is a slight conical projection, which springs from the root of the manubrium; it is directed outward, and is attached to the upper part of the tympanic membrane by cartilage and to the margins of the notch of Rivinus by the two malleolar folds.

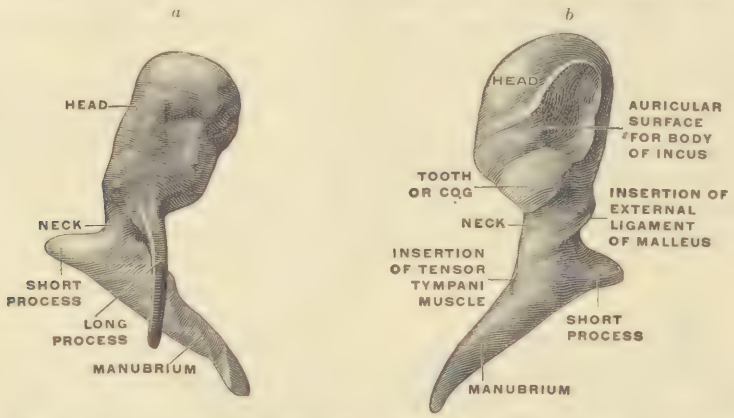

Fig. 764.—The right malleus: *a*, viewed from in front; *b*, viewed from behind. (Spalteholz.)

The Incus or Anvil (Fig. 765).—The incus or anvil has received its name from its supposed resemblance to an anvil, but it is more like a bicuspid tooth with two roots, which differ in length, and are widely separated from each other. It consists of a **body** and **two processes**. The body and the short process are placed in the epitympanic recess (Fig. 763).

The Body (*corpus incudis*).—The body is somewhat quadrilateral, but compressed laterally. On its anterior surface is a deeply concavo-convex facet, which articulates with the head of the malleus, and the lower part is hollowed for the spur of the malleus. In the fresh state the articular surface is covered with cartilage and the joint is lined with synovial membrane.

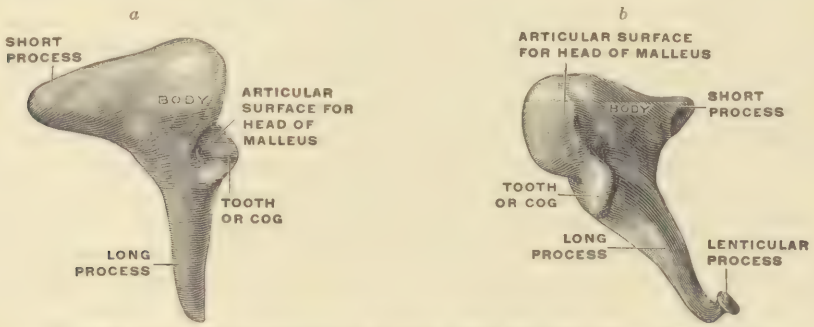

Fig. 765.—The right incus: *a*, lateral view; *b*, medial and front view. (Spalteholz.)

Processes.—The two processes diverge from one another at an angle of from 90 to 100 degrees.

The **Short Process** (*crus breve*), somewhat conical in shape, projects nearly horizontally backward, and articulates with a depression, the **incus fossa** (*fossa incudis*), in the lower and back part of the epitympanic recess.

The **Long Process** (*crus longum*), longer and more slender than the preceding, descends nearly vertically behind and parallel to the handle of the malleus, and,

bending inward, terminates in a rounded globular projection, the **os orbiculare or lenticular process** (*processus lenticularis*), which is tipped with cartilage, and articulates with the head of the stapes. In the fœtus the os orbiculare exists as a separate bone.

The Stapes or Stirrup (Fig. 766).—The stapes or stirrup, so called from its close resemblance to a stirrup, consists of a **head, neck, two crura,** and a **base.**

The Head (*capitulum stapedis*).—The head presents a depression, tipped with cartilage, which articulates with the os orbiculare.

The Neck.—The neck, the constricted part of the bone succeeding the head, receives the insertion of the Stapedius muscle.

The Crura.—The two crura (*crus anterius* and *crus posterius*) diverge from the neck and are connected at their extremities by a flattened, oval-shaped plate, the **foot-plate** or **base** (*basis stapedis*), which forms the foot-plate of the stirrup and is fixed to the margin of the fenestra ovalis by ligamentous fibres. The foot-plate almost fills the oval window (Fig. 757. Of the two crura, the anterior is shorter and less curved than the posterior. In a recent specimen a membrane will be observed filling the space between the crura and the foot-plate. This membrane is connective tissue and is called the *membrana obturatoria stapedis*. The stirrup lies practically horizontal.

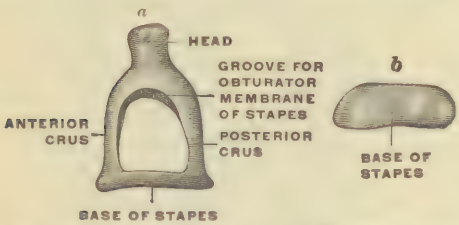

FIG. 766.—The right stirrup: *a*, viewed from above; *b*, medial vein. (Spalteholz.)

Articulations of the Ossicles of the Tympanum (*articulationes ossiculorum auditus*) (Fig. 763).—These small bones are connected with each other and with the walls of the tympanum by ligaments, and are moved by small muscles. There is an articulation between the head of the hammer and the body of the anvil; one between the os orbiculare of the anvil and the head of the stirrup; and there is a syndesmosis between the margins of the oval window and the base of the stirrup. The bones are fastened in the tympanum, the handle of the hammer being fastened in the drum membrane and the base of the stirrup to the oval window. The articular surfaces of the malleus and incus and the orbicular process of the incus and head of the stapes are covered with cartilage, connected together by delicate capsular ligaments and lined by synovial membrane.

Ligaments Connecting the Ossicula with the Walls of the Tympanum (*ligamenta ossiculorum auditus*).—The malleus is fastened to the wall of the tympanum by three ligaments: the **anterior, superior,** and **external ligaments.**

The **Anterior Ligament of the Malleus** (*ligamentum mallei anterius*) consists of two parts, the **band of Meckel** and the **anterior ligament of Helmholtz.**

The **band of Meckel** is attached to the base of the processus gracilis and passes through the Glaserian fissure to reach the spine of the sphenoid. It was formerly described by Sömmering as a muscle, and it was called the **laxator tympani muscle.** It is now, however, believed by most observers to consist of ligamentous fibres only.

The **anterior ligament of Helmholtz** extends from the anterior margin of the notch of Rivinus to the anterior portion of the malleus, just above the processus gracilis.

The **Superior Ligament of the Malleus** (*ligamentum mallei superius*) is a delicate round bundle of fibres which descends perpendicularly from the roof of the epitympanic recess to the head of the malleus. It is sometimes called the **suspensory ligament.**

The **External Ligament of the Malleus** (*ligamentum mallei laterale*) is a triangular plane of fibres passing from the posterior part of the notch in the tympanic ring

(*incisura Rivini*) to the crest of the malleus. The posterior portion of the external ligament is sometimes called the **posterior ligament of Helmholtz** (*ligamentum mallei posterius* [*Helmholtzi*]). The malleus rotates around an axis composed of the external and anterior ligaments, hence these two ligaments constitute what Helmholtz called the **axis ligament of the malleus.**

The incus is fastened to the wall of the tympanum by two ligaments, the **posterior** and the **superior.**

The **Posterior Ligament of the Incus** (*ligamentum incudis posterius*) is a short, thick, ligamentous band which connects the extremity of the short process of the incus to the posterior and lower part of the epitympanic recess, near the margin of the opening of the mastoid cells.

A **Superior Ligament of the Incus** (*ligamentum incudis superius*) has been described by Arnold, but it is little more than a fold of mucous membrane.

The inner surface and the circumference of the base of the stapes are covered with hyaline cartilage, and the **annular ligament of the stapes** (*ligamentum annulare baseos stapedis*) connects the circumference of the base to the margin of the fenestra ovalis.

The Muscles of the Tympanum (*m. ossiculorum auditus*).—The muscles of the tympanum are two:

Tensor tympani. Stapedius.

The **Tensor Tympani** (*m. tensor tympani*) (Fig. 762), the larger, is contained in the bony canal above the osseous portion of the Eustachian tube, from which it is separated by the processus cochleariformis. It *arises* from the under surface of the petrous bone, from the cartilaginous portion of the Eustachian tube, and from the osseous canal in which it is contained. Passing backward through the canal, it terminates in a slender tendon which enters the tympanum and makes a sharp bend outward around the extremity of the processus cochleariformis, and is inserted into the handle of the malleus near its root. Its nerve-supply is from the motor root of the fifth cranial nerve by way of the otic ganglion.

The **Stapedius** (*m. stapedius*) (Fig. 762) *arises* from the side of a conical cavity hollowed out of the interior of the pyramid; its tendon emerges from the orifice at the apex of the pyramid, and, passing forward, is inserted into the neck of the stapes. Its surface is aponeurotic, its interior fleshy, and its tendon occasionally contains a slender bony spine, which is constant in some mammalia. It is supplied by the tympanic branch of the facial nerve.

Actions.—The **Tensor tympani** draws the handle of the malleus inward and thus heightens the tension of the drum membrane. It also causes slight rotation of the bone around its long axis. When the Stapedius contracts it draws the head of the stirrup backward, and in consequence the anterior end of the foot-plate passes outward toward the tympanum, and the posterior end inward toward the vestibule, and the annular ligament is made tense.

Movements of the Ossicles of the Tympanum.—The chain of bones is a lever-like arrangement, by means of which the vibrations of the membrana tympani are transferred to the membrane covering the oval window, and from this to the perilymph in the labyrinth. When the drum membrane moves inward, the handle of the malleus moves with it. The movement of the malleus moves the incus, and the movement of the incus drives the foot of the stapes toward the labyrinth. When the handle of the malleus moves inward, the spur on the head becomes locked with the body of the incus. During outward movement it is unlocked. The ordinary outward movement of the drum membrane causes the above-described movements to be reversed. When there is overforcible outward movement the incus does not go outward quite as far as the malleus, but slides at the joint between the malleus and incus. This reluctance of the incus saves the foot of the stapes from being pulled away from the oval window.

The Mucous Membrane of the Tympanum (*tunica mucosa tympanica*).—The mucous membrane of the tympanum is continuous with the mucous membrane of the naso-pharynx through the Eustachian tube, and is firmly united to the periosteum. It invests the ossicula, and the muscles and nerves contained in the tympanic cavity; forms the internal layer of the membrana tympani, and the outer layer of the membrana tympani secundaria, and is reflected into the mastoid antrum and air-cells, which it lines throughout. It forms several vascular folds (*plicae*), which extend from the walls of the tympanum to the ossicles. In these folds the ossicles are enveloped.

The **anterior malleolar fold** (*plica malleolaris anterior*) comes off from the membrana tympani between the anterior edge of the notch of Rivinis and the handle of the malleus, envelops the processus gracilis of the malleus, the anterior ligament of the malleus, and the anterior portion of the chorda tympani nerve, and terminates in a free concave edge (Spalteholz). The **posterior malleolar fold** (*plica malleolaris posterior*) is the larger of the two. It comes off from the margin of the notch of Rivinis, envelops the external ligament of the malleus, the posterior part of the chorda tympani nerve, is attached to the handle of the malleus, and ends in a free concave margin (Spalteholz). The **fold of the incus** (*plica incudis*) takes origin from the roof of the epitympanic recess and passes to the body and short process of the incus; and a similar fold passes from the head of the malleus to the anterior wall of the epitympanic recess. The entire stapes, with its obturator membrane, is enwrapped by the **fold of the stapes** (*plica stapedis*). This fold also ensheaths the tendon of the stapedius muscle and often reaches to the posterior wall of the cavity of the tympanum. The mucous membrane over the round window forms the **membrana tympani secundaria.** These folds separate off pouch-like cavities, and give the interior of the tympanum a somewhat honey-comb appearance. One of these pouches is well marked—viz., the **pouch of Prussak,** which lies between the neck of the malleus and the membrana flaccida.

The **inferior external pouch of the tympanum** or the **pouch of Prussak** (*recessus membranae tympani superior*) is between the flaccid portion of the membrana tympani, the external ligament of the malleus, and the neck of the malleus. The anterior and posterior malleolar folds with the tympanic membrane form two pouches. These are the **anterior** and **posterior pouches** or **recesses of Tröltsch** (*recessus membranae tympani, anterior* and *posterior*). The anterior pouch is blind above and has a slit-like opening below. The posterior pouch is continued into the blind superior pouch of the drum membrane. In the tympanum this membrane is pale, thin, slightly vascular, and covered for the most part with columnar ciliated epithelium, but that covering the pyramid, ossicula, and membrana tympani possesses a flattened, non-ciliated epithelium. In the antrum and mastoid cells its epithelium is also non-ciliated. In the osseous portion of the Eustachian tube the membrane is thin; but in the cartilaginous portion it is very thick, highly vascular, covered with ciliated epithelium, and provided with numerous mucous glands.

The Arteries of the Tympanum.—The arteries supplying the tympanum are six in number. Two of them are larger than the rest—viz., the tympanic branch of the internal maxillary, which enters by way of the Glaserian fissure and supplies the membrana tympani; and the stylo-mastoid branch of the posterior auricular, which passes through the stylo-mastoid foramen and the aqueduct of Fallopius, and supplies the inner wall and floor of the tympanum, the mastoid cells, and antrum and the Stapedius muscle. This vessel anastomoses around the drum membrane with the tympanic. The middle meningeal sends a small branch to the Tensor tympani muscle near its origin. The petrosal branch of the middle meningeal enters the tympanum by way of the hiatus Fallopii. Minute branches from the posterior branch of the middle meningeal pass through the petro-

squamous fissure and are distributed to the antrum and epitympanic recess (Cunningham). Two tympanic branches come off from the internal carotid artery in its course through the carotid canal. A branch from the ascending pharyngeal and another from the Vidian, accompany the Eustachian tube. The two tympanic branches from the internal carotid are given off in the carotid canal and perforate the thin anterior wall of the tympanum.

The Veins of the Tympanum.—The veins of the tympanum terminate in the pterygoid plexus, the middle meningeal vein, and the superior petrosal sinus.

The Nerves of the Tympanum.—The nerves of the tympanum constitute the **tympanic plexus** (*plexus tympanicus* [*Jacobsoni*]), which ramifies upon the surface of the promontory (Fig. 762). The plexus is formed by (1) the tympanic branch of the glosso-pharyngeal; (2) the small deep petrosal nerve; (3) the small superficial petrosal nerve; and (4) a branch which joins the great superficial petrosal.

The **Tympanic Branch of the Glosso-pharyngeal** or **Jacobson's Nerve** (*n. tympanicus*) enters the tympanum by an aperture in its floor close to the inner wall and divides into branches, which ramify on the promontory and enter into the formation of the plexus. The **small deep petrosal nerve** (*n. petrosus profundus*), from the carotid plexus of the sympathetic, passes through the wall of the carotid canal, and joins the branches of Jacobson's nerve. The branch to the great superficial petrosal passes through an opening on the inner wall of the tympanum in front of the fenestra ovalis. The **small superficial petrosal nerve** (*n. petrosus superficialis minor*), derived from the otic ganglion, passes through a foramen in the middle fossa of the base of the skull (sometimes through the foramen ovale), passes backward and enters the petrous bone through a small aperture, situated external to the hiatus Fallopii on the anterior surface of this bone; it then courses downward through the bone, and, passing by the gangliform enlargement of the facial nerve, receives a connecting filament from it (Fig. 676) and enters the tympanic cavity, where it communicates with Jacobson's nerve, and assists in forming the tympanic plexus.

The **branches of distribution** of the tympanic plexus are distributed to the mucous membrane of the tympanum; one special branch passing to the fenestra ovalis, another to the fenestra rotunda, and a third to the Eustachian tube. The small superficial petrosal may be looked upon as a branch from the plexus to the otic ganglion.

In addition to the tympanic plexus there are the nerves supplying the muscles. The Tensor tympani is supplied by a branch from the third division of the fifth through the otic ganglion, and the Stapedius by the tympanic branch of the facial.

The **chorda tympani** (Figs. 758 and 761) crosses the tympanic cavity. It is given off from the facial as it passes vertically downward at the back of the tympanum, about a quarter of an inch before its exit from the stylo-mastoid foramen. It passes from below upward and forward in a distinct canal, and enters the cavity of the tympanum through an aperture, **iter chordae posterius**, already described (p. 1151), and becomes invested with mucous membrane. It passes forward, through the cavity of the tympanum, crossing internal to the membrana tympani and over the handle of the malleus to the anterior inferior angle of the tympanum, and emerges from that cavity through the **iter chordae anterius** or **canal of Huguier** (p. 1152). It is invested by the fold of mucous membrane already mentioned, and therefore lies between the mucous and fibrous layers of the membrana tympani.

THE INTERNAL EAR OR LABYRINTH (AURIS INTERNA).

The internal ear is the essential part of the organ of hearing, receiving the ultimate distribution of the auditory nerve. It is called the **labyrinth**, from the

complexity of its shape, and consists of two parts: the **osseous labyrinth**, a series of cavities channelled out of the substance of the petrous bone, and the **membranous labyrinth**, the latter being contained within the former.

The Osseous Labyrinth (Labyrinthus Osseus) (Fig. 767).

The osseous labyrinth consists of three parts: the **vestibule**, **semicircular canals**, and **cochlea**. These are cavities hollowed out of the substance of the bone, and lined by periosteum. A clear fluid is contained in the space between the osseous labyrinth and the membranous labyrinth. The space is called the **perilymph space**, and the fluid is called **perilymph** or **liquor Cotunnii**.

The Vestibule (*vestibulum*) (Figs. 763 and 767).—The vestibule is the common central cavity of communication between the parts of the internal ear. It is situated on the inner side of the tympanum, behind the cochlea, and in front of the semicircular canals. It is somewhat ovoidal in shape from before backward, flattened from within outward, and measures about one-fifth of an inch from before back-

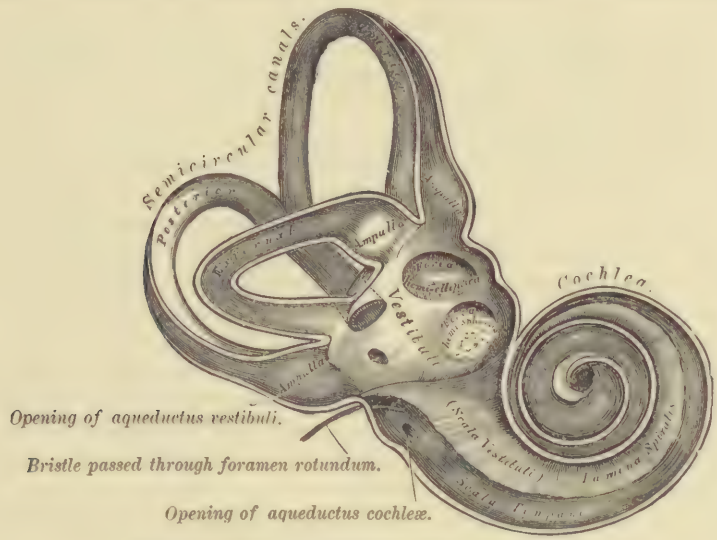

FIG. 767.—The osseous labyrinth laid open (enlarged).

ward, as well as from above downward, and about one-eighth of an inch from without inward. On its *outer* or *tympanic wall* is the **fenestra ovalis** (*fenestra vestibuli*), closed, in the recent state, by the base of the stapes, and its annular ligament. On its *inner wall*, at the forepart, is a small circular depression, **fovea hemisphaerica** or **spherical recess** (*recessus sphaericus*), in which the saccule is placed. This recess is perforated, at its anterior and inferior part, by about a dozen minute holes (*macula cribrosa media*), for the passage of filaments of the auditory nerve to the saccule. Above and behind this depression is an oblique ridge, the **crista vestibuli**. The anterior extremity of the crista vestibuli is the shape of a triangle, and is called the **pyramid** (*pyramis vestibuli*). This ridge bifurcates posteriorly to enclose a small depression, the **recessus cochlearis of Reichert**, which is perforated by eight small holes for the passage of filaments of the auditory nerve which supply the posterior end of the ductus cochlearis. An oval depression is placed in the roof and inner wall of the vestibule above and behind the crista vestibuli. It is called the **fovea hemielliptica**, **elliptical recess** or **spherical recess** (*recessus ellipticus*), and receives the utricle. The pyramid and the adjacent elliptical recess are perforated by numerous minute foramina (*macula cribrosa superior*),

The openings in the pyramid transmit filaments from the vestibular nerve to the utricle; the openings in the elliptical recess transmit filaments from the vestibular nerve to the ampullae of the superior and external semicircular canals. Below and behind the elliptical recess is a groove which deepens into a canal and is called the **aquaeductus vestibuli**. This canal passes to the posterior surface of the petrous portion of the temporal bone and opens as a mere crack between the internal auditory meatus and the groove for the lateral sinus. It transmits a small vein, and contains a tubular prolongation of the lining membrane of the vestibule, the **ductus endolymphaticus**, which ends in a *cul-de-sac* between the layers of the dura mater within the cranial cavity. *Behind*, the semicircular canals open into the vestibule by five orifices. In *front* is an elliptical opening, which communicates with the scala vestibuli of the cochlea by an orifice, **apertura scalae vestibuli cochleae**. This opening is bounded below by a thin plate of bone (*lamina spiralis ossea*), which takes origin from the vestibular floor external to the spherical recess and in the cochlea forms the bony portion of the partition between the scala tympani and the scala vestibuli. In the anterior portion of the vestibular floor is a fissure (*fissura vestibuli*), which passes into the bony part of the canal of the cochlea. The external boundary of this fissure is a small, thin plate of bone (*lamina spiralis secundaria*).

The Semicircular Canals (*canales semicirculares ossei*) (Fig. 767).—The semicircular canals are three bony canals situated above and behind the vestibule. They are of unequal length, compressed from side to side, and each describes the greater part of a circle. They measure about one-twentieth of an inch in diameter, and each presents a dilatation at one end, called the **ampulla ossea**, which measures more than twice the diameter of the tube. These canals open into the vestibule by five orifices, one of the apertures being common to two of the canals.

The Superior Semicircular Canal (*canalis semicircularis superior*).—The superior semicircular canal is vertical in direction, and is placed transversely to the long axis of the petrous portion of the temporal bone, on the anterior surface of which its arch forms a round projection. It describes about two-thirds of a circle. Its outer extremity, which is ampullated, communicates by a distinct orifice with the upper part of the vestibule; the opposite end of the canal, which is not dilated, joins with the corresponding part of the posterior canal to form the **crus commune**, which opens into the upper and inner part of the vestibule.

The Posterior Semicircular Canal (*canalis semicircularis posterior*).—The posterior semicircular canal, also vertical in direction, is directed backward, nearly parallel to the posterior surface of the petrous bone; it is the longest of the three; its ampullated end commences at the lower and back part of the vestibule, its opposite end joining to form the common canal already mentioned. In the wall of the ampulla of the posterior canal are a number of small openings (*macula cribrosa inferior*) for the entrance of nerves to the ampulla.

The External or Horizontal Canal (*canalis semicircularis lateralis*).—The external or horizontal canal is the shortest of the three, its arch being directed outward and backward; thus each semicircular canal stands at right angles to the other two. Its ampullated end corresponds to the upper and outer angle of the vestibule, just above the fenestra ovalis, where it opens close to the ampullary end of the superior canal; its opposite end opens by a distinct orifice at the upper and back part of the vestibule.

The Cochlea (Figs. 767, 768, 769, and 770).—The cochlea bears some resemblance to a common snail-shell; it forms the anterior part of the labyrinth, is conical in form, and placed almost horizontally in front of the vestibule; its apex is directed forward and outward, with a slight inclination downward, toward the upper and front part of the inner wall of the tympanum; its base corresponds with the anterior depression at the bottom of the internal auditory meatus, and is perforated by numerous

apertures for the passage of the cochlear divisions of the auditory nerve. It measures nearly a quarter of an inch (5 mm.) from base to apex, and its breadth across

FIG. 768.—Osseous cochlea in vertical section. The broken, white lines indicate the position of the basilar membrane of the canal of the cochlea. Semidiagrammatic. (Testut.)

the base is somewhat greater (about 9 mm.). It consists of a conical-shaped central axis, the **modiolus** or **columella**; of a canal, the **bony canal of the cochlea**, the inner wall of which is formed by the central axis, wound spirally around it for two

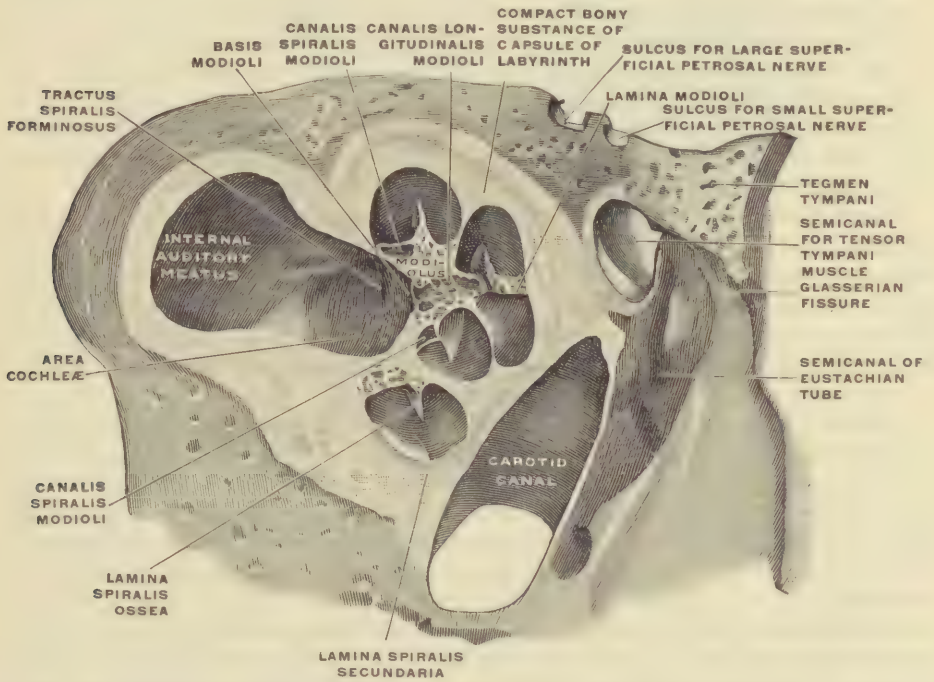

FIG. 769.—Vertical section through the right cochlea, medial portion, viewed from the lateral side. (Spalteholz.)

turns and three-quarters, from the base to the apex, and of a delicate lamina, the **lamina spiralis ossea**, which projects from the modiolus, and, following the windings

of the canal, partially subdivides into two. In the recent state certain membranous layers are attached to the free border of this lamina, which project into the canal and completely separate it into two passages, which, however, communicate with each other at the apex of the modiolus by a small opening, named the **helicotrema.**

The Modiolus (Figs. 769 and 770).—The modiolus or **columella** is the central axis or pillar of the cochlea. It is conical in form, and extends from the base to the apex of the cochlea. Its **base** (*basis modioli*) is broad, and appears at the bottom of the internal auditory meatus, where it corresponds with the area cochleae. It is perforated by numerous orifices, which transmit filaments of the cochlear division of the auditory nerve, the nerves for the first turn and a half being transmitted through the foramina of the **tractus spiralis foraminosus**; the fibres for the apical turn passing up through the foramen centrale. The foramina of the tractus spiralis foraminosus pass up through the modiolus and successively bend outward to reach the attached margin of the lamina spiralis ossea. Here they become enlarged, and by their apposition form a **spiral canal** (*canalis spiralis modioli*), which follows the course of the attached margin of the lamina spiralis ossea and lodges the **ganglion of Corti** (*ganglion spirale cochleae*). The **foramen centrale** is continued as a canal up the middle of the modiolus to its apex, and from this canal numerous minute foramina pass outward to the unattached edge of the lamina spiralis. In the foramina are vessels and nerves. The axis diminishes rapidly in size in the second and succeeding coil.

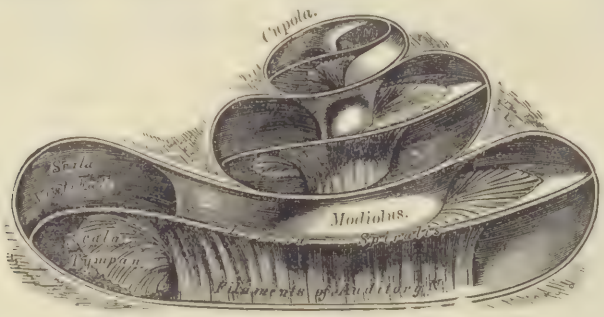

FIG. 770. The cochlea laid open (enlarged).

The Bony Canal or the Spiral Canal of the Cochlea (*canalis spiralis cochleae*) (Fig. 770).—The bony canal of the cochlea takes two turns and three-quarters round the modiolus. The first turn of the canal is called the **basal coil,** the second is called the **central coil,** the third turn is called the **apical coil.** The promontory on the inner wall of the tympanic cavity is caused by the basal coil. The bony canal of the cochlea is a little over an inch in length (about 30 mm.), and diminishes gradually in size from the base to the summit, where it terminates in a *cul-de-sac*, the **cupola** (*cupula*), which forms the apex of the cochlea. The commencement of this canal is about the tenth of an inch in diameter; it diverges from the modiolus toward the tympanum and vestibule, and presents three openings. One, the **fenestra rotunda,** communicates with the tympanum; in the recent state this aperture is closed by a membrane, the **membrana tympani secundaria.** Another aperture, of an elliptical form, enters the vestibule. The third is the aperture of the **aquaeductus cochleae,** leading to a minute funnel-shaped canal, which opens on the basilar surface of the petrous bone internal to the jugular fossa, and transmits a small vein, and also forms a communication between the subarachnoidean space of the skull and the perilymph contained in the scala tympani.

The Lamina Spiralis Ossea.—The lamina spiralis ossea is a bony shelf or ledge which projects outward from the modiolus into the interior of the spiral canal,

and, like the canal, takes two and three-quarter turns around the modiolus. It reaches about half-way toward the outer wall of the spiral tube, and partially divides its cavity into two passages or **scalae**, of which the upper is named the **scala vestibuli**, while the lower is termed the **scala tympani**. Near the summit of the cochlea the lamina terminates in a hook-shaped process, the **hamulus** (*hamulus laminae spiralis*), which assists in forming the boundary of a small opening, the **helicotrema**, by which the two scalae communicate with each other. From the canalis spiralis modioli numerous foramina pass outward through the osseous spiral lamina as far as its outer or free edge. In the lower part of the first turn a second bony lamina (*lamina spiralis secundaria*) projects inward from the outer wall of the bony tube; it does not, however, reach the primary osseous spiral lamina, so that if viewed from the vestibule a narrow fissure, the **fissura vestibuli**, is seen between them.

The membrana basilaris (Fig. 768) is stretched from the unattached edge of the lamina spiralis ossea to the outer wall of the cochlea. The lamina spiralis

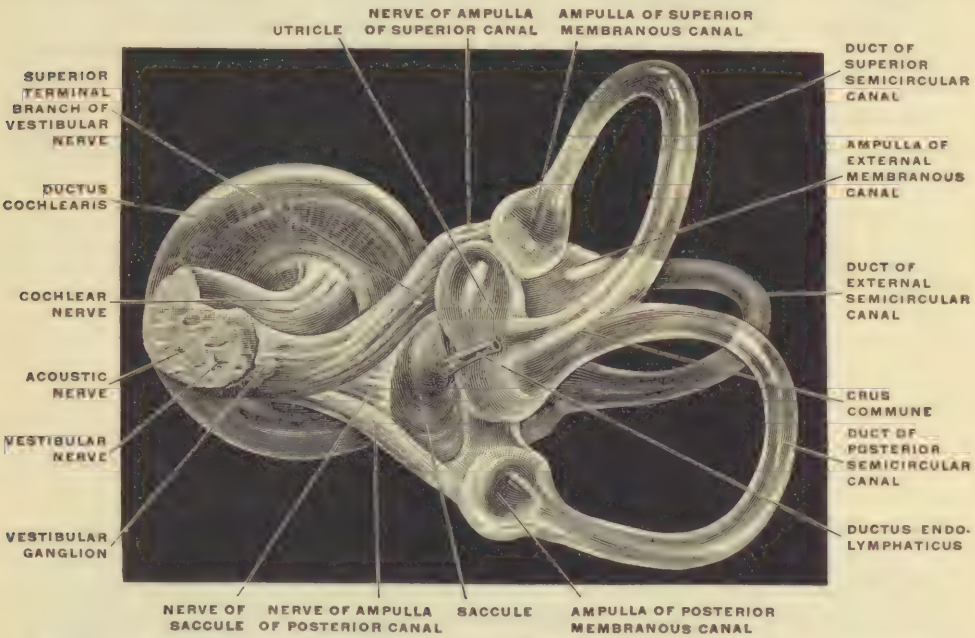

FIG. 771.—The right membranous labyrinth of an adult, isolated, medial and posterior view. (Spalteholz.)

makes an incomplete septum between the scala tympani and scala vestibuli; the membrana basilaris completes the septum. Even with the perfected septum the two scalae communicate at the apex of the cochlea by means of the helicotrema.

The Fundus of the Internal Auditory Meatus (*fundus meatus acustici interni*).—This structure is the inner wall of the vestibule and the base of the modiolus. A transverse ridge (*crista transversa*) maps it off into two parts, the **fossula superior** and the **fossula inferior**. The **facial area** (*area n. facialis*) is in the anterior portion of the fossula superior. The opening seen here is the beginning of the **aqueduct of Fallopius** (*canalis facialis*) for the transmission of the facial nerve. The **superior area of the vestibule** (*area vestibularis superior*) is the posterior portion of the fossula superior. Here the nerves perforate which supply the utricle and the ampullae of the superior and external semicircular canals (Cunningham). The **area cochleae** is the anterior portion of the fossula inferior. In it is the *canalis centralis* for the nerve-fibres to the apical turn of the cochlea; and the *tractus spiralis foraminosa* for the transmission of nerves to the first turn and a half of the cochlea. The

inferior area of the vestibule (*area vestibularis inferior*) is back of the area cochleae and a ridge separates the two. It transmits nerves to the saccule. At the posterior part of the fossula inferior is a solitary foramen, the **foramen singulare**, which transmits nerves to the ampulla of the posterior semicircular canal.

The Membranous Labyrinth (Labyrinthus Membranaceus) (Figs. 771, 772).

The membranous labyrinth is contained within the bony cavities just described, having the same general form as the cavities in which it is contained, though considerably smaller, being separated from the bony walls by a quantity of fluid, the **perilymph** or **liquor Cotunnii** (*perilympha*). It does not, however, float loosely in this fluid, but in places is fixed to the walls of the cavity. The membranous sac contains fluid, the **endolymph** (*endolympha*), and on the sac the ramifications of the auditory nerve are distributed.

Within the osseous vestibule the membranous labyrinth does not quite preserve the form of the bony cavity, but presents two membranous sacs, the **utricle** and the **saccule**.

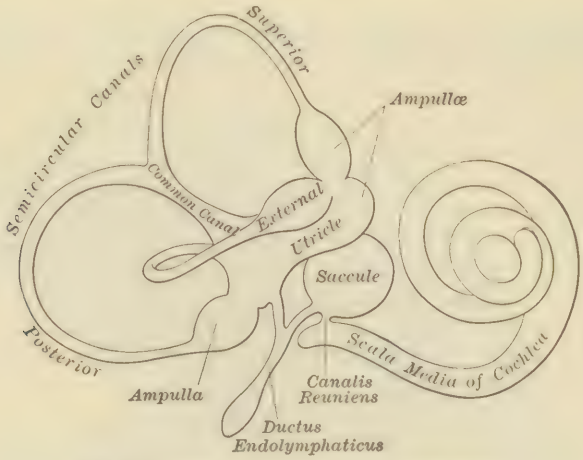

FIG. 772.—The membranous labyrinth (enlarged).

The Utricle (*utriculus*).—The utricle is the larger of the two, of an oblong form, compressed laterally, and occupies the upper and back part of the vestibule, lying in contact with the fovea semi-elliptica and the part below it. The highest portion of the utricle is called the **recess** (*recessus utriculi*); it is placed in the elliptical recess, and opening into it are the ampulla of the superior and external semicircular canals. The central portion of the recess of the utricle receives upon the side the external semicircular canal. This opening has not an ampulla. The **superior sinus** is a prolongation upward and backward from the central portion of the utricle and in the superior sinus the crus commune and the superior and posterior semicircular canals open. The lower and inner portion of the utricle is the **inferior sinus**, and into it the ampulla of the posterior semicircular canal opens. The floor and anterior wall of the recess of the utricle are much thicker than elsewhere, and form the **macula acustica utriculi**, which receives the utricular filaments of the auditory nerve and has attached to its internal surface a layer of calcareous particles which are called **otoliths**. The cavity of the utricle communicates behind with the membranous semicircular canals by five orifices. From its anterior wall is given off a small canal (*ductus utriculosaccularis*), which joins with a canal from the saccule, the **ductus endolymphaticus**. The utricle is joined to the bony wall by numerous fibrous bands.

The Saccule (*sacculus*).—The saccule is the smaller of the two vesicular sacs; it is globular in form, lies in the elliptical recess near the opening of the **scala vestibuli** of the cochlea. Its anterior part exhibits an oval thickening, the **macula acustica sacculi**, to which are distributed the saccular filaments of the auditory nerve. Its cavity does not directly communicate with that of the utricle. From the posterior wall is given off a canal, the **ductus endolymphaticus**. This duct passes along the aquaeductus vestibuli and ends in a blind pouch on the posterior surface of the petrous portion of the temporal bone, where it is in contact with the dura mater. The upper extremity of the saccule looks upward and backward and forms the **sinus utricularis sacculi**. This lies in contact with but is not a part of the wall of the utricle. The vestibule contains the closed end of the ductus cochlearis. This is known as the **caecum vestibulare**. The **ductus cochlearis** lies below the saccule in what Reichert described as the **recessus cochlearis**, and it enters the spiral canal. From the lower part of the saccule a short tube, the **canalis reuniens of Hensen** (*ductus reuniens* [*Henseni*]), passes downward and outward to open into the ductus cochlearis. The saccule is held in position by numerous fibrous bands which pass between the saccule and the bony wall.

The Membranous Semicircular Canals (*ductus semicirculares*).—The membranous semicircular canals are about one-third the diameter of the osseous canals, but in number, shape, and general form they are precisely similar, and present at one end within the osseous ampulla a membranous ampulla. These ampullae are called **ampullae membranaceae**. The canals open by five orifices into the utricle, one opening being common to two canals. In the ampullae the wall is thickened, and projects into the cavity as a fiddle-shaped, transversely placed elevation, the **septum transversum**, in which the nerves end.

The membranous canals are attached here and there to the bone by numerous fibrous bands, the so-called ligaments (*ligamenta labyrinthi canaliculorum*).

Structure.—The walls of the utricle, saccule, and membranous semicircular canals consist of three layers. The *outer layer* is a loose and flocculent structure, apparently composed of ordinary fibrous tissue, containing blood-vessels and pigment-cells analogous to those in the pigment coat of the retina. The *middle layer*, thicker and more transparent, bears some resemblance to the hyaloid membrane, but it presents on its internal surface, especially in the semicircular canals, numerous papilliform projections, and, on the addition of acetic acid, presents an appearance of longitudinal fibrillation and elongated nuclei. The *inner layer* is formed of polygonal nucleated epithelial cells. The **raphé** of each semicircular canal is a line upon the concave side of the canal. Along the raphé the height of the epithelial cells is distinctly increased. In the ampullae adjacent to the cristae acusticae the cells are cylindrical and constitute the **plana semilunata**. In the maculae of the utricle and saccule, and in the transverse septa of the ampullae of the canals, the middle coat is thickened and the epithelium is columnar, is increased in height, and passes into the neuro-epithelium. The **neuro-epithelium** consists of supporting cells and hair-cells.

1. The **supporting cells** are long, wider at the ends than in the centre, contain an oval nucleus, and the lower end of the cell is fissured.

2. The **hair-cells** are columnar, with bulged lower ends and free upper ends. The bulged lower ends, each of which contains a spherical nucleus, do not reach higher than the middle of the epithelial layer. Each free upper end is surmounted by a long, tapering filament. These filaments constitute **auditory hair**, and they project into the cavity. The filaments of the auditory nerve enter these parts, and, having pierced the outer and thickened middle layer, they lose their medullary sheath, and their axis-cylinders divide into three or four branches at the larger and deeper ends of the hair-cells. These branches form a horizontal plexus

(*stratum plexiforme*). "These surround the hair-cells like the calyx of a flower, and give off ascending branches, which, however, do not reach the surface. In this way one branch usually comes in contact with many hair-cells."[1]

together in a mesh of delicate fibrous tissue, are contained in the walls of the utricle and saccule opposite the distribution of the nerves. The membrane is

called the **otolith membrane**. A calcareous material is also, according to Bowman, sparingly scattered in the cells lining the ampullae of the semicircular canals. The conical thickening in the ampulla corresponds to the otolith membrane and is called the **cupola**.

The **Membranous Cochlea Ductus Cochlearis** or **Scala Media** consists of a spirally arranged tube enclosed in the bony canal of the cochlea and lying along its outer wall. It begins as a blind end in the recessus cochlearis of the vestibule. This beginning is the **caecum vestibulare**. It ascends inside the bony cochlea and terminates at the apex of the cochlea by a blind end, the **lagena** (*caecum cupulare*). The manner in which it is formed will now be described.

The osseous spiral lamina, as above stated, extends only part of the distance between the modiolus and the outer bony wall of the cochlea. A membrane, the **basilar membrane** (*membrana basilaris*) (Fig. 773), stretches from its free edge to the outer wall of the cochlea,and completes the roof of the scala tympani. A second and more delicate membrane, the **membrane of Reissner** (*membrana vestibularis* [*Reissneri*]) (Fig.773), extends from the thickened periosteum covering the lamina spiralis ossea to the outer wall of the cochlea, to which it is attached at some little distance above the membrana basilaris. A canal is thus shut off between the scala tympani below and the scala vestibuli above; this is the **membranous canal of the cochlea** (*ductus cochlearis* or *scala media*) (Fig. 774). It is triangular on transverse section, its roof being formed by the membrane of Reissner, its outer wall by the periosteum which lines the bony canal, and its floor by the membrana basilaris, and the outer part of the lamina spiralis ossea, on the former of which is placed the organ of Corti. Reissner's membrane is thin and homogeneous, and is covered on its upper and under surfaces by a layer of epithelium. The periosteum, which forms the outer wall of the ductus cochlearis, is greatly thickened and altered in character, forming what is called the **spiral ligament of the cochlea** (*ligamentum spirale cochleae*)(Fig.773). It projects inward below as a triangular prominence, the **crista basilaris**, which gives attachment to the outer edge of the membrana basilaris,and immediately above which is a concavity, the **sulcus spiralis externus** (Fig. 773). The upper portion of the ligamentum spirale contains numerous capillary loops and small blood-vessels, and forms what is termed the **stria vascularis**. The stria is limited below by a prominence (*prominentia spiralis*), in which a blood-vessel (*vas prominens*) is distinctly visible.

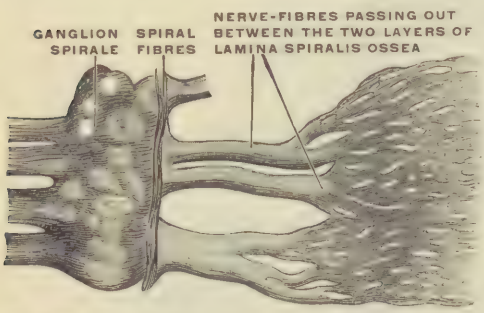

Fig. 775.—Part of the cochlear nerve, highly magnified. (Henle.)

The **lamina spiralis ossea** (Fig. 774) consists of two plates of bone extending outward; between these are the canals for the transmission of the filaments of the auditory nerve. On the upper plate of that part of the osseous spiral lamina which is outside Reissner's membrane the periosteum is thickened to form the **limbus laminae spiralis**, and this terminates externally in a concavity, the **sulcus spiralis internus**, which presents, on section, the form of the letter C; the upper part of the letter, formed by the overhanging extremity of the limbus, is named the **labium vestibulare**; the lower part, prolonged and tapering, is called the **labium tympanicum**, and is perforated by 4000 foramina (*foramina nervosa*) for the passage of the cochlear nerves. Externally, the labium tympanicum is continuous with the membrana basilaris. The upper surface of the labium vestibulare is intersected at right angles by a number of furrows, between which are numerous elevations; these present the appearance of teeth along the free margin of the

labium, and have been named by Huschke the **auditory teeth**. There are 7000 auditory teeth. The basilar membrane may be divided into two areas, inner and outer. The inner is thin, and is named the **zona arcuata** or **zona tecta** (Fig. 773); it supports the organ of Corti. The outer is thicker and striated, and is termed the **zona pectinata**. The under surface of the membrane is covered by a layer of

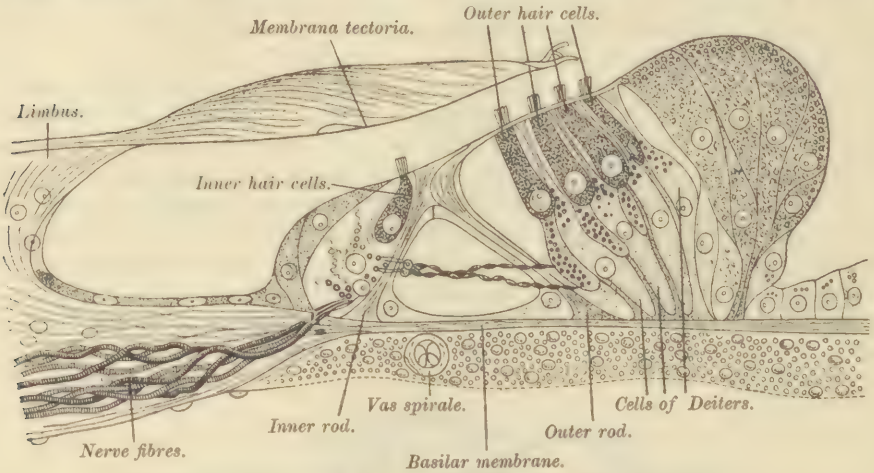

FIG. 776.—Section through the organ of Corti. Magnified. (G. Retzius.)

vascular connective tissue. One of these vessels is somewhat larger than the rest, and is named the **vas spirale** (Fig. 776); it lies below Corti's tunnel.

Organ of Corti[1] (*organon spirale* [*Cortii*]) (Figs. 773, 774, 776, and 777).—The inner part of the membrana basilaris—that is, the part directed toward the canal of the ductus cochlearis—is covered with epithelium, which is largely neuro-epithe-

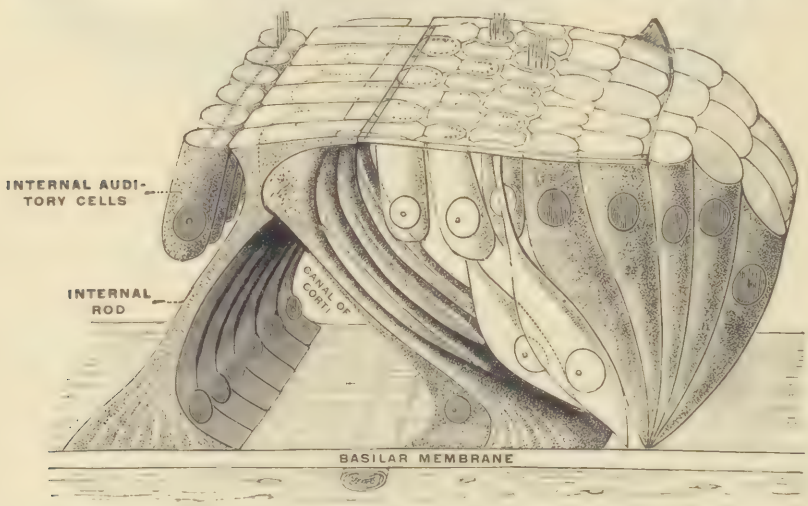

FIG. 777.—Organ of Corti. Diagrammatic view of a small portion. (Testut.)

lium. It forms the **organ of Corti**. In this lie the terminations of the cochlear nerve. It appears at first sight as a papilla, winding spirally throughout the whole length of the ductus cochlearis, from which circumstance it has been designated the **papilla spiralis**. More accurately viewed, it is seen to be composed of a remarkable arrangement of cells, which may be likened to the keyboard of a

[1] Corti's original paper is in the Zeitschrift f. Wissen. Zool., iii., 109.

pianoforte. The organ of Corti consists of an *inner part* and an *outer part*. Each part contains **auditory cells** and **supporting cells**. Of these cells, the two central ones are rod-like bodies and are called the **inner and outer rods of Corti**. They are placed on the basilar membrane, at some little distance from each other, but are inclined toward each other, so as to meet at their opposite extremities, and form a series of arches roofing over a minute tunnel, the **canal** or **tunnel of Corti**, between them and the basilar membrane, which ascends spirally through the whole length of the cochlea.

The **inner rods** (Fig. 776), some 6000 in number, are more numerous than the outer ones, and rest on the basilar membrane, close to the labium tympanicum; they project obliquely upward and outward, and terminate above in expanded extremities which resemble in shape the upper end of the ulna, with its sigmoid cavity, coronoid and olecranon processes. On the outer side of the rod, in the angle formed between it and the basilar membrane, is a nucleated mass of protoplasm; while on the inner side is a row of epithelial cells, **inner hair-cells** (Fig. 776), surmounted by a brush of fine, stiff, hair-like processes. On the inner side of these cells are two or three rows of columnar supporting cells, which are continuous with the cubical cells lining the sulcus spiralis internus.

FIG. 778.—Longitudinal section of the cochlea, showing the relations of the scalae, the ganglion spirale, etc. S. V., Scala vestibuli. S. T., Scala tympani. S. M., Scala media. L. S., Ligamentum spirale. G. S., Ganglion spirale.

The **outer rods** (Fig. 776), numbering about 4000, also rest by a broad foot on the basilar membrane; they incline upward and inward, and their upper extremity resembles the head and bill of a swan; the back of the head fitting into the concavity—the analogue of the sigmoid cavity—of one or more of the internal rods, and the bill projecting outward as a phalangeal process of the membrana reticularis, presently to be described.

In the head of these outer rods is an oval portion, where the fibres of which the rod appears to be composed are deficient, and which stains more deeply with carmine than the rest of the rod. At the base of the rod, on its internal side—that is to say, in the angle formed by the rod with the basilar membrane—is a similar protoplasmic mass to that found on the outer side of the base of the inner rod; these masses of protoplasm are probably the undifferentiated portions of the cells from which the rods are developed. External to the outer rod are three or four successive rows of epithelial cells, more elongated than those found on the

internal side of the inner rod, but, like them, furnished with minute hairs or cilia. These are termed the **outer hair-cells**, in contradistinction to the inner hair-cells above referred to. There are about 12,000 outer hair-cells, and about 3500 inner hair-cells.

The hair-cells are somewhat oval in shape; their free extremities are on a level with the heads of Corti's rods, and from each some twenty fine hairlets project and are arranged in the form of a crescent, the concavity of which opens inward. The deep ends of the cells are rounded and contain large nuclei; they reach only as far as the middle of Corti's rods, and are in contact with the ramifications of the nervous filaments. Between the rows of the outer hair-cells are rows of supporting cells, called the **cells of Deiters**; their expanded bases are planted on the basilar membrane, while their opposite ends present a clubbed extremity or **phalangeal process**. Immediately to the outer side of Deiters's cells are some five or six rows of columnar cells, the **supporting cells of Hensen**. Their bases are narrow, while their upper parts are expanded and form a rounded elevation on the floor of the ductus cochlearis. The columnar cells lying outside Hensen's cells are termed the **cells of Claudius**. A space is seen between the outer rods of Corti and the adjacent hair-cells; this is called the **space of Nuel**.

The **lamina reticularis** or **membrane of Kölliker** is a delicate framework perforated by rounded holes. It extends from the inner rods of Corti to the external row of the outer hair-cells, and is formed by several rows of "minute fiddle-shaped cuticular structures" called **phalanges**, between which are circular apertures containing the free ends of the hair-cells. The innermost row of phalanges consists of the phalangeal processes of the outer rods of Corti; the outer rows are formed by the modified free ends of Deiters's cells.

Covering over these structures, but not touching them, is the **membrana tectoria** or **membrane of Corti** (Figs. 773 and 776), which is attached to the vestibular surface of the lamina spiralis close to the attachment of the membrane of Reissner. It is thin near its inner margin, and overlies the auditory teeth of Huschke. Its outer half is thick, and along its lower edge, opposite the inner hair-cells, is a clear band, named **Hensen's stripe**. Externally, the membrane becomes much thinner, and is attached to the outer row of Deiters's cells (Retzius).

The fibres from the cochlear nerve enter the organ of Corti as axis-cylinders, which pass directly to the deepest portions of the inner and outer hair-cells by way of the canal of Corti or by the space of Nuel. The terminations arborize about the lower portions of the hair-cells and end on the surfaces of the hair-cells.

The **inner surface of the osseous labyrinth** is lined by an exceedingly thin fibro-serous membrane, analogous to a periosteum, from its close adhesion to the inner surfaces of these cavities, and performing the office of a serous membrane by its free surface. It lines the vestibule, and from this cavity is continued into the semicircular canals and the scala vestibuli of the cochlea, and through the helicotrema into the scala tympani. A delicate tubular process is prolonged along the aqueduct of the vestibule to the inner surface of the dura mater. This membrane is continued across the fenestra ovalis and fenestra rotunda, and consequently has no communication with the lining membrane of the tympanum. Its attached surface is rough and fibrous, and closely adherent to the bone; its free surface is smooth and pale, covered with a layer of epithelium, and secretes a thin, limpid fluid, the **aqua labyrinthi, liquor Cotunnii** or **perilymph** (Blainville).

The scala media is closed above and below. The upper blind extremity is termed the **lagena**, and is attached to the cupola at the upper part of the helicotrema; the lower end is lodged in the recessus cochlearis of the vestibule. Near this blind extremity, the scala media receives the **canalis reuniens of Hensen** (Fig. 772), a very delicate canal, by which the ductus cochlearis is brought into continuity with the saccule.

The Arteries of the Labyrinth.—The arteries of the labyrinth are the **internal auditory,** from the basilar, and the **stylo-mastoid,** from the posterior auricular. The internal auditory divides at the bottom of the internal auditory meatus into two branches, cochlear and vestibular.

The **cochlear artery** divides into numerous minute branches, which enter foramina in the tractus spiralis foraminosa and course in the lamina spiralis ossea to reach the membranous structures. The largest of the cochlear branches is in the canalis centralis.

The **vestibular branches** accompany the nerves, and supply the membranous structures in the vestibule and semicircular canals. Two arteries go to each canal. The two vessels enter opposite extremities of the canal, and anastomose at the summit of the canal. The vestibular vessels form a minute capillary network in the substance of each membranous labyrinth.

The Veins of the Labyrinth.—The veins of the vestibule and semicircular canals, the **auditory veins,** accompany the arteries, and receive those of the cochlea at the base of the modiolus, to form the **internal auditory vein** (*vv. auditivae internae*), which opens into the posterior part of the inferior petrosal sinus or into the lateral sinus.

The Nerves of the Labyrinth.—The **auditory nerve** (*n. acusticus*), the special nerve of the sense of hearing, divides, at the bottom of the internal auditory meatus, into two branches, the **cochlear** and **vestibular.**

The **Vestibular Nerve** (*n. vestibularis*), the posterior of the two, presents, as it lies in the internal auditory meatus, a ganglion, the **vestibular ganglion** or the **ganglion of Scarpa** (*ganglion vestibulare*); the nerve divides into three branches which pass through minute openings at the upper and back part of the bottom of the meatus (*area vestibular posterior*), and, entering the vestibule, are distributed to the utricle and to the ampulla of the external and superior semicircular canals.

The nervous filaments enter the ampullary enlargements opposite the septum transversum, and arborize around the hair-cells. In the utricle and saccule the nerve-fibres pierce the membrana propria of the maculae, and end in arborizations around the hair-cells.

The **Cochlear Nerve** (*n. cochlearis*) gives off the branch to the saccule, the filaments of which are transmitted from the internal auditory meatus through the foramina of the *area vestibularis inferior*, which lies at the lower and back part of the floor of the meatus. It also gives off the branch for the ampulla of the posterior semicircular canal, which leaves the meatus through the **foramen singulare**.

The rest of the cochlear nerve divides into numerous filaments at the base of the modiolus; those for the basal and middle coils pass through the foramina in the tractus foraminosus, those for the apical coil through the canalis centralis, and the nerves bend outward to pass between the lamellae of the osseous spiral lamina. Occupying the spiral canal of the modiolus is the **spiral ganglion** or **ganglion of Corti** (*ganglion spirale*), consisting of bipolar nerve-cells, which really constitute the true cells of origin of this nerve, one pole being prolonged centrally to the brain and the other peripherally to the hair-cells of Corti's organ. Reaching the outer edge of the osseous spiral lamina, the nerve fibres pass through the foramina in the labium tympanicum, where they lose their axis-cylinders. They enter the organ of Corti and pass directly to the deep portions of the inner and outer hair-cells by way of the canal of Corti and the space of Nuel. The terminations arborize about the lower portions of the hair-cells and end in the surfaces of the cells.

Surgical Anatomy.—*Malformations*, such as imperfect development of the external parts, absence of the meatus, or supernumerary auricles, are occasionally met with. Or the pinna may present a *congenital fistula*, which is due to defective closure of the first visceral cleft, or rather of that portion of it which is not concerned in the formation of the Eustachian tube, tympanum, and meatus. In some cases the cephalo-auricular angle is almost absent; in others it is nearly

a right angle. *Projecting ears* and *long ears* are said by some observers to be more common among degenerates, criminals, and the insane than among the normal, the non-criminal, and the sane. The skin of the auricle is thin and richly supplied with blood, but in spite of this it is frequently the seat of *frost-bite*, due to the fact that it is much exposed to cold, and lacks the usual underlying subcutaneous fat found in most other parts of the body. A collection of blood is sometimes found between the cartilage and perichondrium (*haematoma auris*), usually the result of traumatism, but not necessarily due to this cause. It is said to occur most frequently in the ears of the insane. *Keloid* sometimes grows in the auricle around the puncture made for ear-rings, and *epithelioma* occasionally affects this part. Deposits of *urate of soda* are often met with in the pinna in gouty subjects.

The external auditory meatus can be most satisfactorily examined by light reflected down a funnel-shaped speculum; by gently moving the latter in different directions the whole of the canal and membrana tympani can be brought into view. The points to be noted are: the presence of wax or foreign bodies, the size of the canal, and the condition of the membrana tympani. The *accumulation of wax* is often the cause of deafness, and may give rise to very serious consequences, causing ulceration of the membrane and even absorption of the bony wall of the canal. *Foreign bodies* are not infrequently introduced into the ear by children, and, when situated in the first portion of the canal, may be removed with tolerable facility by means of a minute hook or loop of fine wire, the parts being illuminated with reflected light; but when they have slipped beyond the narrow middle part of the meatus, their removal is in nowise easy, and attempts to effect it, in inexperienced hands, may be followed by destruction of the membrana tympani and possibly injury of the contents of the tympanum. The calibre of the external auditory canal may be narrowed by *inflammation* of its lining membrane, running on to *suppuration;* by *periostitis;* by *polypi*, *sebaceous tumors*, and *exostoses*. The membrana tympani, when seen in a healthy ear, "reflects light strongly, and, owing to its peculiar curvature, presents a bright spot of triangular shape at its lower and anterior portion." From the apex of this, proceeding upward and slightly forward, is a white streak formed by the handle of the malleus, while near the upper part of the membrane may be seen a slight projection, caused by the short process of the malleus. In disease alterations in color, lustre, curvature or inclination, and perforation must be noted. Such perforations may be caused by a blow, a loud report, a wound, or as the result of suppuration in the middle ear.

The upper wall of the meatus is separated from the cranial cavity by a thin plate of bone; the anterior wall is separated from the temporo-mandibular joint and parotid gland by the bone forming the glenoid fossa; and the posterior wall is in relation with the mastoid cells; hence *inflammation* of the external auditory meatus may readily extend to the membranes of the brain, to the temporo-mandibular joint, or to the mastoid cells; and, in addition to this, blows on the chin may cause fracture of the wall of the meatus.

The nerves supplying the meatus are the *auricular branch of the pneumogastric*, the *auriculo-temporal*, and the *auricularis magnus*. The connections of these nerves explain the fact of the occurrence, in cases of any irritation of the meatus, of constant coughing and sneezing from implication of the pneumogastric, or of yawning from implication of the auriculo-temporal. No doubt also the association of *earache with toothache* in cancer of the tongue is due to implication of the same nerve, a branch of the fifth, which supplies also the teeth and the tongue. The vessels of the meatus and membrana tympani are derived from the *posterior auricular*, *temporal*, and *internal maxillary arteries*. The upper half of the membrana tympani is much more richly supplied with blood than the lower half. For this reason, and also to avoid the chorda tympani nerve and ossicles, *incisions through the membrane* should be made at the lower and posterior part.

The principal point in connection with the *surgical anatomy of the tympanum* is its relations to other parts. Its roof is formed by a thin plate of bone, which, with the dura mater, is all that separates it from the temporal lobe of the brain. Its floor is immediately above the *jugular fossa* and the *carotid canal*, the fossa being behind and the canal in front. Its posterior wall presents the openings of the *mastoid cells*. On its anterior wall is the opening of the *Eustachian tube*. Thus it follows that in disease of the middle ear we may get *subdural abscess*, *septic meningitis*, or *abscess of the cerebrum* or *cerebellum* from extension of the inflammation through the bony roof; *thrombosis of the lateral sinus*, with or without pyæmia, by extension through the floor; or *mastoid abscess* by extension backward. In addition to this, we may get fatal hemorrhage from the internal carotid in destructive changes of the middle ear; and in throat disease we may get the inflammation extending up the Eustachian tube to the middle ear. The Eustachian tube is accessible from the nose. If the nose and mouth be closed and an attempt made to expire air, a sense of pressure with dulness of hearing is produced in both ears, from the air finding its way up the Eustachian tube and bulging out the membrana tympani. During the act of swallowing, the pharyngeal orifice of the tube, which is normally closed, is opened, probably by the action of the Dilator tubea muscle. This fact was employed by Politzer in devising an easy method of inflating the tube. The nozzle of an india-rubber syringe is inserted into the nostril; the patient takes a mouthful of water and holds it in his mouth, both nostrils are closed with the finger and thumb to prevent the escape of air, and the patient is then requested to swallow; as he does so the

surgeon squeezes the bulb and the air is forced out of the syringe into his nose, and is driven into the Eustachian tube, which is now open. The impact of the air against the membrana tympani can be heard by the surgeon, if the membrane is intact, sound being conveyed by means of a piece of india-rubber tubing, one end of which is inserted into the meatus of the patient's ear, the other into that of the surgeon. The direct examination of the Eustachian tube is made by the Eustachian catheter. This is passed along the floor of the nostril, close to the septum, with the point touching the floor, to the posterior wall of the pharynx. When this is felt, the catheter is to be withdrawn about half an inch, and the point rotated outward through a quarter of a circle, and pushed again slightly backward, when it will enter the orifice of the tube, and will be found to be caught, and air forced into the catheter will be heard impinging on the tympanic membrane if the ears of the patient and surgeon are connected by an india-rubber tube.

THE SKIN (INTEGUMENTUM COMMUNE).

The skin covers the body surface and is continuous with the mucous membrane at the origin and termination of the alimentary canal and at the openings of other canals. The skin is a protective coat, a regulator of body-temperature, contains multitudes of the terminations of sensory nerves, and is the seat of the **organ of touch** (*organon tactus*). These nerve-terminations are connected with nerve-fibres of temperature, pressure, and pain. Connected with the skin are sweat-glands which have important excretory functions and sebaceous glands. From its superficial part come appendages, the hairs, and nails. The skin is elastic and varies in thickness from 0.5 mm. to 4 mm. It is thinnest in the eyelids and prepuce, and thickest over the back of the neck, back of the shoulders, palms of the hands, and soles of the feet. Its color depends in part on the blood within it, and in part upon pigment. The deepest hue is about the anus, in the genital region, in the axillae, over the mammary glands, and in the parts exposed to air, light, and varied temperatures. The color varies with age, being pinkish in extreme youth and becoming yellow in old age. It varies with exposure and with climate, being deepest in those who brave all weathers and temperatures and in those who dwell beneath a tropical sun. It also varies with race, and this is so well recognized that races are classified by the color of the skin into the Black, White, Yellow, and Brown races. The color of the skin is also affected in certain diseases; being extremely pale in anæmia, brown in Addison's disease, yellow in jaundice, etc.

FIG. 779.—The furrows and ridges of the surface of the skin from the palm or surface of the middle finger. (Toldt.)

In most situations the skin is movable, but in some it is attached closely to underlying structures, and is consequently immovable on the scalp, the palms of the hands, the soles of the feet, and the outer portion of the pinna of the ear. The skin is fairly smooth, but close examination discloses multitudes of openings, creases, furrows, depressions, folds, and hairs.

Hair-follicles open upon the surface, and the ducts of sebaceous glands and of sweat-glands perforate the skin.

About the joints are **folds of skin** (*retinacula cutis*), and temporary folds or wrinkles are created by the contraction of superficial muscles. The *facial wrinkles* of advancing years are due to habitual expression and loss of skin elasticity. A *dimple* is a permanent pit or depression due to adhesion of the surface to parts beneath. The ridges and furrows on the palms, soles, and flexor aspects of the

digits are permanent, and over the palmar surface of the digits they are arranged in definite forms which endure through life and are so distinctive that they have been utilized by police officials in determining the identity of individuals. These folds are due to the papillae of the skin being arranged in rows; some of the papillae proliferate, and linear depressions occur in the horny layer (Philippson).

FIG. 780.—Anterior surface.

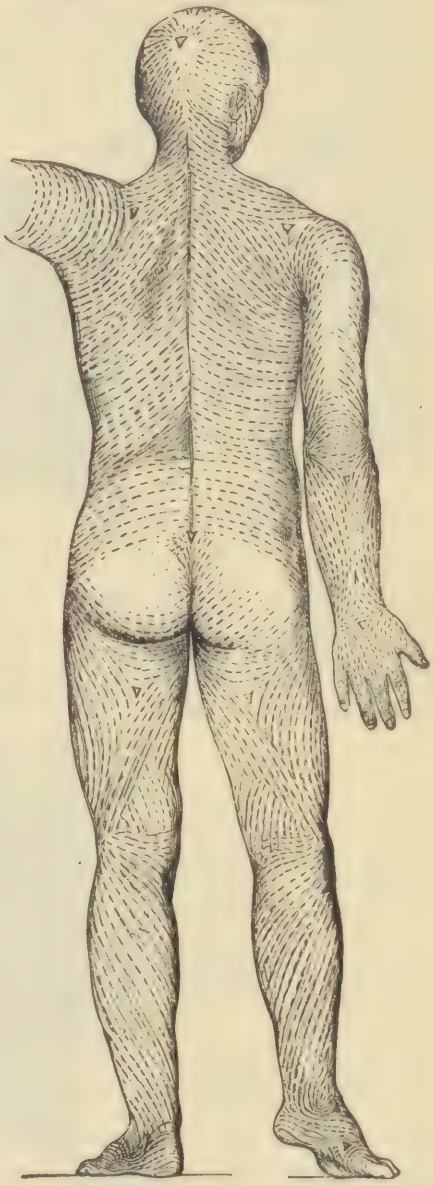

FIG. 781.—Posterior surface.

The general course of the connective-tissue bundles of the corium, determined by the direction assumed by the linear clefts made in the skin when it is punctured by a round awl. (Langer.)

Fig. 779 shows **skin ridges** (*cristae cutis*), **skin furrows** (*sulci cutis*), furrows opposite joints due to acts of flexion, and called **flexure furrows**, and **longitudinal furrows**.

When the skin is punctured by a round awl it tends to split in a definite direction, which direction varies with the region stabbed. These clefts are known

as the **lines of cleavage of Langer** (Figs. 780 and 781), and depend upon the arrangement of the connective-tissue bundles of the corium. These connective-tissue bundles certainly influence the formation of folds and furrows. In many portions of the body the cutaneous surface is divided by linear furrows into irregularly shaped areas (Fig. 782). The skin consists of two layers: a superficial layer, the **epidermis**, and a deep layer, the **corium** or **dermis**.

The **Corium, Cutis Vera, Dermis** or **True Skin** (Figs. 783, 784, and 786) is a connective-tissue structure which arises from the mesoderm. It consists especially of connective tissue and elastic fibres; it contributes elasticity to the skin, and is the seat of the sensitive layer. The corium is composed of two layers, the **reticular** and the **papillary.**

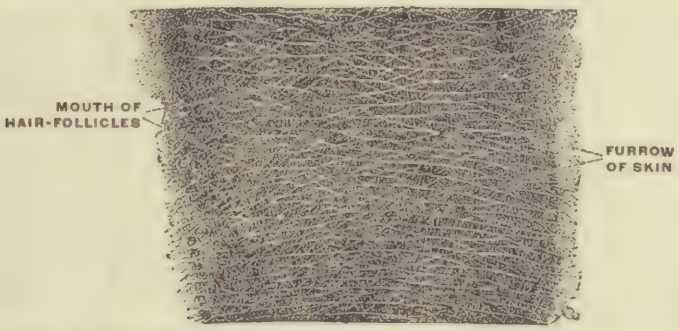

FIG. 782.—The furrows of the skin and the areas which these furrows delimit, reproduced from an impression of the dorsal surface of the wrist. (Toldt.)

The **Deep** or **Reticular Layer** or **Tunica Propria** (*stratum reticulare*) rests upon the subcutaneous tissue. It passes superficially into the papillary layer, and at most places into the subcutaneous tissue without a sharp line of differentiation. At some places, for instance in the nipple, the deep layer of the corium rests upon a layer of muscular fibre. In the face this muscle-fibre is striated and sends

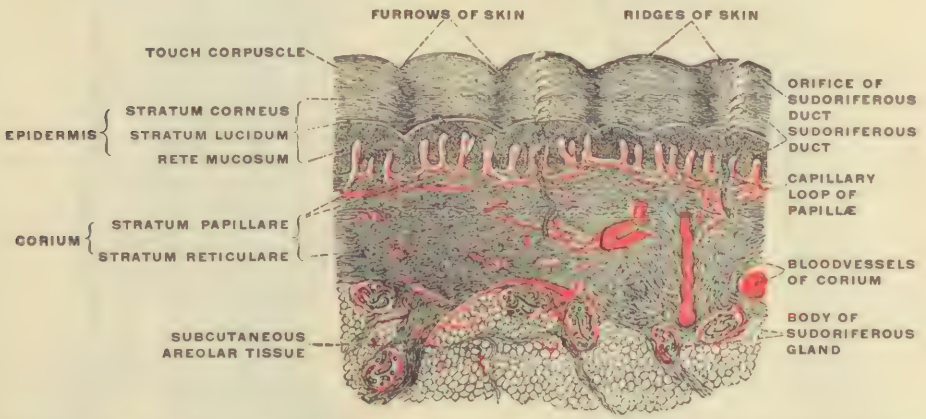

FIG. 783.—Vertical section through the skin of the finger-tip. The layers of the epidermis and of the corium. The subcutaneous areolar tissue. The sudoriferous or sweat-gland. (Toldt.)

prolongations to the papillary layer; in the nipple and scrotum it is non-striated. The reticular layer is composed of bundles of white fibrous tissue, arranged in a network. In the meshes of the network are fat, blood-vessels, lymphatics, sebaceous glands, sweat-glands, and hair-follicles.

The **Subcutaneous Areolar Tissue** or **Tela Subcutanea** (*panniculus adiposus*) connects the skin to the parts beneath; it is composed of bundles of connective tissue

which cross repeatedly and form spaces. In almost all regions the spaces contain fat, but in the scrotum and external ear they do not contain fat. When the connective-tissue fibres of the panniculus adiposus are long and nearly parallel to the skin-surface the skin becomes wrinkled; when they are short and nearly at right angles to the surface, the skin cannot wrinkle.

The **Superficial** or **Papillary Layer** or **Corpus Papillare of the Corium** (*stratum papillare*) lies just beneath the epidermis, contains the papillae, and is composed of a network of fine bundles of fibrous tissue. The papillae are composed of fine strands of connective tissue and elastic tissue. They project from the corium beneath the epidermis and enter into depressions of the epidermis. They vary greatly in size, averaging $\frac{1}{100}$ of an inch in height and $\frac{1}{250}$ of an inch in width at the base. In the face, especially in the eyelids, they are insignificant. On the glans penis, the palms of the hands, and the soles of the feet, and in the nipples, they are large. In the palmar surfaces of the hands and fingers and the plantar surfaces of the feet and toes they produce permanent ridges (Fig. 785). A ridge is composed of two or more rows of papillae, and the ducts of sweat-glands emerge between rows of papillae, and open on the curved surface ridges (Fig. 785). Most of the papillae contain loops of capillaries, and are called **vascular papillae**. Some contain nerve-terminations and are called **nervous papillae**. Between the papillary layer of the corium and the epidermis is a very thin and structureless membrane called the **basal membrane**.

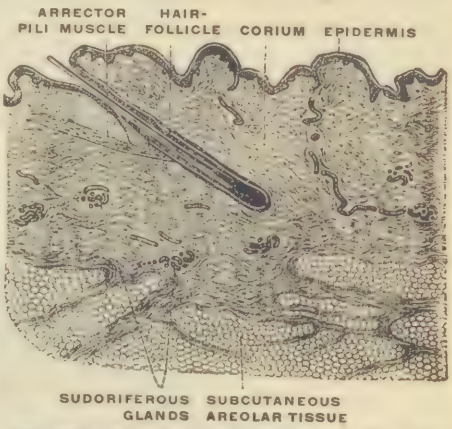

FIG. 784. Vertical section through the skin of the trunk in the region of the arch of the ribs. One of the small hairs is seen in longitudinal section. (Toldt.)

FIG. 785.—The furrows and ridges of true skin on the palmar surface of one of the fingers, the epidermis having been removed. (Toldt.)

The Cuticle, Scarf Skin or **Epidermis** (Figs. 783, 784, 786, and 787).—The cuticle, scarf skin or epidermis is composed of layers of epithelium and is derived from the ectoderm. The epithelium is stratified, and there are no blood-vessels. Two layers can be readily made out, the **superficial** or **horny layer** and the **deeper** or **Malpighian layer**.

The Horny Layer (*stratum corneum*).—The horny layer is formed by several layers of non-nucleated scaly cells. The cells consist of keratin. The surface cells of the horny layers are being constantly rubbed off, and are being replaced by cells from the Malpighian layer, which are converted into keratin as they near the surface.

The Malpighian Layer.—The Malpighian layer of the epidermis is divided into four layers, named, from without inward, the **stratum lucidum**, the **stratum granulosum**, the **stratum mucosum**, and the **stratum germinativum**.

The **Stratum Lucidum** is not classified by all writers as part of the Malpighian layer. Some anatomists classify it as a separate layer. It is here regarded as the most superficial part of the Malpighian layer. It consists of several layers of flat cells, the nuclei of which are beginning to disappear. The cells contain eleidin granules. In regions where the epidermis is thin the stratum lucidum is absent.

The **Stratum Granulosum** consists of several layers of nucleated flat cells, containing keratohyaline granules. These granules are probably formed from the disintegrating nucleus, and in the stratum lucidum are converted into eleidin.

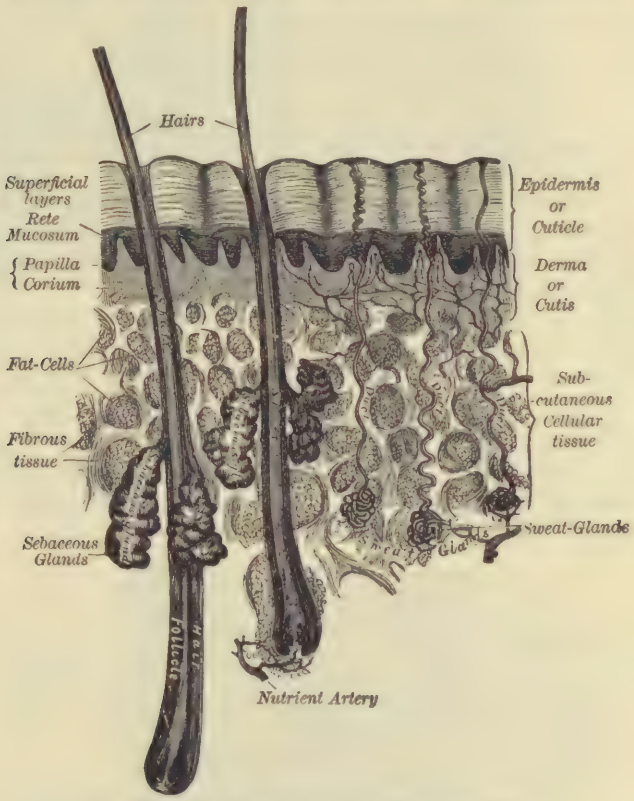

FIG. 786.—A sectional view of the skin (magnified).

The **Mucous Layer**, the **Stratum Spinosum** or the **Stratum Mucosum** consists of numerous layers of nucleated, polygonal, spine-shaped cells known as **prickle cells** or **finger cells**. Between the cells of the stratum mucosum are spaces containing pigment granules and leukocytes. Processes from the prickle-cells join adjacent cells. This layer contains numerous connective-tissue fibres arranged in a network, and known as **epidermic fibrils**.

The **Stratum Cylindricum** or **Stratum Germinativum** is composed of cylindrical or prickle-cells, the points of which are directed downward. Fine fibrils pass up from the corium between the cells, and there is cement-substance as well between them.

Pigmentation of the Skin.—As previously stated, in certain regions the skin of the white race is brown because of pigmentation (areolae, nipples, around the anus, axillae, scrotum, labia majora). This is due to pigment within the epithelial and

connective-tissue cells of the papillary layer of the corium, and in the basal cells of the epidermis. There are few or none of these pigmented cells in the stratum corneum of one of the Caucasian race.

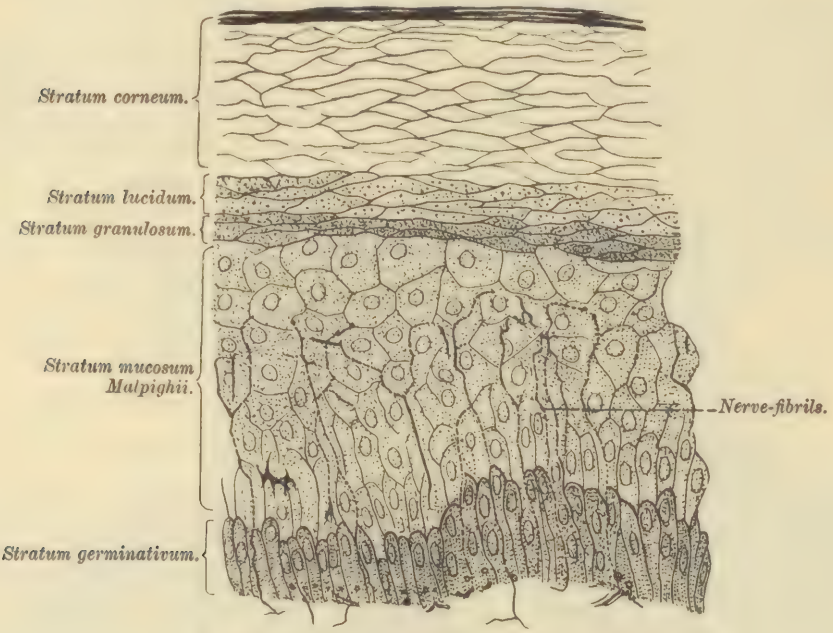

FIG. 787.—Section of epidermis. (Ranvier.)

"In negroes and other colored races the deep pigmentation is due to a similar distribution of the pigment granules in the entire epidermis; but even here the pigmentation decreases toward the surface, although the uppermost cells of the

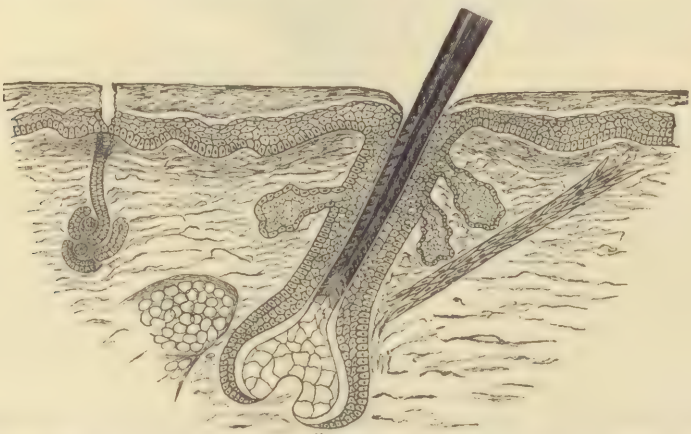

FIG. 788.—Microscopic section of skin, showing the epidermis and derma; a hair in its follicle; the Erector pili muscle; sebaceous and sudoriferous glands.

stratum corneum always contain some pigment. The nuclei of the cells are always free from coloring matter. The question as to the origin of the pigment is as yet unsolved."[1]

[1] A Text-book of Histology. By A. A. Böhm and M. von Davidoff. Translated and edited by G. Carl Huber.

The Arteries and Veins of the Skin (Fig. 789).—The arteries supplying the skin vary in number, and vary much in size, being largest in regions exposed to pressure, as the skin of the palms, soles, and buttocks. The arteries enter the skin from a network in the subcutaneous tissue, and by an anastomosis in the deepest part of the corium form a network (*rete arteriosum cutaneum*). The vessels send branches to the fat and to the sweat-glands. Branches from the network just described ascend and form a second network in the corium beneath the papillae. This is called the **subpapillary network** (*rete arteriosum subpapillare*). From this network fine capillary vessels pass into the papillae, forming, in the smaller papillae, a single capillary loop, but in the larger a more or less convoluted vessel. From this network branches go to the hair-follicles and sebaceous glands. The blood from the papillae passes into a plexus (*rete venosum*) beneath the papillae. This communicates with another plexus (*rete venosum*), between the corium and sub-

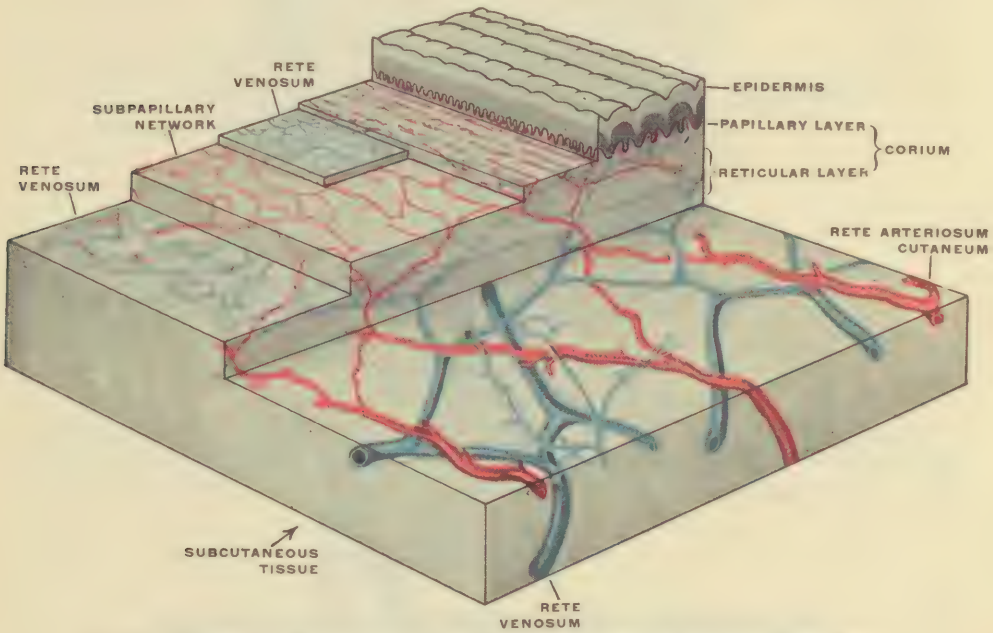

Fig. 789.—The distribution of the blood-vessels in the skin of the sole of the foot. (Spalteholz.)

cutaneous tissue. In some regions one or more retia are interposed between these two. The veins from the sweat-glands, sebaceous glands, superficial fat, and hair-follicles are received by the *retia venosa*. From the deepest rete veins pass to the subcutaneous tissue, and these veins enter the large subcutaneous veins.

The Lymphatics of the Skin.—There are numerous **lymphatics** supplied to the skin which form two networks, superficial and deep, communicating with each other and with the lymphatics of the subcutaneous tissue by oblique branches. They originate in the cell-spaces of the tissue.

The Nerves of the Skin.—The *nerves* of the skin terminate partly in the epidermis (Figs. 783 and 787) and partly in the cutis vera (Fig. 783). The former are prolonged into the epidermis from a dense plexus in the superficial layer of the corium and terminate between the cells in bulbous extremities; or, according to some observers, in the deep epithelial cells themselves. The latter terminate in end-bulbs, touch-corpuscles, or Pacinian bodies (Fig. 783), in the manner already described; and, in addition to these, a considerable number of fibrils are distributed to the hair-follicles, which are said to entwine about the follicle in a circular

manner. Other nerve-fibres are supplied to the plain muscular fibres of the hair-follicles (arrectores pili) and to the muscular coat of the blood-vessels. These are probably non-medullated fibres.

The Appendages of the Skin.

The appendages of the skin are the **nails**, the **hairs**, the **sudoriferous** and **sebaceous glands**, and their ducts.

The nails and hairs are peculiar modifications of the epidermis, consisting essentially of the same cellular structure as that tissue.

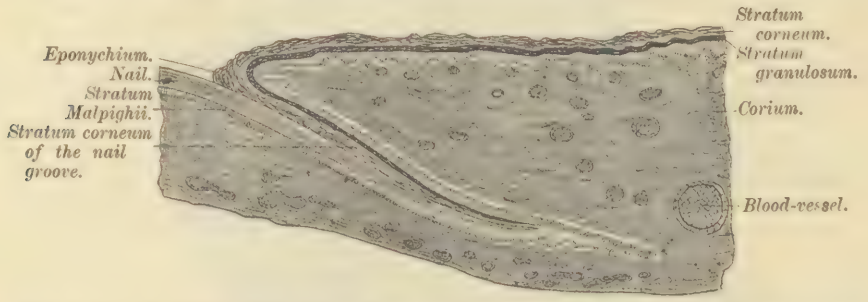

FIG. 790.—Longitudinal section through human nail and its nail groove (sulcus). (From Böhm and Davidoff's Histology.

The Nails (*ungues*) (Figs. 790, 791, 792, 793, 794, and 795).—The nails are flattened, elastic structures of a horny texture, placed upon the dorsal surface of the terminal phalanges of the fingers and toes. Each nail is convex on its outer surface, concave within. Its chief mass, called the **body** (*corpus unguis*), lies upon the nail-bed. The **free edge** is called the *margo liber*. Each **lateral margin** (*margo lateralis*), like the proximal **short edge** of the nail (*margo occultus*), lies in a groove of the cutis, the **ungual fold** (*sulcus matricis unguis*). The **ungual wall** (*vallum unguis*) overlies the lateral and posterior edges. The nail is implanted by means of a portion, called the **root** (*radix unguis*), into a groove in the skin. The root is beneath the ungual wall and is composed of cells which have not yet become

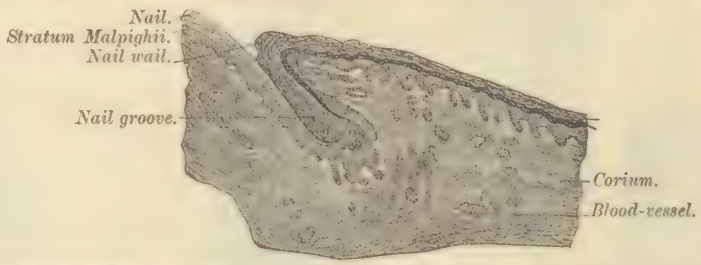

FIG. 791.—Transverse section through human nail and its sulcus. (From Böhm and Davidoff's Histology.)

horny. It is white in color. The nail has a very firm adhesion to the cutis vera, being accurately moulded upon the surface of the true skin, as the epidermis is in other parts. The part of the cutis beneath the body and root of the nail is called the **matrix** (*matrix unguis*), because it is the part from which the nail is produced. Corresponding to the body of the nail, the matrix is thick, and raised into a series of **longitudinal ridges** (*cristae matricis unguis*), which are very vascular, and the color is seen through the transparent tissue. Behind this, near the root of the nail, the papillae are small, less vascular, and have no regular arrangement, and here the tissue of the nail is somewhat more opaque; hence this portion is of a whiter color, and is called the **lunula** on account of its crescentic shape.

The cuticle, as it passes forward on the dorsal surface of the finger or toe, is attached to the surface of the nail, a little in advance of the nail root; at the extremity of the finger it is connected with the under surface of the nail a little behind its free edge. The cuticle and the horny substance of the nail (both epidermic structures) are thus directly continuous with each other. The nails consist of a greatly thickened stratum lucidum, the stratum corneum forming merely

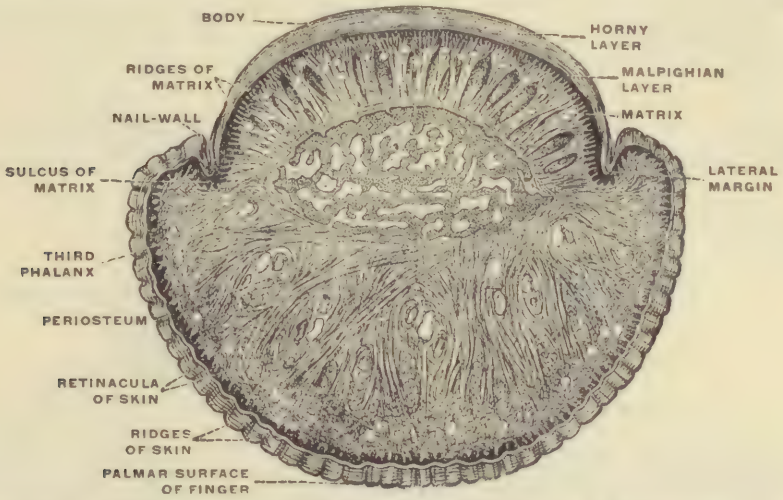

FIG. 792.—Transverse section through the nail and the terminal portion of the ring finger. (Toldt.)

the thin cuticular fold (*eponychium*) which overlaps the lunula. The cells have a laminated arrangement, and are essentially similar to those composing the epidermis. The deepest layer of cells, which lie in contact with the papillae of the matrix, are columnar in form and arranged perpendicularly to the surface; those which succeed them are of a rounded or polygonal form, the more superficial ones becoming broad, thin, and flattened, and so closely compacted as to make the

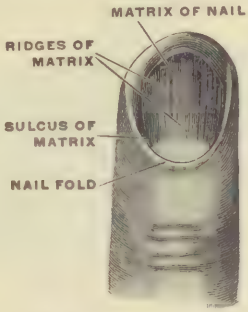

FIG. 794.—The matrix of the nail or nail-bed, with the nail-fold and nail-walls displayed by the removal of the epidermic portion of the nail or nail proper and the surrounding epidermis. (Toldt.)

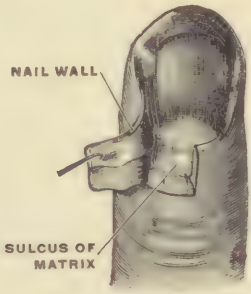

FIG. 795.—Matrix of the nail with partly opened marginal groove of the nail-bed. (Toldt.)

limits of each cell very indistinct. It is by the successive growth of new cells at the root and under surface of the body of the nail that it advances forward and maintains a due thickness, while, at the same time, the growth of the nail in the proper direction is secured. As these cells in their turn become displaced by the growth of new ones, they assume a flattened form, and finally become closely compacted together into a firm, dense, horny texture. In *chemical composition* the

nails resemble the upper layers of the epidermis, containing, however, a somewhat larger proportion of carbon and sulphur (Mulder).

The Hairs (*pili*) (Figs. 784, 786, 788, 796, 797, and 798).—The hairs are peculiar modifications of the epidermis, and consist essentially of the same structure as that membrane. They are found on nearly every part of the surface of the body, excepting the palms of the hands, soles of the feet, the vermilion borders of the lips, the dorsal surfaces of the phalanges, the nipples, the inner surface of the prepuce, and the glans penis. Hairs include **hairs of the head** (*capilla*); of the **eyebrows** (*supercilia*); of the **beard** (*barba*); of the **ears** (*tragi*); of the **nostrils** (*vibrissae*); the **eyelashes** (*cilia*); hairs of the **axilla** (*hirci*); **pubes** (*pubes*); and the small hairs of the **skin** or **woolly hairs** (*lanugo*). They vary much in length, thickness, and color in different parts of the body and in different races of mankind. In some parts, as in the skin of the eyelids, they are so short as not to project beyond the follicles containing them; in others, as upon the scalp, they are of considerable length; again, in other parts, as the eyelashes, the hairs of the pubic region, and the whiskers and beard, they are remarkable for their thickness. Straight hairs are stronger than curly hairs, and present on transverse section a cylindrical or oval outline; curly hairs, on the other hand, are flattened. The hairs are usually oblique to the surface from which they arise (Fig. 784). Their direction depends upon the region from which they spring, being fairly regular in certain regions. Thus are formed **hair-streams** (*flumina pilorum*) and **hair-whirlpools** (*vortices pilorum*).

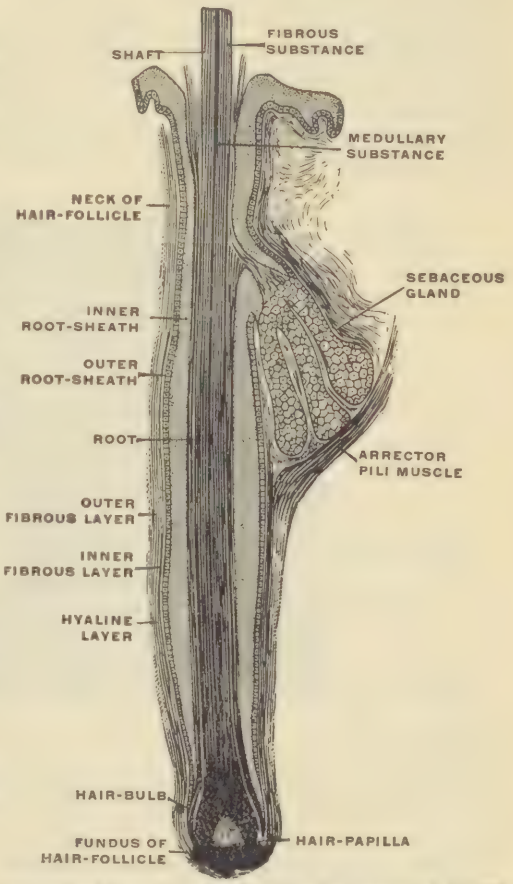

FIG. 796.—A hair of the head still in the course of growth, with hair-bulb in longitudinal section. (Toldt.)

A hair consists of the **root**, the part implanted in the skin; the **shaft** or **stem**, the portion projecting from its surface; and the **point**.

The **Root of the Hair** (*radix pili*) presents at its extremity a bulbous enlargement, the **hair-bulb** (*bulbus pili*) (Figs. 786 and 796), which is whiter in color and softer in texture than the shaft, and is lodged in a follicular involution of the epidermis called the **hair-follicle** (*folliculus pili*) (Figs. 784 and 788). When the hair is of considerable length the follicle extends into the subcutaneous cellular tissue (Fig. 786). The hair-follicle commences on the surface of the skin with a funnel-shaped opening, and passes inward in an oblique or curved direction—the latter in curly hair—to become dilated at its deep extremity or **fundus** (*fundus folliculi pili*), where it corresponds with the bulbous condition of the hair which it contains. It has opening into it, near its free extremity, the orifices of the ducts of one or more sebaceous glands (Figs. 786, 788, 796, and 797). At the bottom of each hair-follicle is a small conical, vascular eminence or papilla, the **hair-papilla** (*papilla pili*) (Figs. 796 and 797),

similar in every respect to the papillae found upon the surface of the skin; it is continuous with the dermic layer of the follicle, is highly vascular, and is probably supplied with nervous fibrils. In structure the hair-follicle consists of two coats—an **outer** or **dermic**, and an **inner** or **epidermic** (Figs. 796 and 798).

The **Outer** or **Dermic Coat** is formed mainly of fibrous tissue; it is continuous with the corium, is highly vascular, and is supplied by numerous minute nervous filaments. It consists of three layers. The most internal, the **cuticular lining** of the **follicle,** consists of a hyaline basement-membrane, the **hyaline layer,** having a glassy, transparent appearance, which is well marked in the larger hair-follicles, but is not very distinct in the follicles of minute hairs. It is continuous with the basement-membrane of the surface of the corium. External to this is the **inner fibrous layer,** a compact layer of fibres and spindle-shaped cells arranged circularly around the follicle. This layer extends from the bottom of the follicle as high as the entrance of the ducts of the sebaceous glands. Externally is the **outer fibrous layer,** a thick layer of connective tissue, arranged in longitudinal bundles, forming a more open texture and corresponding to the reticular part of the corium. In this are contained the blood-vessels and nerves.

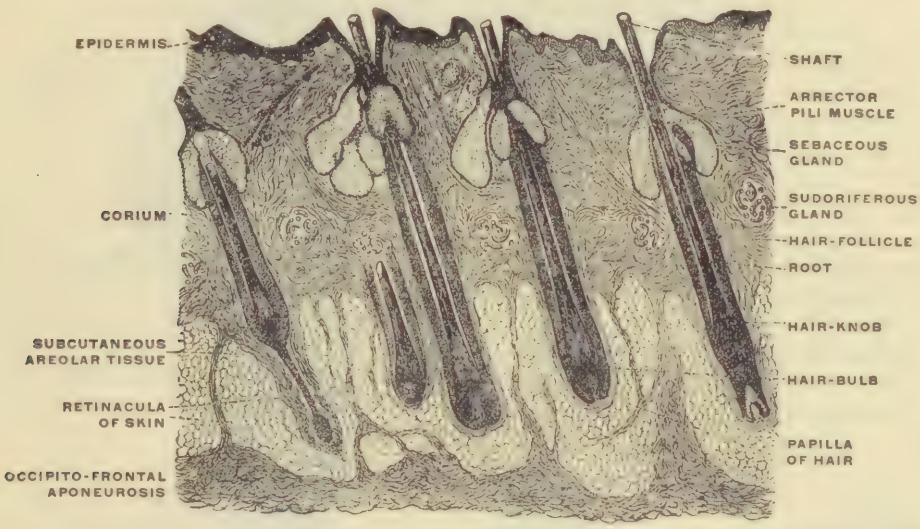

FIG. 797.—Vertical section through the skin of the head. The hairs of the head in longitudinal section. (Toldt.)

The **Inner** or **Epidermic Layer** is closely adherent to the root of the hair, so that when the hair is plucked from its follicle this layer most commonly adheres to it and forms what is called the **root-sheath.** It consists of two strata, named respectively the **outer** and **inner root-sheaths**; the former of these corresponds with the Malpighian layer of the epidermis, and resembles it in the rounded form and soft character of its cells; at the bottom of the hair-follicle these cells become continuous with those of the root of the hair. The inner root-sheath consists of a delicate cuticle next the hair, composed of a thin layer of imbricated scales having a downward direction, so that they fit accurately over the upwardly directed imbricated scales of the hair itself; then of one or two layers of horny, flattened nucleated cells, known as **Huxley's layer**; and finally of a single layer of horny oblong cells without visible nuclei, called **Henle's layer.**

The hair-follicle contains the **root of the hair,** which terminates in a bulbous extremity, and is excavated so as to exactly fit the papilla from which it grows. The bulb is composed of polyhedral epithelial cells, which as they pass upward into the root of the hair become elongated and spindle-shaped, except some in the centre which remain polyhedral. Some of these latter cells contain pigment-

granules, which give rise to the color of the hair. It occasionally happens that these pigment-granules completely fill the cells of the medullary substance in the centre of the bulb, which gives rise to the dark tract of pigment often found, of greater or less length, in the axis of the hair.

The **Stem** or **Shaft of the Hair** (*scapus pili*) (Fig. 796), consists of a central pith or **medulla**, the fibrous part of the hair, and the true cuticle externally. The **medulla** (*substantia medullaris pili*) occupies the centre of the shaft and ceases toward the point of the hair. It is usually wanting in the fine hairs covering the surface of the body, and commonly in those of the head. It is found in the shafts of all thick hairs and in the deeper parts of the root of most hairs. It is more opaque and deeper colored when viewed by transmitted light than the fibrous part; but when viewed by reflected light it is white. It is composed of rows of polyhedral cells, which contain granules of eleidin and frequently air-bubbles. The **fibrous portion** or **cortical substance of the hair** (*substantia corticalis pili*) constitutes the chief part of the shaft; its cells are elongated and unite to form flattened fusiform fibres. Between the fibres are found minute spaces which contain either pigment-granules in dark hair or minute air-bubbles in white hair. In addition to this there is also a

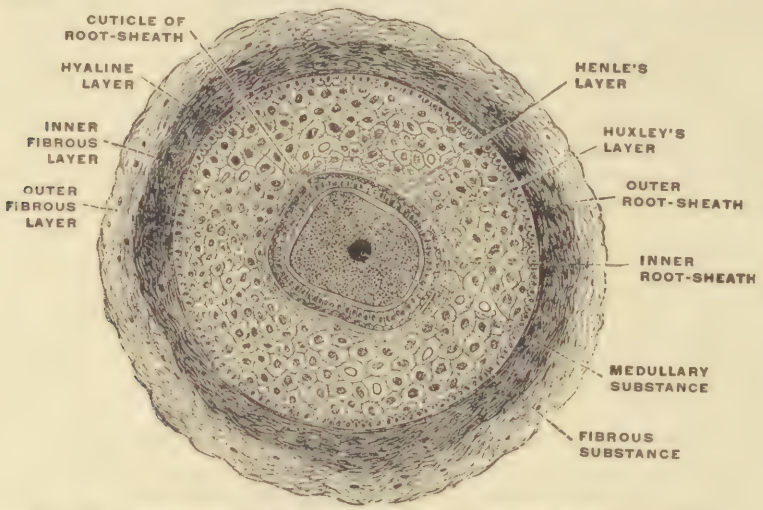

FIG. 798.—A moustache hair with its hair-follicle in transverse section. (Toldt.)

diffused pigment contained in the fibres. The cells which form the **outer hair membrane** or **true cuticle** (*cuticula pili*) consist of a single layer which surrounds those of the fibrous part; they are converted into thin, flat scales, having an imbricated arrangement.

Connected with the hair-follicles are minute bundles of involuntary muscular fibres, termed **arrectores pili** (*mm. arrectores pilorum*) (Figs. 784 and 796). They arise from the superficial layer of the corium, and are inserted into the outer surface of the hair-follicle, below the entrance of the duct of the sebaceous gland. They are placed on the side toward which the hair slopes, and by their action elevate the hair.[1] When the hair is elevated a depression forms over the seat of origin of the muscle, and the parts about the hair are elevated. This condition is known as **goose-skin**. It is probable that the contraction of these muscles aids in emptying sebaceous glands.

Blood-vessels and Nerves (Fig. 786).—A hair-follicle possesses a rich network of capillaries about the hyaline membrane, and capillary loops pass to the papilla.

[1] Arthur Thomson suggests that the contraction of these muscles on follicles which contain weak, flat hairs will tend to produce a permanent curve in the follicle, and this curve will be impressed on the hair which is moulded within it, so that the hair, on emerging through the skin, will be curled. Curved hair-follicles are characteristic of the scalp of the Bushman.—ED. of 15th English edition.

We have little knowledge as to nerve-terminations of the human hair. "In other mammals the nerves end below the sebaceous glands. Medullated fibres lose their medullary sheaths, divide, and penetrate to the hyaline membrane. Here some of the branches encircle the hair, while others end freely on the hyaline membrane as naked axis-cylinders. These branch regularly and run parallel to the long axis of the hair."[1]

The Sudoriferous or Sweat-glands (*glandulae sudoriferae*) (Figs. 783, 784, 786, 788, and 797).—The sudoriferous or sweat-glands are the organs by which a large portion of the aqueous and gaseous materials is excreted by the skin. They are found in almost every part of this structure, being absent on the red border of the lips, the glans penis, and inner surface of the prepuce. On the eyelids they are somewhat modified, and are called **ciliary glands** (*glandulae ciliares* [*Molli*]); about the anus they are extremely large, and are called **circumanal glands** (*glandulae circumanales*). The sweat-glands are situated in small pits below the under surface of the corium, or, more frequently, in the subcutaneous areolar tissue, surrounded by a quantity of adipose tissue. They are small, lobular, reddish bodies, consisting of a single convoluted tube, from which the efferent **duct** (*ductus sudoriferus*) proceeds upward through the corium and cuticle. The duct in the corium has true walls; in the epidermis it has not individual walls, but is simply an epidermic tube. It becomes somewhat dilated at its extremity, and opens on the surface of the cuticle by an oblique valve-like aperture (*porus sudoriferus*). The duct, as it passes through the epidermis, presents a spiral arrangement, being twisted like a corkscrew, in those parts where the epidermis is thick; where, however, the epidermis is thin, the spiral arrangement does not exist. In the superficial layers of the corium the duct is straight, but in the deeper layers it is convoluted or even twisted. The spiral course of these ducts is especially distinct in the thick cuticle of the palm of the hand and sole of the foot. The size of the glands varies. They are especially large in those regions where the flow of perspiration is copious, as in the axillae, where they form a thin, mamillated layer of a reddish color, which corresponds exactly to the situation of the hair in this region; they are large also in the groin. Their number varies. They are most numerous on the palm of the hand, presenting, according to Krause, 2800 orifices on a square inch of the integument, and are rather less numerous on the sole of the foot. In both of these situations the orifices of the ducts are exceedingly regular, and open on the curved surface ridges. In other situations they are more irregularly scattered, but the number in a given extent of surface presents a fairly uniform average. In the neck and back they are least numerous, their number amounting to 417 on the square inch (Krause). Their total number is estimated by the same writer at 2,381,248, and, supposing the aperture of each gland to represent a surface of $\frac{1}{5^1_6}$ of a line in diameter, he calculates that the whole of these glands would present an evaporating surface of about eight square inches. Each gland consists of a single tube intricately convoluted, terminating at one end by a blind extremity, and opening at the other end upon the surface of the skin.

The wall of the tubercle of the secreting coil is lined with cubical epithelial cells, external to these is a layer of smooth muscle-cells, and more externally a layer of connective tissue, the membrana propria. The duct in the corium, in contrast to the secreting coil, has no layer of muscle-cells, but instead a second layer of epithelial cells covered by connective tissue. As previously stated, the duct becomes spiral in the epidermis, its own wall disappears, and the channel is bounded by epidermic cells.

Blood-vessels and Nerves.—The blood-vessels are branches from the subcutaneous vessels and the arterial plexus of the deep part of the corium. Numerous

[1] Histology and Microscopic Anatomy. By Dr. Ladislaus Szymonowicz. Translated and edited by John Bruce MacCallum, M.D.

non-medullated nerve-fibres lie upon the membrana propria of a sweat-gland. From them fibrils pass inward and terminate by end-bulbs upon the cells of the gland.

The Sebaceous Glands (*glandulae sebaceae*).—The sebaceous glands are small, sacculated, glandular organs, lodged in the substance of the corium. They are found in most parts of the skin, and are usually connected with hair-follicles. This connection is so common that they are sometimes called **hair-follicle glands.** They are found in some regions which are devoid of hairs—the vermilion borders of the lips, the labia minora, the glans penis, and prepuce. These glands are especially abundant in the scalp and face; they are also very numerous around the apertures of the anus, nose, mouth, and external ear; but are wanting in the palms of the hands and soles of the feet. Each gland consists of a single duct, more or less capacious, which terminates in a cluster of small secreting pouches or saccules. The sacculi connected with each duct vary, in number, as a rule, from two to five, but in some instances may be as many as twenty. They are composed of a transparent, colorless membrane, enclosing a number of epithelial cells. Those of the outer or marginal layer are small and polyhedral, and are continuous with the lining cells of the duct. The remainder of the sac is filled with larger cells, containing fat, except in the centre, where the cells have become broken up, leaving a cavity containing their débris and a mass of fatty matter, which constitutes the sebaceous secretion. The orifices of the ducts open most frequently into the hair-follicles, but occasionally upon the general surface, as in the labia minora and the free margins of the lips. On the nose and face the glands are of large size, distinctly lobulated, and often become much enlarged from the accumulation of pent-up secretion. The largest sebaceous glands are those found in the eyelids—the Meibomian glands.

THE ORGANS OF DIGESTION.

THE Apparatus for the Digestion of the Food (*apparatus digestorius*) consists of the **alimentary canal** and of certain **accessory organs.**

THE ALIMENTARY CANAL.

The alimentary canal is a musculo-membranous tube, about thirty feet in length, extending from the mouth to the anus, and lined throughout its entire extent by mucous membrane. It has received different names in the various parts of its course; at its commencement, the **mouth,** we find provision made for the mechanical division of the food (*mastication*), and for its admixture with a fluid secreted by the salivary glands (*insalivation*); beyond this are the **pharynx** and the **oesophagus,** the organs which convey the food (*deglutition*) into that part of the alimentary canal, the **stomach,** in which the principal chemical changes occur, and in which the reduction and solution of the food take place; in the **small intestines** the nutritive principles of the food, the **chyle,** are separated, by its admixture with the bile, pancreatic and intestinal fluids, from that portion which passes into the **large intestine,** most of which is expelled from the system.

THE MOUTH, ORAL OR BUCCAL CAVITY (CAVUM ORIS).

The mouth is placed at the commencement of the alimentary canal; it is a nearly oval-shaped cavity, in which the mastication and insalivation of the food take place (Figs. 799, 818, and 824).

The **aperture of the mouth** (*rima oris*) is bounded by the lips. The **angle of the mouth** (*angulus oris*) is formed on each side by the meeting of the upper and lower lips (*commissura labiorum*). When at rest with the lips in contact, the rima is a slightly curved line. Every movement which the lips make alters the shape of the rima. When the mouth is closed the floor and roof are usually in contact and its sides are approximated to the dental arches. The mouth consists of two

parts: an outer, smaller portion, the **vestibule**, and an inner, larger part, the **cavity proper of the mouth.**

The Vestibule (*vestibulum oris*).—The vestibule is a slit-like space, bounded in front and laterally by the lips and cheeks; behind and internally by the gums and teeth. Above and below it is limited by the reflection of the mucous membrane from the lips and cheeks to the gum covering the upper and lower alveolar arch respectively. It receives the secretion from the parotid glands, and communicates, when the jaws are closed, with the cavum oris by an aperture on each side behind the wisdom teeth.

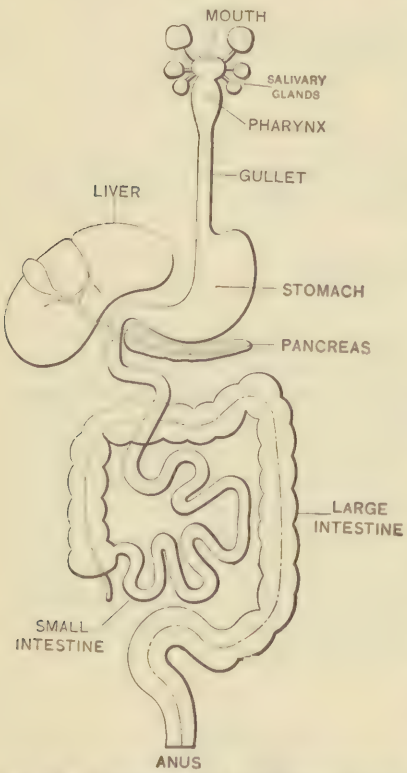

FIG. 799. Diagram of the alimentary tube and its appendages. (Testut.)

The Cavity of the Mouth Proper (*cavum oris proprium*).—The cavity of the mouth proper is bounded laterally and in front by the alveolar arches with their contained teeth; behind it communicates with the pharynx by a constricted aperture termed the **isthmus faucium.** It is roofed in by the hard and soft palate. The greater part of the floor is formed by the tongue, the remainder being completed by the reflection of the mucous membrane from the sides and under surface of the tongue to the gum lining the inner aspect of the mandible. It receives the secretion from the submaxillary and sublingual glands.

The Mucous Membrane.—The mucous membrane lining the mouth is continuous with the integument at the free margin of the lips and with the mucous lining of the pharynx behind; it is of a rose-pink tinge during life, and very thick where it covers the hard parts bounding the cavity. It is covered by stratified epithelium.

The Lips (Labia Oris).

The lips are two fleshy folds which surround the orifice of the mouth, formed externally by integument and internally by mucous membrane, between which are found the Orbicularis oris muscle (Fig. 263), the coronary vessels (Fig. 395), some nerves (Fig. 395), areolar tissue, and fat, and numerous small labial glands. The upper lip is called the **labium superius**; the lower lip is called the **labium inferius.** The inner surface of each lip is connected in the middle line to the gum of the corresponding jaw by a fold of mucous membrane, the **frenulum** (*frenulum labii superioris* and *frenulum labii inferioris*). The frenulum labii superioris is the larger of the two. On each side, external to the angle of the mouth, the lips become continuous (*commissura labiorum*).

The Labial Glands (*glandulae labiales*) (Fig. 395).—The labial glands are situated between the mucous membrane and the Orbicularis oris muscle around the orifice of the mouth. They are rounded in form, about the size of small peas, and their ducts open by minute orifices upon the mucous membrane. In structure they resemble the salivary glands.

The Cheeks (Buccae).

The cheeks form the sides of the face and are continuous in front with the lips. They are composed externally of integument, internally of mucous membrane, and between the two of a muscular stratum, besides a large quantity of fat, areolar tissue, vessels, nerves, and buccal glands.

The Mucous Membrane.—The mucous membrane lining the cheek is reflected above and below upon the gums, where its color becomes lighter; it is continuous behind with the lining membrane of the soft palate. Opposite the second molar tooth of the upper jaw is a **papilla**, the summit of which presents the aperture of the **duct of the parotid gland** (*ductus parotideus* [*Stenonis*]) (Fig. 824.) The principal muscle of the cheek is the Buccinator, but numerous other muscles enter into its formation—viz., the Zygomatici, Risorius Santorini, and Platysma myoides.

The Buccal Glands (*glandulae buccales*).—The buccal glands are placed in the submucous tissue between the mucous membrane and Buccinator muscle; they are similar in structure to the labial glands, but smaller. Four or five glands of larger size than the previously mentioned glands are placed beneath the mucous membrane in the neighborhood of the last molar tooth. They are called the **molar glands** (*glandulae molares*). Their ducts open into the mouth opposite the last molar tooth.

The Gums (Gingiva).

The gums are composed of a dense fibrous tissue closely connected to the periosteum of the alveolar processes and surrounding the necks of the teeth. They are covered by smooth and vascular mucous membrane, which is remarkable for its limited sensibility. Around the necks of the teeth this membrane presents numerous fine papillae; and from this point it is reflected into the alveolus, where it is continuous with the periosteal membrane lining that cavity.

The Teeth (Dentes).

The human subject is provided with two sets of teeth, which make their appearance at different periods of life. The first set appear in childhood, and are called the **temporary, deciduous** or **milk teeth**. The second set are named **permanent.**

The **temporary teeth** are twenty in number—four incisors, two canine, and four molars in each jaw (Figs. 800 and 817).

The **permanent teeth** are thirty-two in number—four incisors (two central and two lateral), two canines, four bicuspids, and six molars in each jaw (Figs. 802 and 806).

General Characters (Fig. 807).—Each tooth consists of three portions; the **crown** or **body** (*corona dentis*), projecting above the gum; the **root** or **fang** (*radix dentis*), entirely concealed within the alveolus; and the **neck** (*collum dentis*), the constricted portion, between the root and crown.

Surfaces.—The surfaces of a tooth are named thus: that which comes in contact with the teeth of the opposite jaw is the **grinding** or **masticating surface** (*facies masticatoria*); that which touches the next tooth in the same row is the **contact surface** (*facies contactus*). That surface which is toward its predecessor is called the **proximal surface** (in incisors and canines, *facies medialis;* in molars and premolars, *facies anterior*). That surface which is toward its successor is called the **distal surface** (in incisors and canines, *facies lateralis;* in molars and premolars, *facies posterior*). That which looks toward the lips and cheek is the **labial** or **buccal surface** (*facies labialis*). That toward the tongue is the **lingual surface** (*facies lingualis*). In part this method of designation applies to the roots as well as to the crowns of teeth.

The Roots of the Teeth.—The roots of the teeth are firmly implanted within the **sockets** or **alveoli of the jaws** (*alveoli dentales*) (see pp. 109 and 124). These depressions are lined with periosteum, called the **pericementum**, which is reflected on to the tooth at the point of the root and covers it as far as the neck. This is the **root membrane** (*periosteum alveolare*). At the margin of the alveolus the periosteum becomes continuous with the fibrous structure of the gums.

Fig. 800.—Deciduous teeth. Left side.

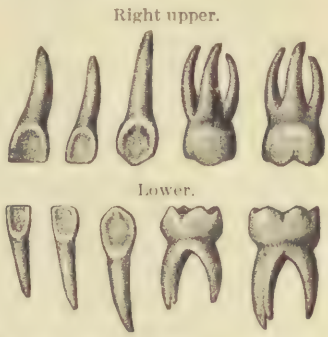

Fig. 801.—Deciduous teeth. Lingual view.

Temporary, Deciduous or Milk Teeth (*dentes decidui*) (Figs. 800, 801, and 817).—The temporary or milk teeth are smaller, but resemble in form those of the permanent set. The neck is more marked, owing to the greater degree of convexity of the labial and lingual surfaces of the crown. The hinder of the two temporary molars is the largest of all the deciduous teeth, and is succeeded by the second bicuspid. The first upper molar has only three cusps—two labial, one lingual; the second upper molar has four cusps. The first lower molar has four cusps; the second lower molar has five. The roots of the temporary molar teeth are smaller and more diverging than those of the permanent set, but in other respects bear a strong resemblance to them.

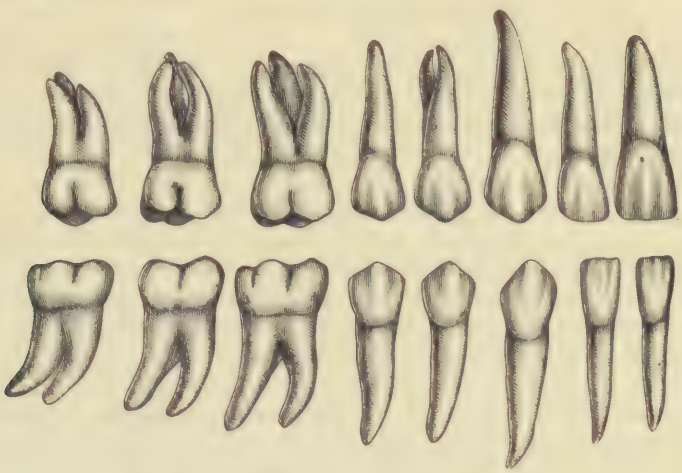

Fig. 802.—Permanent teeth, right side. (Burchard.)

Permanent Teeth (*dentes permanentes*) (Figs. 802, 803, 804, and 806). **The Incisors** (*dentes incisivi*).—The incisors or cutting teeth are so named from their presenting a sharp cutting edge, adapted for incising the food. They are eight in number, and comprise the four front teeth in each jaw.

The **crown** is directed almost vertically and is spade-like in form; it has the form of a truncated cone whose top has been compressed into a sharp horizontal cutting

edge. Before being subjected to attrition this edge presents three small elevations. The **labial surface** is convex, and marked by free longitudinal ridges extending from the edge tubercles toward the neck of the tooth. The **lingual surface** is concave, and is marked by two marginal ridges extending from an encircling ridge at the neck to the angles of the cutting edge of the tooth. The ridge at the neck is termed the **cingulum** or **basal ridge**. The **mesial** and **distal surfaces** are triangular, the apex of the triangle being at the cutting edge. The **neck** of the tooth is constricted. The **root** is long, single, and has the form of a transversely flattened cone, thicker before than behind. The root may be curved.

The **Incisors of the Upper Jaw** are altogether larger and stronger than those of the lower jaw, the central incisors being larger and flatter than the lateral incisors. They are directed obliquely downward and forward.

The **Incisors of the Lower Jaw** are smaller and flatter than the upper, and the elevations upon their lingual faces are not marked. The two central are smaller than the two lateral incisors, being the smallest of all the teeth. The **roots** of these teeth are flattened laterally.

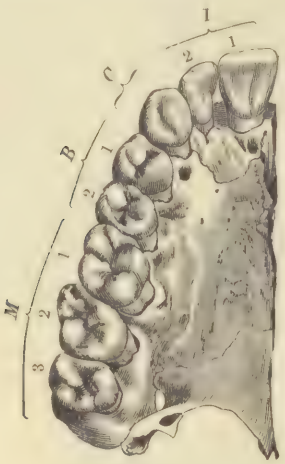

FIG. 803.—Right half of upper jaw (from below), with the corresponding teeth. The letters and numbers point to the classes of teeth and the numbers in classes.

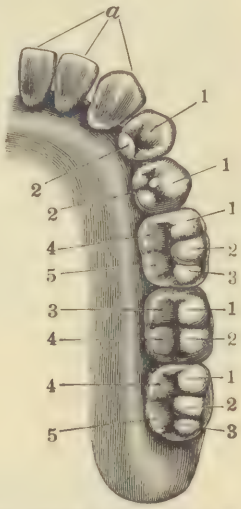

FIG. 804.—Right half of lower jaw, with the corresponding teeth. The letter and numbers point to the various cusps or their modifications on the different teeth. (Burchard.)

The Canine Teeth or Cuspidati (*dentes canini*).—The canine teeth are four in number, two in the upper, two in the lower jaw—one being placed distal to each lateral incisor. They are larger and stronger than the incisors, especially in the roots, which are deeply implanted and each causes a well-marked prominence of the process at the place of insertion.

The **crown** is large, of spear-head form, and its very convex labial surface is marked by three longitudinal ridges. The **concave lingual surface** is also marked by three ridges which unite at a basal ridge. The **point** or **cusp** is longer than in the other teeth, and is the point of division between a short mesial and a long distal cutting edge. These two edges form an obtuse angle with each other.

The **root** is single, oval, or elliptical on transverse section, and is longer and more prominent than the roots of the incisors.

The **Upper Canines** or cuspids, vulgarly called the **eye teeth**, are larger and longer than the two lower, and in occlusion are distal to them to the extent of half the width of the crown.

The **Lower Canines**, vulgarly called the **stomach teeth**, have the general form of the upper cuspids, but their lingual surfaces are much more flattened, owing to

the absence of the elevations marking the upper. Their roots are more flattened and may be bifid at their apices.

The Bicuspid Teeth or the Premolars (*dentes premolares*).—The bicuspid teeth are eight in number, four in each jaw; they are placed distal to the cuspid teeth, two upon each side of the jaw. They are double cuspids in form.

The **crown** is surmounted by two cusps, one buccal and one lingual, separated by a groove, the buccal being more prominent and larger than the lingual. The lower bicuspids are not truly bicuspid, the first having but a primitive lingual cusp, the second having the lingual cusp divided into two sections—*i. e.*, it is usually tricuspid. The **necks** of the teeth are oval; the **roots** are single and laterally compressed, that of the first upper bicuspid being frequently bifid. The first upper bicuspid is usually the largest of the series. The roots of the lower bicuspids are less compressed and more rounded.

The Molar Teeth, the Multicuspidati or Grinders (*dentes molares*).—The molar teeth are the largest and strongest teeth of the denture. They are adapted by their forms for the crushing and grinding of the food. They are twelve in number, six in each jaw, three being placed posterior to each second bicuspid.

The **crowns** are cuboidal in form, are convex buccally and lingually; they are flattened mesially and distally. They are formed by the fusion of three primitive cuspids in the upper and four in the lower. To these are added in the first and second upper molars a **disto-lingual tubercle,** and in the first and third molars of the lower jaw a **disto-buccal tubercle.** The unions of the primitive forms are marked by sulci. The necks of these teeth are large and rhomboidal in form. The **roots** of the upper molars are three in number—one large **lingual** or **palatal root,** and two smaller **buccal roots.** In the lower molars, two roots are found, a mesial and a distal, each of which is much flattened from before backward.

The **First Molar Teeth** are the largest of the dental series; they have four cusps on the upper and five in the lower—three buccal and two lingual.

The **Second Molars** are smaller; the crowns of the upper are compressed until the disto-lingual cusp is reduced. The crowns of the lower are almost rectangular, with a cusp at each angle.

The **Third Molars** are called the wisdom teeth or **dentes sapientae** (*dentes serotini*), from their late eruption; they have three cusps upon the upper and five upon the lower. The three roots of the upper are frequently fused together, forming a grooved cone, which is usually curved backward. The roots of the lower, two in number, are compressed together, and curve backward.

Arrangement of the Teeth.[1]—The human teeth are arranged in two parabolic arches, the **upper row** or **arch** (*arcus dentalis superior*) being larger, its teeth overlapping the **lower row** or **arch** (*arcus dentalis inferior*). The average distance between the centres of the condyles of the inferior maxillary bones is about four inches, which is also the distance from either of these points to the line of junction between the lower incisor teeth. Whether the jaw be large or small, the equilateral triangle indicated is included in it; the range of size is between three and one-half and four and one-half inches.

Owing to the smaller sizes of the lower incisors, the teeth of the lower jaw are each one-half a tooth in advance of its upper fellow, so that each tooth of the dental series has two antagonists, with the exception of the lower central incisors and upper third molars (Figs. 805 and 806).

The grinding faces of the upper bicuspids and molars curve progressively upward and point outward, the first molar being at the lowest point of the curve, the third molar at the highest. The curve of the lower dental arch is the reverse, the first molar at its deepest part, the third molar at its extremity. The greater the depth

[1] After Dr. W. G. A. Bonwill.

to which the upper incisors overlap the lower, the more marked this curve and the more pointed are the cusps of the grinding teeth.

FIG. 805.—View of teeth *in situ*, with the external plates of the alveolar processes removed. (Cryer.)

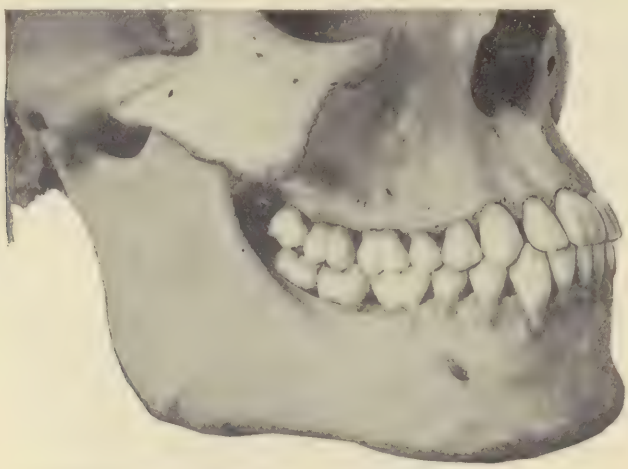

FIG. 806.—Front and side views of the teeth and jaws. (Cryer.)

The movement of the human mandible is forward and downward, the resultant of these directions being an oblique line, upon an average of 35 degrees from the horizontal plane.[1] When the lower jaw is advanced until the cutting edges of

[1] W. E. Walker, Dental Cosmos, 1896.

the incisors are in contact, the jaws are separated, but at the highest point of the lower arch its third molar advances, and meets and rests upon a high point, the second molar of the upper arch, and thus undue strain upon the incisors is obviated.

In the lateral movements of the mandible but one side is in effective action at one time; the oblique positions of the cusps of the opposite teeth are such that

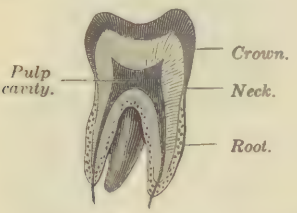

FIG. 807.—Vertical section of a molar tooth.

when either side is in action the other is balanced at two or more points.

There is an anatomical correspondence between the forms and arrangement of the teeth, the form of the condyle of the mandible, and the muscular arrangement. Individuals who have teeth with long cusps have the head of the bone much rounded from before backward, and have a preponderance of the direct over the oblique muscles of mastication, and *vice versa;* teeth with short or no cusps are associated with a flattened condyle and strong oblique muscles.

Very great aberrations in the dental arrangement are frequently followed by accommodative changes in the heads of the mandible.

FIG. 808.—Vertical section of a tooth *in situ* (15 diameters). *c* is placed in the pulp-cavity, opposite the cervix or neck of the tooth; the part above is the crown, that below is the root (fang). 1. Enamel with radial and concentric markings. 2. Dentine with tubules and incremental lines. 3. Cement or crusta petrosa, with bone corpuscles. 4. Dental periosteum. 5. Bone of lower jaw.

Structure of the Teeth. The Dental Pulp (*pulpa dentis*).—A longitudinal section of a tooth will show the presence of a central chamber having the general form of the crown of the tooth. Processes of the chamber pass from its body, one for each root and down each root, and open at the apex by a minute orifice. This cavity is known as the **pulp-chamber** or **pulp-cavity** (*cavum dentis*) (Figs. 807 and 808). The minute canal in each root is called the **pulp-canal** or **root-canal** (*canalis radicis dentis*). The foramen at the apex of the root is the **apical foramen** (*foramen apicis dentis*). The cavity contains a soft, vascular, and sensitive organ called the **dental pulp** (*pulpa dentis*). It is made up of fibrous cellular connective tissue, the fibres of which are extremely fine, and contains numerous blood-vessels and nerves, which enter by way of the apical foramina. It has not been proved that there are lymphatics in the dental pulp, although some authors assert that they exist (Wangermann and others). It seems to have been proved that the spaces between the fibres of the pulp communicate with the lymphatic system. The periphery of the pulp is bounded by a layer of cells arranged like columnar epithelium, each cell sending one or more branched processes through the basic substance

of the dentine. These processes constitute the **dentine fibres**. Other processes come off from the cells which pass in the direction of the pulp and surround it. The cells at the periphery of the pulp are the **dentine-forming cells**, the **odontoblasts of Waldeyer**. The blood-vessels break up into innumerable capillary loops which lie beneath the layer of odontoblasts. The nerve-fibrils break up into numberless non-medullary filaments, which spread out beneath the odontoblasts, and probably send terminal filaments to the extreme periphery of the pulp outside the odontoblasts.

The matrix cells and their processes are irregularly arranged in the body of the pulp, but in the canal portion the fibrillae are in the direction of the axis of the root.

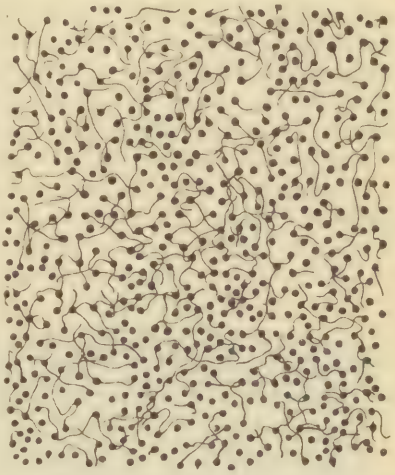

FIG. 809.—From a ground-section through the parts of a dentine, near the pulp, of a human canine tooth which has been impregnated with pigment. The dental canaliculi are cut across and are joined together by side branches. × 400.

The Solid Portion of the Tooth.—The section will exhibit three hard tissues in a tooth: one, the **proper dental substance**, forming the greater mass of the tooth; hence its name **dentine** or **ivory**. The dentine upon the exposed crown is sheathed by a layer called the **enamel**; the dentine of the root is enclosed in a distinct tissue, the **cementum** or **crusta petrosa**; both cementum and enamel are thinnest at the neck and thickest upon their distal portions.

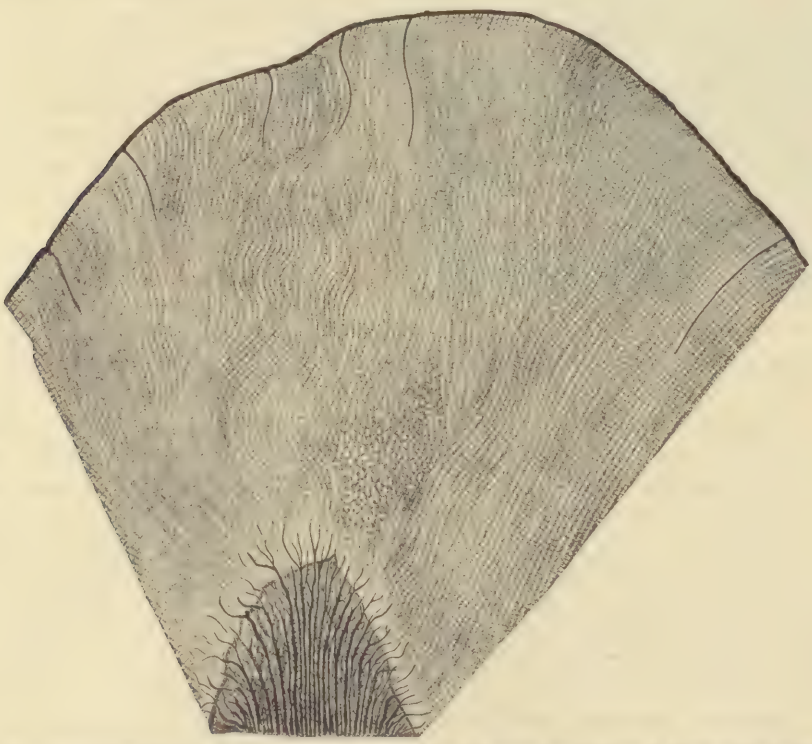

FIG. 810.—Longitudinal ground-section through the apex of a canine tooth from a three-and-a-half-year-old boy. The entrance of the dental canaliculi between the enamel prisms and the course taken by the latter are shown. × 135. (Szymonowicz.)

The **Ivory** or **Dentine** (*substantiae eburnea*) (Figs. 808, 809, 810, and 811) forms the principal mass of a tooth; in its central part is the cavity enclosing the pulp. It is a modification of osseous tissue, from which it differs, however, in the fact that it does not *contain* cells placed in cavities, but the cells lie in the periphery of the pulp, against but not in the dentine. The dentine contains the *processes* of the cells, which are known as **dental** or **dentinal fibres.** On microscopic examination it is seen to consist of a number of minute wavy and branching tubes having distinct parietes. They are called the **dentinal tubuli** or **dental canals,** and are embedded in a dense homogeneous substance, the **intertubular tissue.**

The **dentinal tubuli** (*canaliculi dentales*) (Fig. 811) are placed parallel with one another, and open at their inner ends into the pulp-cavity. In their course to the periphery they present two or three curves, and are twisted on themselves in a spiral direction. The direction of these tubes varies; they are vertical in the upper portion of the crown, oblique in the neck and upper part of the root, and toward the lower part of the root they are inclined downward. The tubuli, at their commencement, are about $\frac{1}{4500}$ of an inch in diameter; in their course they divide and subdivide dichotomously, so as to give to the cut surface of the dentine a striated appearance. From the sides of the tubes, especially in the root, ramifications of extreme minuteness are given off, which join together in loops in the intertubular substance, or terminate in small dilatations, from which branches are given off. Near the pulp the lateral branches are few and are almost at right angles to the canals. Nearer the periphery the lateral branches are more numerous, and they come off at acute angles. The terminations of the chief canals at the periphery vary. In the crown they break up into branches like fingers just beneath the enamel. Some of these finger-like branches leave the dentine and enter the cement substance between enamel prisms. The majority of the chief canals end in blind extremities at the margin of the enamel and do not enter this structure. In the lower portion of the tooth the chief canals do not emerge from the dentine, but end at the margin of the cement in blind extremities. They may reach the spaces of the granular sheath. Near the periphery of the dentine of the crown the finer ramifications of the tubuli pass through a layer of irregular branched spaces which communicate with each other. These are called the **interglobular spaces of Czermak** (*spatia interglobularia*) (Fig. 811, *J*). These spaces are gaps in the dentine due to failure of calcification and are filled with uncalcified dentine. The outer part of the dentine in the lower portion of the tooth contains a layer of interglobular spaces known as the **granular layer** or **granular sheath of Tomes.** The dentinal tubuli have comparatively thick walls, and contain slender cylindrical prolongations from the processes of the cells of

FIG. 811.—Ground-section through the root of a human premolar. *D*, dentine; *K*, cement corpuscles; *O*, osteoblasts; *Ep.*, remains of Hertwig's epithelial sheath, 200 diameters; *J*, interglobular spaces. (Rose.)

the pulp-tissue already mentioned, and first described by Mr. Tomes and named **Tomes's fibres** or **dentinal fibres.** These dentinal fibres are analogous to the soft contents of the canaliculi of bone. Between Tomes's fibres and the ivory around the canals there is a tissue which is markedly resistant to the action of acids—the **dentinal sheath of Neumann.**

The **intertubular substance** or **tissue** is translucent and contains the chief part of the earthy matter of the dentine. After the earthy matter has been removed by steeping a tooth in weak acid the animal basis remaining may be torn into laminae which run parallel with the pulp-cavity across the direction of the tubules. These laminae show the method of growth to be by deposition of successive strata of dentine. Fibrils have been found in the matrix of the intertubular substance, and are probably continuous with the dentinal fibres of Tomes. In a *dry* tooth a section of dentine often displays a series of lines—the **incremental lines of Salter**—which are parallel with the laminae above mentioned. These lines are caused by two facts: (1) The imperfect calcification of the dentinal laminae immediately adjacent to the line. (2) The drying process, which reveals these defects in the calcification. These lines are wide or narrow according to the number of laminae involved, and along their course, in consequence of the imperfection in the calcifying process, little irregular cavities are left, which are the **interglobular spaces** already referred to. They have received their name from the fact that they are surrounded by minute nodules or globules of dentine. Other curved lines may be seen parallel to the surface. These are the **concentric lines of Schreger,** and are due to the optical effect of simultaneous curvature of the dentinal tubules.

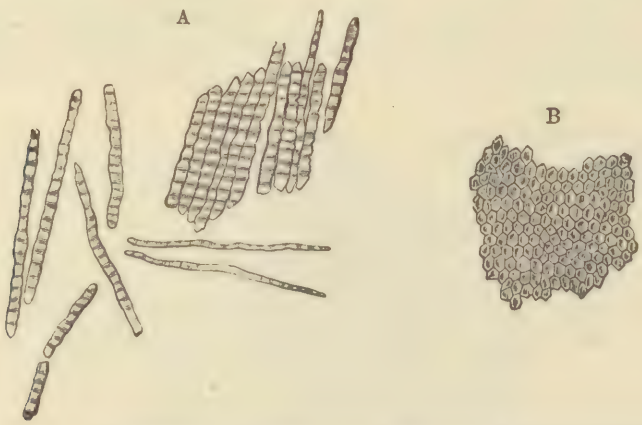

FIG. 812.—Enamel prisms (350 diameters). *A*, fragments and single fibres of the enamel isolated by the action of hydrochloric acid. *B*, surface of a small fragment of enamel, showing the hexagonal ends of the fibres.

CHEMICAL COMPOSITION.—According to Berzelius and Bibra, dentine consists of twenty-eight parts of animal and seventy-two of earthy matter. The animal matter is resolvable by boiling into gelatin. The earthy matter consists of phosphate and carbonate of calcium, with a trace of fluoride of calcium, phosphate of magnesia, and other salts.

The **Enamel** (*substantia adamantina*) (Figs. 808, 810, and 812) is the hardest and most compact part of a tooth, and forms a thin crust over the exposed part of the crown as far as the commencement of the root. It is thickest on the grinding surface of the crown until worn away by attrition, and becomes thinner toward the neck. It consists of a congeries of minute hexagonal rods, columns, or prisms known as **enamel fibres** or **enamel prisms** (*prismata adamantina*) (Fig. 812). In general, they lie parallel with one another, resting by one extremity upon the dentine, which presents a number of minute depressions for their reception, and

forming the free surface of the crown by the other extremity. There are occasional collections of prisms which run diagonally. The prisms are directed vertically on the summit of the crown, horizontally at the sides; they are about the $\frac{1}{5500}$ of an inch in diameter, and pursue a more or less wavy course. By reflected light radial striations are visible. These are **Schreger's lines,** and are due to the fact that the prisms take an undulatory course and those of two layers may have opposite directions. Another series of lines, having a brown appearance from pigmentation, and denominated the **parallel striae** or **brown striae of Retzius** or the **colored lines,** are seen on a section of the enamel. These lines are concentric and *cross* the enamel rods. They are caused by the mode of enamel deposition. Inasmuch as the enamel columns, when near the dentine, cross each other and only become parallel farther away, a series of radial markings, light and dark alternately, is obtained (Fig. 808). The enamel prisms are themselves calcified and are fixed to each other by a very small amount of cement substance. Numerous minute interstices intervene between the enamel-fibres near their dentinal surface. It is noted that some of the dentinal canals at the crown penetrate a certain distance between the rods of the enamel (Fig. 810). No nutritive canals exist in the enamel, except the very few dentinal canals which at the crown penetrate a short distance, and these are found only in a small area.

Chemical Composition.—According to Bibra, enamel consists of 96.5 per cent. of earthy matter and 3.5 per cent. of animal matter. The earthy matter consists of the phosphate and the carbonate of calcium, with traces of fluoride of calcium, phosphate of magnesia, and other salts.

The enamel of a recently erupted tooth is covered by a membrane, the thickness of which is $\frac{1}{2000}$ of an inch. It is known as **enamel cuticle** or **Nasmyth's membrane** (*cuticula dentis*). It is probably the most recent, and hence an uncalcified, or partly calcified enamel layer. Some believe it to be a product of the outer layer of the cells of the enamel organ.

The **Cortical Substance, Cementum** or **Crusta Petrosa** (*substantia ossea*) (Figs. 808 and 811) is disposed as a thin layer on the roots and neck of a tooth, from the termination of the enamel as far as the apex of the root, where it is usually very thick. At the neck it overlays a slight margin of enamel. In structure and chemical composition it is true bone. It contains, sparingly, the lacunae and canaliculi which characterize true bone; the lacunae placed near the surface have the canaliculi radiating from the side of the lacunae toward the periodontal membrane or **dental periosteum,** and those more deeply placed join with adjacent dentinal tubuli. The teeth of the young usually contain Haversian systems in the thicker portions of the cementum. The neck of the tooth does not contain lacunae. The cementum is occasionally laminated. Sharpey's fibres (p. 37) are very numerous. Some of the lacunae of the cementum receive dentinal tubes from the dentine.

As age advances the cement increases in thickness, and gives rise to those bony growths, or exostoses, so common in the teeth of the aged; the pulp-cavity becomes also partially filled up by a hard substance intermediate in structure between dentine and bone (the *osteo-dentine* of Owen; the *secondary dentine* of Tomes). It is formed by the odontoblasts, the dental pulp lessening in volume.

Development of the Teeth (Figs. 813, 814, 815, and 816).—The teeth are an evolution from the dermoid system, and not of the bony skeleton; they are developed from two of the blastodermic layers, the epiblast and mesoblast. From the former the enamel is developed; from the latter the dentinal pulp, dentine, cementum, and pericementum. It is customary to view the development of the permanent and temporary teeth as separate studies.

The earliest evidence of tooth-formation in the human embryo is observed about the seventh week. The mucous membrane covering the embryonic jaws is seen to rise as a longitudinal ridge along the summit of each jaw. This ridge is

the **maxillary rampart of Kölliker and Waldeyer.** A transverse section through the jaw will show the elevation to be due to a linear and outlined activity of the germinal epithelial layer; a corresponding epithelial growth is seen to sink as a band into the mesoblastic tissue beneath. This band is called the **dental lamina** or **dental band.** The local cell-activity continues, and in its descent the band appears to meet with a resistance which causes a flattening of its extremity into a continuous lamina. From the inner (toward the tongue) edge of the lamina epithelial cords are given off, ten in number, one for each temporary tooth.

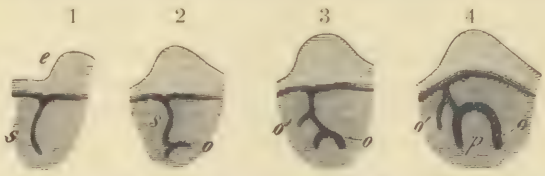

FIG. 813.—Diagram of method of development of the teeth. 1. Early stage. 4. Later stage. 2, 3. Intermediate stages. *s*. Common dental germ. *o*. Special dental germ (milk). *o'*. Special dental germ (permanent). *p*. Papilla. *e*. Dental furrow. (Gegenbauer.)

The growth of each cord continues, and each expands into a flask-like form, the walls covered by a layer of germinal cells, its interior by swollen mature cells. The ingrowing bulb is now seen to flatten upon its lower surface, as though it had met with an outlined resistance from the mesoblastic tissue beneath. The epithelial ingrowth assumes the general form of the several teeth; it is the **enamel-organ of the tooth** (Fig. 813). The cellular tissue of the jaw beneath the cap of the enamel-organ grows and projects into the cap. This projection is the **dentine papilla** (*papilla dentis*). At this period the mesoblastic tissue around each enamel-organ is seen to become differentiated into fibrous tissue surrounding the enamel-organs.

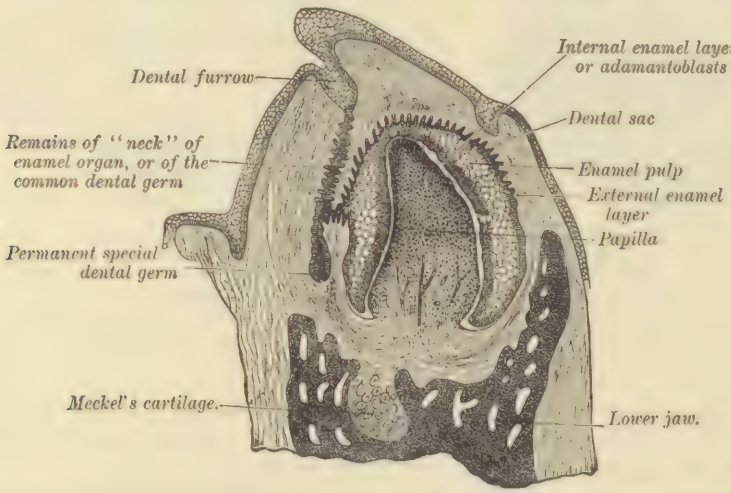

FIG. 814.—Vertical section of the inferior maxilla of an early human fœtus. (Magnified 25 diameters.)

but at some distance from them. Islets of bone are also seen to be forming the beginning of the bony maxillae.

The indentation of the base of the enamel-organ continues until it assumes the form of the future teeth. The cells bounding the organ assumes a cylindrical form; the cells of the interior become much expanded, and irregular in size and form.

The mesoblastic tissue underlying the enamel-organ is much condensed; evidences of cellular differentiation and a vascular system appear. Bone continues to

develop until all of the tooth-follicles are embraced in a gutter of bone. From the lingual side of the cords of the temporary teeth epithelial buds are given off, which sink into the mesoblastic tissue and form the enamel-organs of the permanent teeth. The condensation of fibrous tissue continues until each embryonic tooth is enveloped in a sac, the **dental sac** (Fig. 814); this, together with all of its contents, is called the **dental follicle.**

The tooth which is undergoing development with its enamel-organ and dentine papilla is known as the **tooth germ.** This tooth germ is encompassed and shut off from surrounding structures by the bag of membranous structure known as the **dental sac.**

The cells of the enamel-organ now undergo a series of differentiations: the inner layer, arranged as columnar epithelium, are the **enamel cells,** or **ameloblasts.** The layer is called the **ameloblastic** or **enamel-forming layer** (Figs. 814 and 815). The cells of the outer wall remain cuboidal; the cells which lie between become much distended, and on account of their appearance when seen in section this portion of the organ is called the **enamel jelly** or the **stellate reticulum.** The layer of cells immediately contiguous to the ameloblasts form a layer called the **stratum intermedium** (Fig. 815 A, *D*).

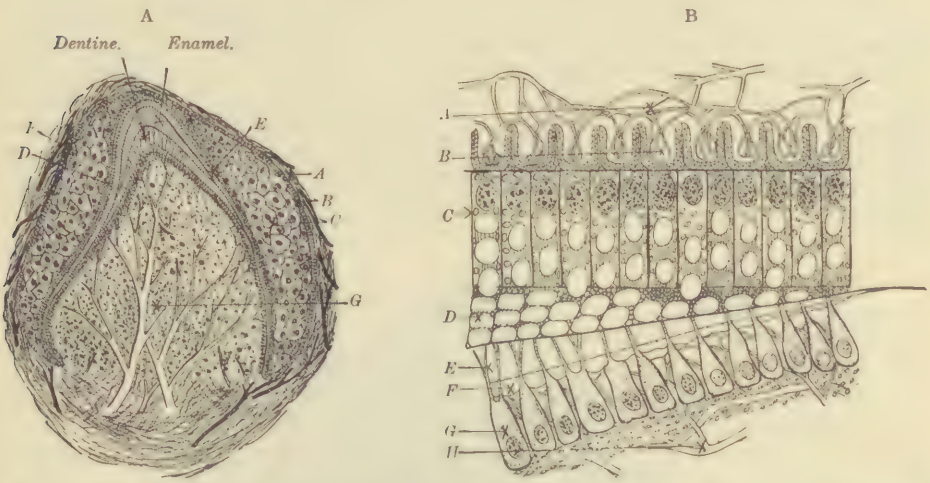

FIG. 815.—A. Section through tooth-follicle—human canine seven and one-half months. *A.* Follicular wall. *B.* Outer epithelial coat. *C.* Stellate reticulum. *D.* Stratum intermedium. *E.* Ameloblasts. *F.* Odontoblasts. *G.* Pulp.

B. Diagram after Williams (Dental Cosmos, 1896), mode of enamel deposition. *A.* Blood-supply to *B*, secreting papillae. *C.* Layer of ameloblasts containing enamel globules and droplets of calcoglobulin. *D.* Enamel-globules deposited. *E.* Formed dentine. *F.* Forming dentine. *G.* Layer of odontoblasts. *H.* Blood-supply to odontoblastic layer.

The enclosed **mesoblastic papilla** (the *future dental pulp*) has its peripheral cells, which are called **odontoblasts,** differentiated into columnar bodies disposed as a layer, each cell having a large nucleus. The vascular supply of the pulp is now well marked. A section of a follicle at this period will exhibit the follicular wall springing from the base of the dental papilla and having a well-marked blood-supply. The bony alveolar walls are well outlined, and evidences of a periosteum appear (Figs. 814 and 815).

Development of Enamel (Fig. 815 B).—In point of time, the deposition of dentine actually begins before that of enamel, so that the first-formed layer of enamel is deposited against a layer of immature dentine. The enamel is built up of two distinct substances—globules of uniform size which are formed by the ameloblasts, and a cementing substance, probably an albuminate of calcium (calcoglobulin), the basis of all the calcified tissues. At the ends of the ameloblasts,

next to the dentine, the secretion of calco-globulin is deposited, and into the plastic mass the enamel-globules are extruded, each globule remaining connected with the ameloblasts by plasmic strings, which also join the globules laterally.[1]

The first deposit of enamel begins in the tips of the cusps, and is quickly followed by a disappearance of the stellate reticulum at that point; the stellate reticulum appears to atrophy, so that the vascular follicular wall is brought into direct apposition with the stratum intermedium, which becomes differentiated into a glandular (secreting) tissue which elaborates the calcic albuminous basis of the enamel. The secretion passes from the cells of the stratum intermedium through a membrane into the ameloblasts, where it is in part combined with the cellular globules, and irregular masses of it are extruded as cementing substance. The deposition continues until the enamel-cap has its typical form. The deposition of the layers of globules is indicated by parallel lines transverse to the axes of the enamel-rods. At the completion of amelification the ameloblasts are partially calcified and form the **enamel cuticle** or **Nasmyth's membrane** (*cuticula dentis*).

Formation of Dentine. — The layer of columnar cells bounding the periphery of the pulp, the **odontoblasts**, are in apposition with a plexus of capillary vessels (Fig. 816). Each cell is a secreting body which selects the material for dentine-building. Against the layer of ameloblasts covering the dental papilla the odontoblasts deposit globules, of the calcium albuminate, and receding as the deposits are made, leave one or more protoplasmic processes in the calcic deposit. These are known as **Tomes's fibres**. The process continues until the normal dentine thickness is formed. The deposit is laid down in a scaffolding of finely fibrillated tissue. The layer of formative cells remains constant. The remains of the dentine papilla constitute the **pulp** and lie in the pulp-cavity (p. 1200).

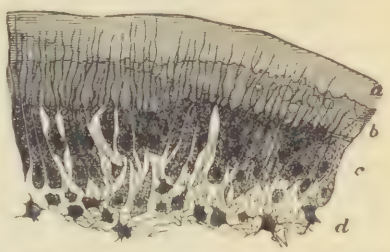

FIG. 816.—Part of section of developing tooth of young rat, showing the mode of deposition of the dentine (highly magnified). *a*. Outer layer of fully-calcified dentine. *b*. Uncalcified matrix with a few nodules of calcareous matter. *c*. Odontoblasts with processes extending into the dentine. *d*. Pulp. The section is stained with carmine, which colors the uncalcified matrix, but not the calcified part.

Formation of Cementum. — Hertwig asserts that the epithelial edge of the enamel organ formed by the inner and outer epithelial layers of the organ grows downward, or rather the developing tooth grows upward until the future root-form of the tooth is outlined by a double layer of epithelial cells, constituting the **root-sheath of Hertwig**. The growth of the alveolar process is synchronous.

Upon the pulp side of the sheath a layer of odontoblasts is developed; upon the outer side the fibrous encasement becomes closely attached to the sheath and a layer of osteogenetic cells is differentiated. These cells are called **cementoblasts**. The growth of the dentine of the root is exactly similar to the growth of that of the crown. The epithelial sheath undergoes atrophic changes, leaving the epithelial whorls which remain in the pericementum. The cementum is developed as subperiosteal bone. The cementum over the apex of the root is not formed until after the eruption of the tooth.

Formation of Alveoli. — By the time the crowns of the teeth have formed, each is enclosed in a loculus of bone which has developed around it and at some distance from it; the loculus is open at the top toward the gums, where it is closed by fibrous tissue; the developing permanent tooth is contained in the same loculus, but is later separated from the temporary tooth by a growth of bone. The alveolar

[1] J. L. Williams, Dental Cosmos, 1896.

process is not completed until after the eruption of the teeth. During eruption that portion of the process overlying the crown undergoes absorption, and as soon as the immature tooth has erupted the alveolar process is developed about the root, whose formation is also completed after eruption.

Development of the Permanent Teeth.—The permanent teeth as regards their development may be divided into two sets: (1) those which replace the temporary teeth, and which, like them, are ten in number; these are the **successional permanent teeth**; and (2) those which have no temporary predecessors, but are superadded at the back of the dental series. These are three in number on either side in each jaw, and are termed the **superadded permanent teeth.** They are the three molars of the permanent set, the molars of the temporary set being replaced by the premolars or bicuspids of the permanent set.

The **Development of the Successional Permanent Teeth**—the ten anterior ones in either jaw—will be first considered. As already stated, the germ of each milk tooth is a special thickening of the "free" edge of the common dental germ or dental lamina. In like manner is formed the special dental germ of each of the successional permanent teeth. But these thickenings are not at the "free" edge of the dental lamina, but occur behind and lateral to each of the milk-tooth germs (Fig. 813). There are ten of these, and they appear in order, about the sixteenth week, on each side, the central incisor germs being the first.

These special dental germs now go through the same transformations as were described in connection with those of the milk teeth, and the changes also eventuate in the germs becoming enamel organs; that is, they recede into the substance of the gum behind the germs of the temporary teeth. As they recede they become flask-shaped, form an expansion of their distal extremity, and finally meet a papilla, which has been formed in the mesoblast, just in the same manner as was the case in the temporary teeth. The apex of the papilla indentates the dental germ, which encloses it, and forming a cap for it, undergoes analogous changes to those described in the development of the milk teeth, and becomes converted into the enamel, whilst the papilla forms the dentine of the permanent tooth. In its development it becomes enclosed in a dentinal sac which adheres to the *back* of the sac of the temporary tooth. The sac of each permanent tooth is also connected with the fibrous tissue of the gum by a slender band of the **gubernaculum,** which passes to the margin of the jaw behind the corresponding milk tooth (see above).

The **Superadded Permanent Teeth**—three on each side in each jaw—arise from successive extensions backward —*i. e.*, along the line of the jaw—of the common dental germ from the back part of the special dental germ of the immediately preceding tooth. During the fourth month or seventeenth week, in that portion of the common dental germ which lies behind—*i. e.*, lateral to the special dental germ of the last temporary molar tooth, and which has hitherto remained unaltered—there is developed the special dental germ of the first permanent molar into which a papilla projects. In a similar manner, about the fourth month after birth the second molar is formed, and about the third year the third molar.

Eruption.—When the calcification of the different tissues of the *milk* tooth is sufficiently advanced to enable it to bear the pressure to which it will be afterward subjected, its eruption takes place, the tooth making its way through the gum. The gum is absorbed by the pressure of the crown of the tooth against it, which is itself pressed up by the increasing size of the fang. At the same time the septa between the dentinal sacs, at first fibrous in structure, ossify and thus form the **loculi** or **alveoli**; these firmly embrace the necks of the teeth and afford them a solid basis.

Previous to the permanent teeth penetrating the gum, the bony partitions which separate their sacs from the deciduous teeth are absorbed, the roots of

the temporary teeth disappear by absorption through the agency of particular multinucleated cells, called **odontoclasts**, which are developed at the time in the neighborhood of the root, and the permanent teeth become placed under the loose crown of the deciduous teeth; the latter finally become detached, and the permanent teeth take their place in the mouth (Fig. 817).

FIG. 817.—The milk-teeth in a child of about four years. The permanent teeth are seen in their alveoli. (Cryer.)

Calcification of the permanent teeth proceeds in the following order: First molar, soon after birth; the central incisor, lateral incisor, and cuspid, about six months after birth; the bicuspids, at the second year or later; second molar, end of second year; third molar, about the twelfth year.

The **Eruption of the Temporary Teeth** commences at the seventh month, and is complete about the end of the second year.

The periods for the eruption of the temporary set are (C. S. Tomes)—

Lower central incisors	6 to 9 months.
Upper incisors	8 to 10 "
Lower lateral incisors and first molars . .	15 to 21 "
Canines	16 to 20 "
Second molars	20 to 24 "

The **Eruption of the Permanent Teeth** takes place at the following periods, the teeth of the lower jaw preceding those of the upper by a short interval:

6½ years, first molars.
7th year, two middle incisors.
8th year, two lateral incisors.
9th year, first bicuspid.
10th year, second biscuspid.
11th to 12th year, canine,
12th to 13th year, second molars.
17th to 21st year, third molars.

The Palate (Palatum).

The palate forms the roof of the mouth; it consists of two portions, the **hard palate** in front, the **soft palate** behind.

The Hard Palate (*palatum durum*) (Figs. 818 and 819).—The hard palate is bounded in front and at the sides by the upper alveolar arches and gums. In front and to the sides it is continuous with the gums; behind, it is continuous with the soft palate. It is formed by the palate processes of the superior maxillary bones and the palate processes of the palate bones (Fig. 72). It is covered by a dense structure formed by the periosteum and mucous membrane of the mouth, which are intimately adherent, particularly to the front and sides, by means of

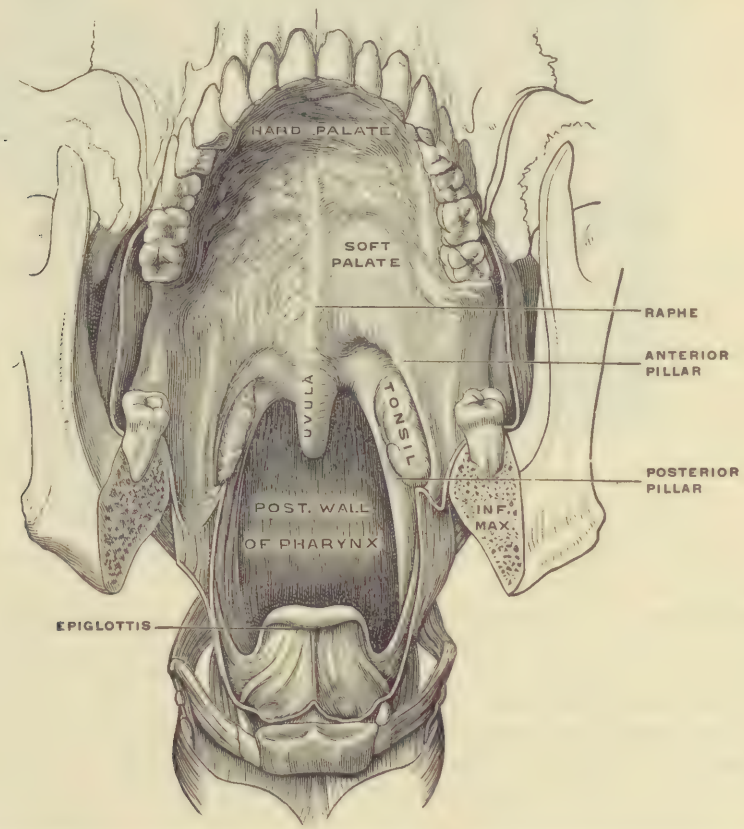

FIG. 818.—Antero-inferior surface of the soft palate. The tongue has been removed, so that the pharyngeal isthmus is distinctly seen. (Luschka.)

a layer of fibrous tissue. Along the middle line is a **linear ridge** or **raphe** (*raphe palati*), which terminates anteriorly in a small papilla, the **incisive papilla** (*papilla incisiva*), corresponding with the inferior opening of the anterior palatine fossa. This papilla receives filaments from the naso-palatine and anterior palatine nerves. The incisive papilla in a recently born child is continuous with the gum and the frenulum of the upper lip. On either side and in front of the raphé the mucous membrane is thick, pale in color, and corrugated; these corrugations, which are composed of fibrous tissue, are the **palatine rugae** (*plicæ palatinæ transversæ*). In very young children the rugæ are distinct and definite. In the aged they are indistinct. Behind, it is thin, smooth, and of a deeper color; it is covered with squamous epithelium, and the fibrous tissue beneath it

contains many mucous glands, the **palatine glands** (*glandulae palatinae*). The palatine vessels and nerves lie in the fibrous tissue beneath the mucous membrane.

The Soft Palate or Velum Pendulum Palati (*palatum molle*) (Figs. 818, 819, and 824).—The soft palate is a movable fold suspended from the posterior border of the hard palate, and forming an incomplete septum between the mouth and pharynx. It consists of a fold of mucous membrane enclosing muscular fibres, an aponeurosis, vessels, nerves, adenoid tissue, and mucous glands. When occupying its usual position it is relaxed and pendent and its oral surface is concave, continuous with the roof of the mouth, and marked by a **median ridge** or **raphé**, which indicates its original separation into two lateral halves. Its pharyngeal surface is convex, and continuous with the mucous membrane cover-

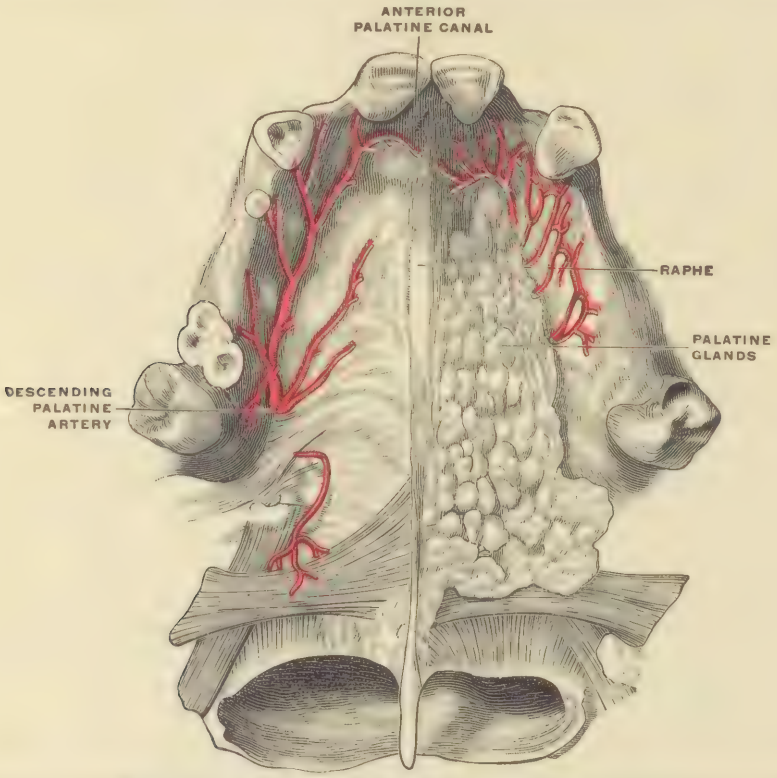

FIG. 819.—The palatine vault on the right side of the mucous membrane has been removed. The left side shows the mucous membrane and the glandular layer. (Poirier and Charpy.)

ing the floor of the posterior nares. Its anterior or upper border is attached to the posterior margin of the hard palate, and its sides are blended with the pharynx. Its posterior or lower border is free. The posterior portion of the soft palate is known as the **vail of the palate** (*velum palatinum*) and terminates posteriorly and externally on each side in a free margin, the posterior arch of the palate.

Hanging from the middle of its lower border is a small, conical-shaped, pendulous process, the **uvula** (*uvula palatina*). The uvula varies greatly in length in different individuals. It is composed of glands and connective tissue, contains a prolongation of the Azygos uvulae muscle and is covered with mucous membrane, and arching outward and downward from the base of the uvula on each side are two curved folds of mucous membrane, containing muscular fibres, called the **arches** or **pillars of the soft palate** or **pillars of the fauces** (*arcus palatini*).

The Anterior Pillar (*arcus glossopalatinus*) (Figs. 818 and 824).—The anterior pillar on each side runs downward, outward, and forward to the side of the base of the tongue. These pillars are formed by the projection of the Palato-glossi muscles, covered by mucous membrane.

The Posterior Pillar (*arcus pharyngopalatinus*) (Figs. 818 and 824).—The posterior pillar on each side is nearer to its opposite arch than is the anterior pillar to its opposite. These pillars are larger than the anterior; they run downward, outward, and backward to the sides of the pharynx, and are formed by the projection of the Palato-pharyngei muscles, covered by mucous membrane. The anterior and posterior pillars are separated below by a triangular interval in which the **tonsil** is lodged.

The space left between the arches of the palate on the two sides is called the **isthmus of the fauces** (*isthmus faucium*). It is bounded, above, by the free margin of the soft palate; below, by the back of the tongue; and on each side by the pillars of the fauces and the tonsils. Through this isthmus the mouth communicates with the pharynx.

The Mucous Membrane of the Soft Palate.—The mucous membrane of the soft palate is thin, and covered with squamous epithelium on both surfaces, excepting near the orifice of the Eustachian tube, where its epithelium is columnar and ciliated.[1] Beneath the mucous membrane on the oral surface of the soft palate is a considerable amount of adenoid tissue. The palatine glands form a continuous layer on the pharyngeal surface and around the uvula.

The Aponeurosis of the Soft Palate.—The aponeurosis of the soft palate is a thin but firm fibrous layer attached above to the posterior border of the hard palate, and becoming thinner toward the free margin of the velum. Laterally, it is continuous with the pharyngeal aponeurosis. It forms the framework of the soft palate, and is joined by the tendons of the Tensor palati muscles.

The Muscles of the Soft Palate.—The muscles of the soft palate are six on each side: the **Levator palati, Tensor palati, Azygos uvulae, Palato-glossus, Palato-pharyngeus** and **Salpingo-pharyngeus** (see pp. 403, 404, 405, and 406). The following is the relative position of these structures in a dissection of the soft palate from the posterior or naso-pharyngeal to the anterior or oral surface: Immediately beneath the pharyngeal mucous membrane is a thin stratum of muscular fibres, the posterior fasciculus of the **Palato-pharyngeus muscle,** joining with its fellow of the opposite side in the middle line. This posterior fasciculus is joined by the Salpingo-pharyngeus muscle. Beneath this are the **Azygos uvulae** and **Salpingo-pharyngeus muscles,** consisting of two rounded fleshy fasciculi, placed side by side in the median line of the soft palate. Next comes the aponeurosis of the **Levator palati,** joining with the muscle of the opposite side in the middle line. Fourthly, the anterior fasciculus of the **Palato-pharyngeus,** thicker than the posterior, and separating the Levator palati from the next muscle, the **Tensor palati.** This muscle terminates in a tendon which, after winding around the hamular process of the internal pterygoid plate of the sphenoid bone, expands into a broad aponeurosis in the soft palate, anterior to the other muscles, which have been enumerated. Finally, we have a thin muscular stratum, the **Palato-glossus muscle,** placed in front of the aponeurosis of the Tensor palati, and separated from the oral mucous membrane by adenoid tissue.

The Blood-vessels of the Palate (Fig. 819).—The palate is supplied with blood by branches of the posterior or **descending palatine branch of the internal maxillary artery** (*a. palatina descendens*) and of the **ascending** or **anterior palatine branch of the facial artery** (*a. palatina ascendens*). The posterior palatine artery divides into the **great and small palatine arteries** (*aa. palatinae major et minor*), which run through the

[1] According to Klein, the mucous membrane on the nasal surface of the soft palate in the fœtus is covered throughout by columnar ciliated epithelium, which subsequently becomes squamous; and some anatomists state that it is covered with columnar ciliated epithelium, except at its free margin, throughout life.—Ed. of 15th English edition.

palatine canals and after emerging give off branches. Branches from the small palatine go to the soft palate, the large branch passes forward on the hard palate near the alveolar margin. The ascending palatine branch of the facial lies upon the medial surface of the Tensor palati muscle and is distributed to the soft palate and pharynx. **A palatine vein** corresponding to the descending palatine artery opens into the anterior facial vein. The pharyngeal veins also receive palatine veins.

The Nerves of the Palate.—The **large posterior palatine nerve** emerges from the posterior palatine canal and accompanies the posterior palatine artery. The **naso-palatine nerve** emerges from the foramen of Scarpa and is distributed to the anterior portion of the hard palate. The soft palate is supplied by the **small posterior palatine** and the **accessory palatine nerves.**

The Tonsil or Amygdala (*tonsilla palatina*) (Figs. 818 and 824).—The tonsils or amygdalae are two prominent bodies situated one on each side of the fauces, between the anterior and posterior pillars of the soft palate. They are of a rounded form, and vary considerably in size in different individuals. A recess, the **supra-tonsillar fossa** (*fossa supratonsillaris*), may be seen, directed upward and backward above the tonsil. His regards this as the remains of the lower part of the second visceral cleft. The recess is covered by a fold of mucous membrane termed the **plica triangularis.** Externally the tonsil is covered with a fibrous capsule which joins the aponeurosis of the pharynx. The outer surface of the capsule is in relation with the inner surface of the Superior constrictor muscle of the pharynx, to the outer side of which is the Internal pterygoid muscle. The *ascending palatine artery* is close to the outer surface of the tonsil, the Superior constrictor muscle of the pharynx and the tonsillar capsule intervening. The **tonsillar artery,** which is sometimes a branch of the ascending palatine, is also close to the outer surface of the tonsil. The internal carotid artery lies behind and to the outer side of the tonsil, and nearly an inch (20 to 25 mm.) distant from it. It corresponds to the angle of the lower jaw. The surface of the tonsil which looks toward the pharynx presents from twelve to fifteen orifices, each leading into a small recess or **crypt** (*fossula tonsillaris*). From the crypts numerous follicles branch out into the substance of the tonsil by means of very irregular channels. The crypts are lined with stratified pavement epithelium. The epithelium of the crypts exhibits marked degenerative changes. The degeneration causes the formation of numerous communicating spaces, which contain leukocytes and lymphocytes. The crypts are surrounded with lymphoid tissue. In this are numerous lymphoid follicles (*noduli lymphatici*), which are placed in the submucous tissue. These follicles are analogous to those of Peyer's glands and consist of adenoid tissue. No openings from the capsules into the follicles can be recognized. They contain a thick grayish secretion.

The Blood-vessels of the Tonsil.—The **arteries** supplying the tonsils are the **dorsalis linguae** from the lingual, the **ascending palatine** and **tonsillar** from the facial, the **ascending pharyngeal** from the external carotid, the **descending palatine** branch of the internal maxillary, and a twig from the **small meningeal.** The **veins** terminate in the **tonsillar plexus,** on the outer side of the tonsil, and the tonsillar plexus joins the pharyngeal plexus, which communicates with the pterygoid plexus of the internal jugular or facial vein.

Lymphatics of the Tonsil.—Surrounding each follicle is a close plexus of lymphatic vessels. From these plexuses the lymphatic vessels pass to the submaxillary lymph glands below the angle of the jaw. From the submaxilliary glands lymph passes to the deep cervical glands.

The Nerves of the Tonsil.—A branch from the **glosso-pharyngeal nerve** by uniting with branches of the **pharyngeal plexus** forms the **tonsillar plexus.** The pharyngeal plexus is formed by the pharyngeal branches of the glosso-pharyngeal and superior cervical ganglions and the pharyngeal branch of the vagus.

The Salivary Glands (Fig. 820).

Numerous glands exist in the lips, cheeks, palate, and tongue, but by the term salivary glands are usually understood the three chief glandular masses on each side of the face. These are the principal salivary glands. They communicate with the mouth, pour their secretion into its cavity, and are named respectively the **parotid, submaxillary,** and **sublingual.**

The Parotid Gland (*glandulae parotis*) (Fig. 646).—The parotid gland, so called from being placed near the ear (*παρά, near; οὖς, ὠτός, the ear*), is the largest of the three salivary glands, varying in weight from half an ounce to an ounce. It lies upon the side of the face immediately below and in front of the external ear. It is limited above by the zygoma; below, by the angle of the jaw and by a line drawn between the angle and the mastoid process: anteriorly, it

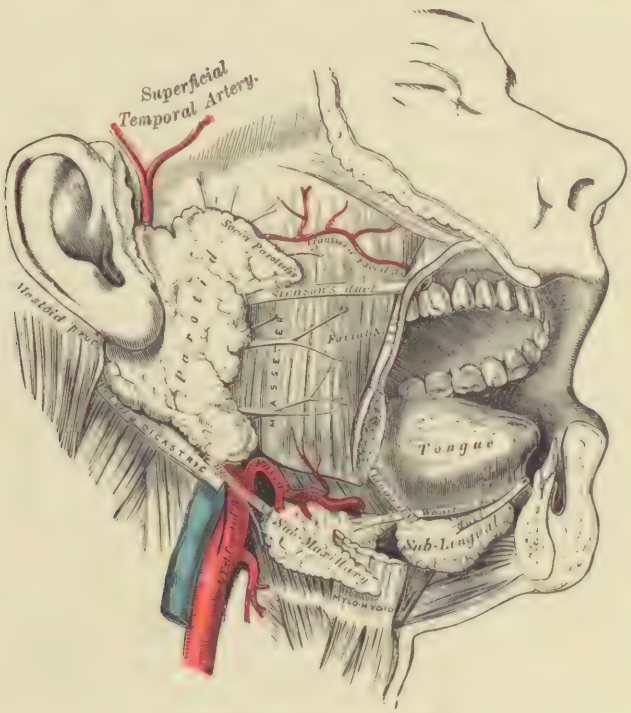

Fig. 820.—The salivary glands.

extends to a variable extent over the Masseter muscle; posteriorly, it is bounded by the external meatus, the mastoid process, and the Sterno-mastoid and Digastric muscles, slightly overlapping the two muscles.

Its *anterior surface* is grooved to embrace the posterior margin of the ramus of the lower jaw, and advances forward beneath the ramus, between the two Pterygoid muscles and superficial to the ramus over the Masseter muscle. Its *outer surface* is triangular and convex, slightly lobulated, is covered by the integument and parotid fascia, and has one or two lymphatic glands resting on it. Its *inner surface* (*processus retromandibularis*) extends deeply into the neck by means of two large processes, one of which dips behind the styloid process and projects beneath the mastoid process and the Sterno-mastoid muscle; the other is situated in front of the styloid process, and passes into the back part of the glenoid fossa, behind the articulation of the lower jaw. The structures passing through the parotid gland are—the **external carotid artery,** giving off its three terminal

branches: the **posterior auricular artery** emerges from the gland behind; the **superficial temporal artery** above; the **transverse facial,** a branch of the temporal, in front; and the **internal maxillary** winds through it as it passes inward, behind the neck of the jaw. Superficial to the external carotid is the trunk formed by the union of the **temporal** and **internal maxillary veins**; a branch, connecting this trunk with the internal jugular, also passes through the gland. The gland is also traversed by the **facial nerve** and its **branches,** which emerge at its anterior border; branches of the **great auricular nerve** pierce the gland to join the facial, and the **auriculo-temporal branch** of the inferior maxillary nerve emerges from the upper part of the gland. The **internal carotid artery** and **internal jugular vein** lie close to its deep surface. The triangular space occupied by the greater part of the gland is bounded in front by the posterior margin of the ramus of the jaw and the internal pterygoid muscle, and behind by the anterior edge of the Sterno-cleido-mastoid muscle, the tympanic portion of the temporal bone and the cartilaginous portion of the external auditory meatus. Its floor is formed by the anterior and posterior walls of the space which meet about the styloid process. These walls are composed of fascia derived from the deep cervical fascia. The remaining side of the space is external and is formed by fascia, derived from the deep cervical fascia and called the **parotid fascia.** This space is called the **parotid recess.** Sir Frederick Treves[1] denies that the fascial covering of the space is complete. He says it is deficient above between the anterior edge of the styloid process and the posterior border of the external pterygoid muscle. A portion of the gland does not occupy the space, but projects forward over the Masseter muscle. This projecting portion is the **facial process.**

Lymph-glands, known as the **parotid lymph-glands,** are in and about the parotid gland, some being embedded in the outer surface of the parotid fascia, others being in the inner surface of the fascia, others in the gland itself, particularly along the temporo-maxillary vein and external carotid artery. They receive lymph from the anterior and lateral portions of the scalp, both eyelids, a portion of the cheek, the root of the nose, the outer portion of the external ear, the soft palate, the posterior nares, and the external auditory meatus. The vessels from them empty into the superficial cervical glands and the superior deep cervical glands. Between the parotid gland and the pharynx are the *subparotid glands.* They receive lymph from the nasal fossae, naso-pharynx and Eustachian tube, and vessels from the glands take lymph to the deep cervical glands.[2]

The Duct of the Parotid Gland, called the Parotid Duct or Stenson's Duct (*ductus parotideus* [*Stenonis*]) (Fig. 820).—The duct of the parotid gland is about two inches and a half in length. It commences by numerous branches from the anterior part of the gland, crosses the Masseter muscle, and at its anterior border dips down into the substance of the Buccinator muscle, which it pierces; it then runs for a short distance obliquely forward between the Buccinator muscle and the mucous membrane of the mouth, and opens upon the inner surface of the cheek by a small orifice opposite the second molar tooth of the upper jaw (Fig. 824). Upon the beginning of Stenson's duct there is often an **accessory parotid gland** (*glandulae parotis accessoria*), which is often called the **socia parotidis.** It is a portion of the facial process. It is a detached portion of gland, and has a duct which opens into Stenson's duct. This accessory gland occasionally exists as a separate lobe, just beneath the zygomatic arch. In this position it has the transverse facial artery above it and some branches of the facial nerve below it.

Surface Form.—The direction of the duct corresponds to a line drawn across the face about a finger's breadth below the zygoma; that is, from the lower margin of the concha to midway between the free margin of the upper lip and the ala of the nose.

[1] Applied Anatomy.

[2] Poirier and Cunéo, Human Anatomy.

Structure of the Parotid Duct.—The parotid duct is dense, it is of considerable thickness, and its canal is about the size of a crowquill; but at its orifice on the inner aspect of the cheek its lumen is greatly reduced in size. The duct consists of an external or fibrous coat, of considerable density, containing contractile fibres, and of an internal or mucous coat lined with short columnar epithelium.

Vessels and Nerves.—The **arteries** supplying the parotid gland are derived from the external carotid, and from the branches given off by that vessel in or near its substance. The **veins** empty themselves into the external jugular through some of its tributaries. The **lymphatics** terminate in the superficial cervical and the deep cervical glands, passing in their course through several lymphatic glands placed on the surface and in the substance of the parotid. The **nerves** are derived from the plexus of the **sympathetic** on the external carotid artery, the **facial,** the **auriculo-temporal,** and **great auricular nerves.** It is probable that the branch from the auriculo-temporal nerve is derived from the **glosso-pharyngeal** through the **otic ganglion.** At all events, in some of the lower animals this has been proved experimentally to be the case.

The Parotid Capsule.—The parotid gland is enclosed by two layers of the **parotid fascia** (*fascia parotideomasseterica*), which almost completely encompass the gland. The sheath is incomplete at one area toward the pharyngeal wall (see p. 1215).

The parotid fascia comes from the deep cervical fascia. The external layer covers the gland. The internal layer lines the parotid recess. The external layer is the structure usually spoken of as the parotid fascia. Anteriorly it joins the fascia of the masseter; below it is continuous with the deep cervical fascia; above it is attached to the zygoma; behind it is adherent to the external auditory meatus and sheath of the Sternomastoid. The deep layer is adherent above to the external auditory meatus and back of the glenoid fossa; internally to the styloid process; below it is continuous with the deep cervical fascia. The **stylomaxillary** or **stylomandibular ligament** comes off from the parotid fascia.

The Submaxillary Gland (*glandula submaxillaris*) (Fig. 820).—The submaxillary gland is situated below the jaw, in the anterior part of the submaxillary triangle of the neck. It is irregular in form and weighs about two drachms (8 to 10 grammes). It is covered by the integument, Platysma, deep cervical fascia, and the body of the lower jaw, corresponding to a depression on the inner surface of the body of the mandible, and lies upon the Mylo-hyoid, Hyo-glossus, and Stylo-glossus muscles, a portion of the gland passing beneath the posterior border of the Mylo-hyoid. In front of it is the anterior belly of the Digastric muscle; behind, it is separated from the parotid gland by the **stylo-maxillary ligament,** and from the sublingual gland in front by the Mylo-hyoid muscle. The facial artery lies embedded in a groove in its posterior and upper border. A process is given off from the deep surface of the anterior portion of the gland. This is the **deep process** (Cunningham), and it passes with the duct beneath the Mylo-hyoid muscle.

The Duct of the Submaxillary Gland or Wharton's Duct (*ductus submaxillaris* [*Whartoni*]).—The duct of the submaxillary gland is about two inches in length, and its walls are much thinner than those of the parotid duct. It commences by numerous branches from the deep portion of the gland which lies on the upper surface of the Mylo-hyoid muscle, and passes forward and inward between the Mylo-hyoid and the Hyo-glossus and Genio-hyo-glossus muscles, then between the sublingual gland and the Genio-hyo-glossus muscle, and opens by a narrow orifice on the summit of a small papilla (*caruncula sublingualis*) at the side of the fraenum linguae. On the Hyo-glossus muscle it lies between the lingual and hypoglossal nerves, but at the anterior border of the muscle it crosses under the lingual nerve, and is then placed above it.

Vessels and Nerves.—The **arteries** supplying the submaxillary gland are branches of the **facial** and **lingual.** Its **veins** follow the course of the arteries. The **lymphatics** drain into the **submaxillary lymph-glands.** There are no lymphatic glands in this salivary gland. The **nerves** are derived from the **submaxillary ganglion,** through which it receives filaments from the *chorda tympani of the facial* and from the **lingual branch of the inferior maxillary,** sometimes from the **mylo-hyoid branch of the inferior dental,** and from the **sympathetic.**

The Sublingual Gland (*glandula sublingualis*) (Fig. 820). The sublingual gland is the smallest of the salivary glands. It is situated beneath the mucous membrane of the floor of the mouth, at the side of the fraenum linguae, in contact with the inner surface of the lower jaw, close to the symphysis. It is narrow, flattened, in shape somewhat like an almond, and weighs about a drachm. It is in relation, *above,* with the mucous membrane; *below,* with the Mylo-hyoid muscle; in *front,* with the depression on the side of the symphysis of the lower jaw, and with its fellow of the opposite side; *behind,* with the deep part of the submaxillary gland; and *internally,* with the Genio-hyo-glossus, from which it is separated by the lingual nerve and Wharton's duct. Its **excretory ducts** or **ducts of Rivinus** (*ductus sublingualis minores*) are from eight to twenty in number.

FIG. 821.—A highly magnified section of the submaxillary gland of the dog, stained with carmine. (Kölliker.)

They open separately into the mouth back of Wharton's duct and upon a fold of mucous membrane known as the **plica sublingualis.** The plica sublingualis is an elevated crest of mucous membrane caused by the projection of the gland on either side of the fraenum linguae. One or more ducts sometimes join to form a tube which opens into the Whartonian duct or remains independent, opening close to Wharton's duct on the sublingual papilla. This single duct is called the **duct of Bartholin** (*ductus sublingualis major*).

Vessels and Nerves.—The sublingual gland is supplied with blood from the **sublingual** and **submental arteries.** Its **nerves** are derived from the **lingual.**

Structure of Salivary Glands (Fig. 821).—The salivary glands are compound racemose glands, consisting of numerous lobes, which are made up of smaller lobules connected together by dense areolar tissue, vessels, and ducts. Each lobule consists of the ramifications of a single duct, dividing frequently like the branches of a tree, the branches terminating in dilated ends or **alveoli,** on which the capillaries are distributed. These alveoli, however, as Pflüger points out, are not necessarily spherical, though sometimes they assume that form; sometimes they are perfectly cylindrical, and very often they are mutually compressed. The alveoli are enclosed by a **basement membrane** which is continuous with the membrana propria of the duct. It presents a peculiar reticulated

structure, having the appearance of a basket with open meshes, and consisting of a network of branched and flattened nucleated cells.

The alveoli of the salivary glands are of two kinds, which differ both in the appearance of their secreting cells, in their size, and in the nature of their secretion. The one variety secretes a ropy fluid which contains mucin, and such alveoli have therefore been named the **mucous alveoli**, whilst the other secretes a thinner and more watery fluid, which contains serum-albumin, and alveoli of this variety have been named **serous** or **albuminous alveoli**. The sublingual gland may be regarded as an example of the former variety, the parotid of the latter. The submaxillary is of the mixed variety, containing both mucous and serous alveoli, the latter, however, preponderating.

Both varieties of alveoli are lined by cells, and it is by the character of these cells that the nature of the gland is chiefly to be determined. In addition, however, the alveoli of the serous glands are smaller than those of the mucous ones.

The Mucous Alveoli.—The cells in the mucous alveoli are spheroidal in shape, glassy, transparent, and dimly striated in appearance. The nucleus is usually situated in the part of the cell which is next the basement membrane, against which it is sometimes flattened. The most remarkable peculiarity presented by these cells is, that they give off an extremely fine process which is curved in a direction parallel to the surface of the alveolus, lies in contact with the membrana propria, and overlaps the process of neighboring cells. The cells contain a quantity of mucin, to which their clear, transparent appearance is due.

Here and there in the alveoli are seen peculiar half-moon-shaped bodies lying between the cells and the membrana propria of the alveolus. They are termed the **crescents of Gianuzzi** or the **domilunes of Heidenhain** (Fig. 821), and are composed of polyhedral granular cells, which Heidenhain regards as young epithelial cells destined to supply the place of those salivary cells which have undergone disintegration. This view, however, is not accepted by Klein.

Serous Alveoli.—In the serous alveoli the cells almost completely fill the cavity, so that there is hardly any lumen perceptible. Instead of presenting the clear, transparent appearance of the cells of the mucous alveoli, they present a granular appearance, due to distinct granules of an albuminous nature embedded in a closely reticulated protoplasm. The ducts which originate from the alveoli are lined at their commencement by epithelium which differs little from the pavement type. As the ducts enlarge, the epithelial cells change to the columnar type, and the part of the cells next the basement-membrane is finely striated. The lobules of the salivary glands are richly supplied with blood-vessels which form a dense network in the interalveolar spaces. Fine plexuses of nerves are also found in the interlobular tissue. The nerve-fibrils pierce the basement-membrane of the alveoli, and end in branched varicose filaments between the secreting cells. There is no doubt that ganglia are to be found in some salivary glands in connection with the nerve-plexuses in the interlobular tissue; they are to be found in the submaxillary, but not in the parotid.

In the submaxillary and sublingual glands the lobes are larger and more loosely united than in the parotid.

Mucous Glands.—Besides the salivary glands proper, numerous other glands are found in the mouth. They appear to secrete mucus only, which serves to keep the mouth moist during the intervals of the salivary secretion, and which is mixed with that secretion in swallowing. Many of these glands are found at the posterior part of the dorsum of the tongue, behind the circumvallate papillae, and also along its margins as far forward as the apex.[1] Others lie around and in the tonsil

[1] It has been shown by Ebner that many of these glands open into the trenches around the circumvallate papillae, and that their secretion is more watery than that of ordinary mucous glands. He supposes that they assist in the more rapid distribution of the substance to be tasted over the region where the special apparatus of the sense of taste is situated.—Ed. of 15th English edition.

between its crypts, and a large number are present in the soft palate. These glands are of the ordinary compound racemose type. Behind the tip of the tongue on each side, external to the anterior extremity of the genio-glossus muscle, is a mucous gland, the **gland of Nuhn and Blandin** (*glandula lingualis anterior*). Its lower surface is partly covered by muscular fibres from the inferior lingualis and styloglossus muscles, and it opens by several ducts.

Surface Form.—The orifice of the mouth is bounded by the *lips*, two thick, fleshy folds covered externally by integument and internally by mucous membrane, and consisting of muscles, vessels, nerves, areolar tissue, and numerous small glands. The size of the orifice of the mouth varies considerably in different individuals, but seems to bear a close relation to the size and prominence of the teeth. Its corners correspond pretty accurately to the outer border of the canine teeth. In the Ethiopian tribes the front teeth are large and inclined forward, the mouth is large; and this, combined with the thick and everted lips which appear to be associated with prominent teeth, gives to the negro's face much of the peculiarity by which it is characterized. The smaller teeth and the slighter prominence of the alveolar arch of the more highly civilized races render the orifice of the mouth much smaller, and thus a small mouth is an indication of intelligence, and is regarded as an evidence of the higher civilization of the individual.

Upon looking into the mouth, the first thing we may note is the tongue, the upper surface of which will be seen occupying the floor of the cavity. This surface is convex, and is marked along the middle line by a raphé which divides it into two symmetrical portions. The anterior two-thirds is rough and studded with papillae; the posterior third smooth and tuberculated, and covered by numerous glands which project from the surface. Upon raising the tongue the mucous membrane which invests the upper surface may be traced covering the sides of the under surface, and then reflected over the floor of the mouth on to the inner surface of the lower jaw, a part of which it covers. As it passes over the borders of the tongue it changes its character, becoming thin and smooth and losing the papillae which are to be seen on the upper surface. In the middle line the mucous membrane on the under surface of the tip of the tongue forms a distinct fold, the *fraenum linguae*, by which this organ is connected to the symphysis of the jaw. Occasionally it is found that this fraenum is rather shorter than natural, and, acting as a bridle, prevents the complete protrusion of the tongue. When this condition exists and an attempt is made to protrude the organ, the tip will be seen to remain buried in the floor of the mouth, and the dorsum of the tongue is rendered very convex, and more or less extruded from the mouth; at the same time a deep furrow will be noticed to appear in the middle line of the anterior part of the dorsum. Sometimes, a little external to the fraenum, the ranine vein may be seen immediately beneath the mucous membrane. The corresponding artery, being more deeply placed, does not come into view, nor can its pulsation be felt with the finger. On either side of the fraenum, in the floor of the mouth, is a longitudinally elevation or ridge, produced by the projection of the sublingual gland, which lies immediately beneath the mucous membrane. And close to the attachment of the fraenum to the tip of the tongue may be seen on either side the slit-like orifices of *Wharton's ducts*, into which a fine probe may be passed without much difficulty. By everting the lips the smooth mucous membrane lining them may be examined, and may be traced from them on to the outer surface of the alveolar arch. In the middle line, both of the upper and lower lip, a small fold of mucous membrane passes from the lip to the bone, constituting the *fraena;* these are not so large as the fraenum linguae. By pulling outward the angle of the mouth, the mucous membrane lining the cheeks can be seen, and on it may be perceived a little papilla which marks the position of the orifice of *Stenson's duct* the duct of the parotid gland. The exact position of the orifice of the duct will be found to be opposite the second molar tooth of the upper jaw. The introduction of a probe into this duct is attended with considerable difficulty. The teeth are the next objects which claim our attention upon looking into the mouth. These are, as stated above, ten in either jaw in the temporary set, and sixteen in the permanent set. The gums, in which they are implanted, are dense, firm, and vascular.

At the back of the mouth is seen the *isthmus of the fauces*, or, as it is popularly called, "the throat:" this is the space between the pillars of the fauces on either side, and is the means by which the mouth communicates with the pharynx. Above, it is bounded by the soft palate, the anterior surface of which is concave and covered with mucous membrane, which is continuous with that lining the roof of the mouth. Projecting downward from the middle of its lower border is a conical-shaped projection, the *uvula*. On either side of the isthmus of the fauces are the anterior and posterior pillars, formed by the Palato-glossus and Palato-pharyngeus muscles respectively, covered over by mucous membrane. Between the two pillars on either side is situated the *tonsil*. The extirpation of this body is not unattended with danger of hemorrhage. Dr. Weir has stated that he believes that when hemorrhage occurs after their removal it arises from one of the palatine arteries having been wounded. These vessels are

large: they lie in the muscular tissue of the palate, and when wounded are constantly exposed to disturbance from the contraction of the palatine muscles. The vessels of the tonsil, Dr. Weir states, are small and lie in the soft tissue, and readily contract when wounded.

When the mouth is wide open a prominent tense fold of mucous membrane may be seen and felt, extending upward and backward from the position of the fang of the last molar tooth to the posterior part of the hard palate. This is caused by the *pterygo-maxillary ligament*, which is attached by one extremity to the apex of the internal pterygoid plate, and by the other to the posterior extremity of the mylo-hyoid ridge of the lower jaw. It connects the Buccinator with the Superior constrictor of the pharynx. The fang of the last molar tooth indicates the position of the *lingual* (gustatory) nerve where it is easily accessible, and can with readiness be divided in cases of cancer of the tongue (see page 1043). On the inner side of the last molar tooth we can feel the hamular process of the internal pterygoid plate of the sphenoid bone, around which the tendon of the Tensor palati plays. The exact position of this process is of importance in performing the operation of *staphylorrhaphy*. About one-third of an inch in front of the hamular process, and the same distance directly inward from the last molar tooth, is the situation of the opening of the posterior palatine canal, through which emerges the posterior or descending palatine branch of the internal maxillary artery and one of the descending palatine nerves from Meckel's ganglion. The exact position of the opening on the subject may be ascertained by driving a needle through the tissues of the palate in this situation, when it will be at once felt to enter the canal. The artery emerging from the opening runs forward in a groove in the bone just internal to the alveolar border of the hard palate, and may be wounded in the operation for the cure of cleft palate. Under these circumstances the palatine canal may require plugging. By introducing the finger into the mouth the anterior border of the coronoid process of the jaw can be felt, and it is especially prominent when the jaw is dislocated. By throwing the head well back a considerable portion of the posterior wall of the pharynx may be seen through the isthmus faucium, and on introducing the finger the anterior surface of the bodies of the upper cervical vertebrae may be felt immediately beneath the thin muscular stratum forming the wall of the pharynx. The finger can be hooked around the posterior border of the soft palate, and by turning it forward the posterior nares, separated by the septum, can be felt, or the presence of any adenoid or other growths in the naso-pharynx can be ascertained.

THE PHARYNX (Figs. 818, 824, 825).

The pharynx (from *φάρυγξ*, *the throat*) is that part of the alimentary canal which is placed behind and communicates with the nose, mouth, and larynx. It is a musculo-membranous tube, somewhat conical in form, with the base upward and the apex downward, extending from the under surface of the skull to the level of the cricoid cartilage in front and that of the intervertebral disk between the fifth and sixth cervical vertebrae behind.

The pharynx is about four inches and a half in length, and broader in the transverse than in the antero-posterior diameter. Its greatest breadth is opposite the cornua of the hyoid bone; its narrowest point, at its termination in the œsophagus. It is attached, *above*, to the periosteum of the petrous portion of the temporal bone and of the basilar process of the occipital bone. To the pharyngeal tubercle of the basilar process of the occipital bone the raphé of the Constrictor muscles is attached. It is bounded above by the body of the sphenoid as well as by the basilar process of the occipital; *below*, it is continuous with the œsophagus; *posteriorly*, it is connected by loose areolar tissue with the cervical portion of the vertebral column and the Longi colli and Recti capitis antici muscles; this areolar tissue is contained in what is called the **retro-pharyngeal space** (*spatia retropharyngeus*); *anteriorly*, it is incomplete, the gap being occupied by the cavities of the nose, mouth, and larynx. *Interiorly*, it is attached in succession to the Eustachian tube, the internal pterygoid plate, the pterygo-maxillary ligament, the posterior termination of the mylo-hyoid ridge of the lower jaw, the mucous membrane of the mouth, the base of the tongue, hyoid bone, the thyroid and cricoid cartilages; *laterally*, it is connected to the styloid processes and their muscles, and is in contact with the common and internal carotid arteries, the internal jugular veins, and the glosso-pharyngeal, pneumogastric, hypoglossal, and sympathetic nerves, and above with a small part of the Internal pterygoid muscles. When the pharynx

is at rest the anterior and posterior walls are near together. Above the larynx they do not come in contact, but leave a channel for air; below the larynx they lie in contact, but open for the passage of food. It has seven openings communicating with it—the two posterior nares, the two Eustachian tubes, the mouth, larynx, and oesophagus. The pharynx may be subdivided from above downward into three parts, **nasal, oral,** and **laryngeal.**

The Nasal Part (*pars nasalis pharyngis*) (Fig. 824). The nasal part of the pharynx or **naso-pharynx** lies behind the nose and above the level of the soft palate; it differs from the two lower parts of the tube in that its cavity always remains patent. In front it communicates through the **posterior nares** (*choanae*) (Fig. 825) with the nasal fossae. On its lateral wall is the **pharyngeal orifice of the Eustachian tube** (*ostium pharyngeum tubae auditivae*) (Figs. 822 and 823), which presents the appearance of a vertical or triangular cleft bounded above and behind by a firm prominence. The anterior portion of the prominence (*labium anterius*) is the smaller portion. The posterior portion (*labium posterius*) is large and thick, is called the **Eustachian cushion** (*torus tubarius*), and is caused by the inner extremity of the cartilage of the tube impinging on the deep surface of the mucous membrane (Fig. 823). A vertical fold of mucous membrane, the **salpingo-pharyngeal fold** (*plica salpingo-*

FIG. 822.—Pharyngeal tonsil in an adult. (Escat.)

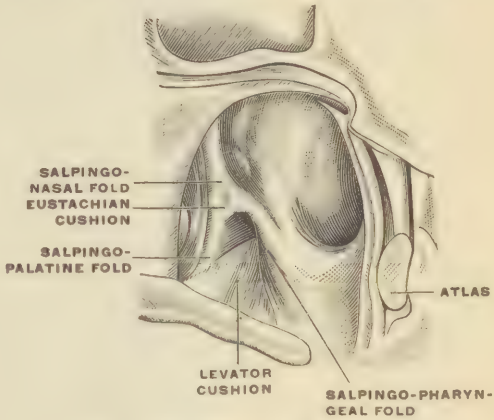

FIG. 823.—The posterior lateral cavity of the naso-pharynx. (Escat).

pharyngea) (Fig. 823), stretches from the lower part of the cushion to the pharynx; it contains the Salpingo-pharyngeus muscle. A second and smaller mucous fold may be seen stretching from the upper part of the cushion to the palate, the **salpingo-palatine fold** (*plica salpingopalatina*) (Fig. 823). Behind the orifice of the Eustachian tube is a deep recess, the **lateral recess** or **fossa of Rosenmüller** (*recessus pharyngeus*) (Fig. 823), which represents the remains of the upper part of the second **branchial cleft.** The posterior wall of the naso-pharynx is directed upward and forward, and it meets the superior wall at an angle. This rounded area of meeting is the **vault of the pharynx** (*fornix pharyngis*). On the posterior wall, at the level and above the level of the orifices of the Eustachian tubes, there is a collection of lymphoid tissue. This is particularly marked in children, and almost or quite disappears in the aged. Over it the mucous membrane is thick and in folds. This collection of lymphoid tissue is the **pharyngeal tonsil** (*tonsilla pharyngea*) (Fig. 822). The naso-pharynx communicates with the oral pharynx through an aperture between the soft palate and the posterior pharyngeal wall. This aperture is the **isthmus of the pharynx** (*isthmus pharyngonasalis*).

The Oral Part (*pars oralis pharyngis*).—The oral part of the pharynx reaches from the soft palate to the level of the hyoid bone. It opens anteriorly, through the isthmus faucium, into the mouth, while in its lateral wall, between the two

pillars of the fauces, is the tonsil. A triangular area on the lateral wall is known as the **sinus tonsillaris** (Fig. 824). It is bounded anteriorly by the anterior palatine arch, posteriorly by the posterior palatine arch, and below by the side of the pharyngeal portion of the tongue.

The Laryngeal Part (*pars laryngea pharyngis*).—The laryngeal part of the pharynx reaches from the hyoid bone to the lower border of the cricoid cartilage, where it is continuous with the oesophagus. In front it presents the triangular aperture of the larynx, the base of which is directed forward and is formed by the epiglottis, while its lateral boundaries are constituted by the aryteno-epiglottidean folds. On either side of the laryngeal orifice is a recess, termed the **sinus pyri-**

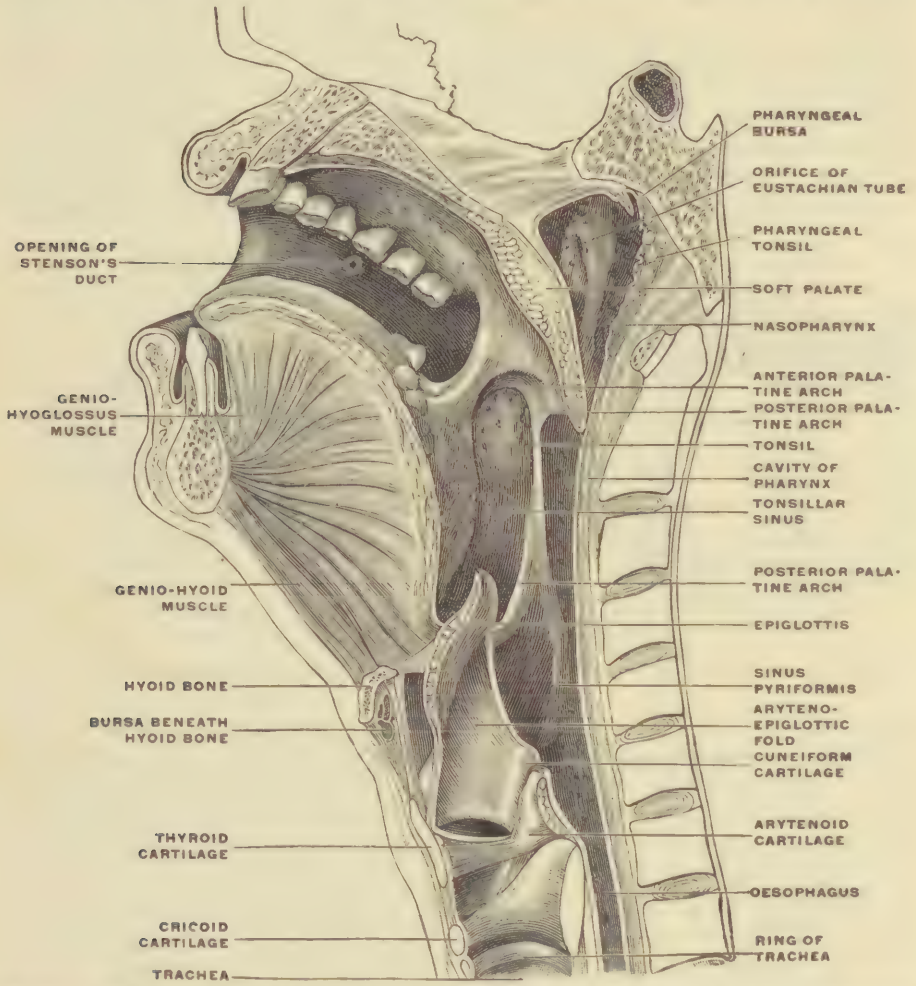

FIG. 824.—Sagittal median section of the head and neck. The head is thrown backward into complete extension, which explains the relations between the lower jaw and the hyoid bone as seen in the figure. (Luschka.)

formis (*recessus piriformis*) (Fig. 824); it is bounded internally by the aryteno-epiglottidean fold, externally by the thyroid cartilage and thyro-hyoid membrane. In the anterior part of the sinus pyriformis is a fold (*plica nervi laryngei*), which passes downward and inward. Extending outward from the epiglottis on each side is a fold, the **pharyngo-epiglottic fold** (*plica pharyngoepiglottica*). This ascends in the lateral wall of the pharynx, nearly to the posterior arch of the fauces.

Structure.—The constrictors of the pharynx (see p. 400) are surrounded by a sheath of thin fascia, the **bucco-pharyngeal fascia** (Cunningham). Forward pro-

longations of this fascia overlay the Buccinator muscles. The connective tissue of the retro-pharyngeal space joins the bucco-pharyngeal fascia to the prevertebral fascia, and it is attached by areolar tissue to the other structures to which the pharynx is in contact (Cunningham). The pharynx is composed of three coats —**fibrous, mucous** and **muscular.**

The **Pharyngeal Aponeurosis** or **Fibrous Coat** is situated between the mucous and muscular layers. It is thick above, where the muscular fibres are wanting, and is firmly connected to the periosteum of the basilar process of the occipital and petrous portion of the temporal bones. It is united to the Eustachian tube, posterior nares, and other points which the pharynx joins. It is thicker above than below, and above the sinuses of Morgagni there is no muscular coat, and the wall

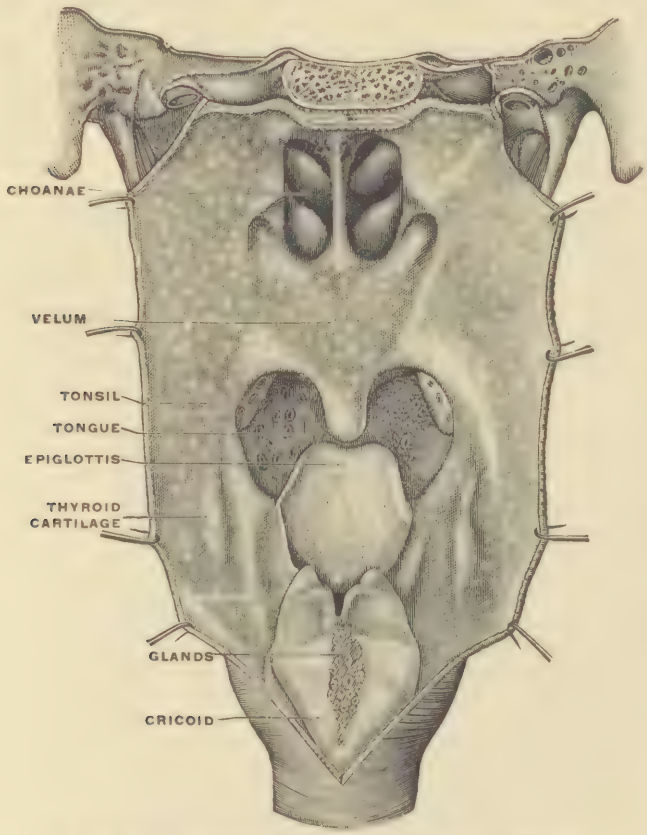

FIG. 825.—The anterior surface of the pharynx. (Sappey.)

of the pharynx is composed of aponeurosis and mucous membrane. As it descends it diminishes in thickness, and is gradually lost. It is strengthened posteriorly by a strong fibrous band which is attached above to the pharyngeal spine on the under surface of the basilar portion of the occipital bone, and passes downward, forming a **median raphé,** which gives attachment to the Constrictor muscles of the pharynx.

The Mucous Coat (*tunica mucosa*).—The mucous coat is continuous with that lining the Eustachian tubes, the nares, the mouth, and the larynx. In the nasopharynx it is covered by columnar ciliated epithelium; in the buccal and laryngeal portions the epithelium is of the squamous variety. Beneath the mucous membrane are found racemose **mucous glands** (*glandulae pharyngeae*); they are especially numerous at the upper part of the pharynx around the orifices of the Eustachian tubes. Throughout the pharynx are also numerous crypts or recesses, the walls

of which are surrounded by lymphoid tissue similar to that found in the tonsils. Across the back part of the pharyngeal cavity, between the two Eustachian tubes, a considerable mass of this tissue exists, and has been named the **pharyngeal tonsil** (Fig. 822). Above this in the middle line is an irregular, flask-shaped depression of the mucous membrane, extending up as far as the basilar process of the occipital bone. It is known as the **pharyngeal bursa** (*bursa pharyngea*), and was regarded by Luschka as the remains of the diverticulum, which is concerned in the development of the anterior lobe of the pituitary body. Other anatomists believe that it is connected with the formation of the pharyngeal tonsils. The **muscular coat** (*tunica muscularis pharyngis*) has been already described (p. 400). The **sinuses of Morgagni,** referred to on a previous page (p. 402 and Fig. 277), are intervals between the Superior constrictor muscles and the basilar process of the occipital bone.

The Lymphatic Pharyngeal Ring.—This name was applied by Waldeyer to the lymphatic structure gathered into a sort of ring about the pharynx. There are three chief collections of this tissue on each side. The first is known as the **lingual tonsil** (p. 1088); the second as the **palatine tonsil** (p. 1212); and the third as the **pharyngeal tonsil** (p. 1221).

Surgical Anatomy of the Mouth, Cheeks, Lips, Gums, Tonsils, Palate, Salivary Glands, and Pharynx.—The duct of a salivary gland may be blocked by a *calculus*, and the condition is often productive of severe pain.

A *wound* of Stenson's duct or of the parotid gland may be followed by a *salivary fistula*.

The parotid recess is completely lined by fascia, except above. "Between the anterior edge of the styloid process and the posterior border of the external pterygoid muscle there is a gap in the fascia, through which the parotid space communicates with the connective tissue about the pharynx."[1]

This explains why there is frequently swelling of the parotid region in post-pharyngeal abscess. A *parotid abscess* rarely bursts through the skin; it may pass into the temporal fossa, may enter the zygomatic fossa, may advance toward the mouth, pharynx, or neck. Because of the situation of the gland, a parotid abscess may cause inflammation of the temporo-mandibular joint or periostitis of the bone about the meatus, and may even burst into the external auditory meatus (Treves).

The facial nerve passes through the gland, and inflammation or tuberculosis of the gland may cause *facial palsy*. Some enlargements of the parotid region are due to inflammation of the parotid lymph-glands, and these glands may become *tuberculous*.

Mumps is characterized by acute inflammation of the parotid gland.

Various *tumors* occur in the parotid (fibroma, sarcoma, carcinoma, enchondroma, etc.). Most parotid tumors contain more or less cartilage. Complete extirpation of the parotid gland surgically is certainly extremely difficult, and Treves and others maintain that it is impossible.

Ranula is a salivary cyst of the floor of the mouth, due to occlusion of ducts of the sublingual gland or the duct of the submaxillary gland. *Mucous cysts* occur in the mouth. A mucous cyst of the gland of Nuhn and Blandin is on the under surface of the tongue near the apex. A *dermoid* cyst of the base of the tongue is occasionally encountered. It is of congenital origin.

What is known as the *sublingual* bursa is an epithelial-lined space, said to exist between the mucous membrane of the floor of the mouth and the Genio-hyo-glossus muscle. When acutely inflamed, it produces rapidly a marked swelling called *acute ranula*. Incomplete closure of the oral end of the thyro-glossal duct causes *thyro-glossal fistula*. If the oral end closes, but a portion of the duct below remains unobliterated, a *thyro-glossal cyst* forms. Such a cyst or fistula is always in the median line. The reader will remember that this duct runs from the foramen caecum to the isthmus of the thyroid gland.

Hare-lip is considered on pp. 110 and 111.

The lower lip, more commonly than any other structure, gives origin to *cancer*. The upper lip is not nearly so often affected. Blocking of mucous glands of the lips causes *mucous cysts*. A *scar* of the lip or about the lip disturbs this structure and pulls it far out of place. Thus great deformity is produced. *Burns* particularly induce hideous cicatricial contraction.

Plastic operations in this region are often successful, because of the great vascularity of the parts, and because adjacent parts admit of being stretched and pulled in.

Cleft palate is a by no means rare congenital deformity. The cleft is in the middle line. It may be a mere cleft of the uvula, it may be limited to the soft palate, or it may involve

[1] Applied Anatomy. By Sir Frederick Treves.

the hard palate to but not including the alveolus. It may pass through the alveolus, but if it does so it ceases to be median at this point, and follows the line of suture between the incisive bone and the superior maxillary (pp. 110 and 111). In a complete cleft palate there is apt to be *hare-lip* at the end of the palate cleft. This cleft in the lip is not median, but is at the termination of the palate cleft. If the cleft of a cleft palate runs along each side of the incisive bone, the bone is isolated from the superior maxillary. In such a case *double hare-lip* results.

When a *tonsil* enlarges it projects inward. The *deafness* which so often attends hypertrophy of the tonsil is not due to blocking of the Eustachian orifice by the tonsil, but is due to thickening of the mucous membrane lining the tube itself. The *profuse bleeding* which sometimes follows an operation for the removal of the tonsil is very seldom due to injury of the internal carotid artery, but is due to *injury of the ascending pharyngeal artery* (p. 621) or one of the palatine arteries.

The *internal carotid artery* is in close relation with the pharynx, so that its pulsations can be felt through the mouth. It has been occasionally wounded by sharp-pointed instruments introduced into the mouth and thrust through the wall of the pharynx. In *aneurism* of this vessel in the neck the tumor necessarily bulges into the pharynx, as this is the direction in which it meets with the least resistance, nothing lying between the vessel and the mucous membrane except the thin Constrictor muscle, whereas on the outer side there is the dense cervical fascia, the muscles descending from the styloid process, and the margin of the Sterno-mastoid muscle.

The mucous membrane of the pharynx is very vascular, and is often the seat of *inflammation*, frequently of a septic character, and dangerous on account of its tendency to spread to the larynx. On account of the tissue which surrounds the pharyngeal wall being loose and lax, the inflammation is liable to spread through it far and wide, extending downward into the posterior mediastinum along the oesophagus. *Abscess* may form in the connective tissue behind the pharynx, between it and the vertebral column, constituting what is known as *retro-pharyngeal abscess*. This is most commonly due to caries of the cervical vertebrae, but may also be caused by suppuration of a lymphatic gland which is situated in this position opposite the axis, and which receives lymphatics from the nares, or by *gumma* or by *acute pharyngitis*. In these cases the pus may be easily evacuated by an incision, with a guarded bistoury, through the mouth, but, for aseptic reasons, it is desirable that the abscess should be opened from the neck. In some instances this is perfectly easy; the abscess can be felt bulging at the side of the neck and merely requires an incision for its relief; but this is not always so, and then an incision should be made along the posterior border of the Sterno-mastoid and the deep fascia should be divided. A director is now to be inserted into the wound, the forefinger of the left hand being introduced into the mouth and pressure made upon the swelling. This acts as a guide, and the director is to be pushed onward until pus appears in the groove. A pair of sinus forceps are now inserted along the director and the opening into the cavity dilated.

Foreign bodies not infrequently become lodged in the pharynx and most usually at its termination at about the level of the cricoid cartilage, just beyond the reach of the finger, as the distance from the arch of the teeth to the commencement of the oesophagus is about six inches.

Hypertrophy of the adenoid tissue of the naso-pharynx produces groups of hypertrophic masses known as *adenoids*. A child with adenoids has a cough, and when awake or asleep, breathes noisily and with the mouth open. The voice is muffled, the hearing is impaired, the expression is vacant, the mind is dull, and the tonsils are enlarged.

THE OESOPHAGUS (Figs. 826, 827, 828, 829).

The oesophagus (*οἴω, οἴσω, I carry; φαγεῖν, to eat*) or **gullet** is a muscular canal, averaging about nine or ten inches in length, extending from the pharynx to the stomach. It commences at the upper border of the cricoid cartilage, opposite the intervertebral disk between the fifth and sixth cervical vertebrae descends, along the front of the spine through the posterior mediastinum, passes through the Diaphragm, and, entering the abdomen, terminates in the stomach wall at the point known as the *cardia* opposite the tenth dorsal vertebra or possibly opposite the intervertebral disk between the tenth and eleventh dorsal vertebrae. The general direction of the oesophagus is vertical, but it presents two or three slight curves in its course. At its commencement it is placed in the median line, but it inclines to the left side as far as the root of the neck, gradually passes to the middle line again, and finally again deviates to the left as it passes forward to

the oesophageal opening of the Diaphragm (*hiatus oesophageus*). The oesophagus also presents an antero-posterior flexure, corresponding to the curvature of the cervical and thoracic portions of the spine. It is the narrowest part of the alimentary canal, being most contracted at its commencement and at the point where it passes through the Diaphragm.

The diameter of the largest portion of the oesophagus where it is contracted is about half an inch; when it is fully dilated, an inch or even more.

In the **neck** the oesophagus, when at rest, is flattened, the anterior and posterior walls approaching each other. The canal in the neck is round or oval, and the lumen is stellate (Cunningham). The oesophagus is somewhat constricted at three points. One constriction is at the very beginning of the tube; another is where the left bronchus crosses it; another is at the point where the oesophagus passes through the Diaphragm. The tube at each constricted point is distinctly flattened. The diameter of each of these constricted parts is slightly under one-half inch, the diameter of the rest of the tube when contracted is one-half inch, but when dilated may reach or exceed one inch. The average distance from the upper

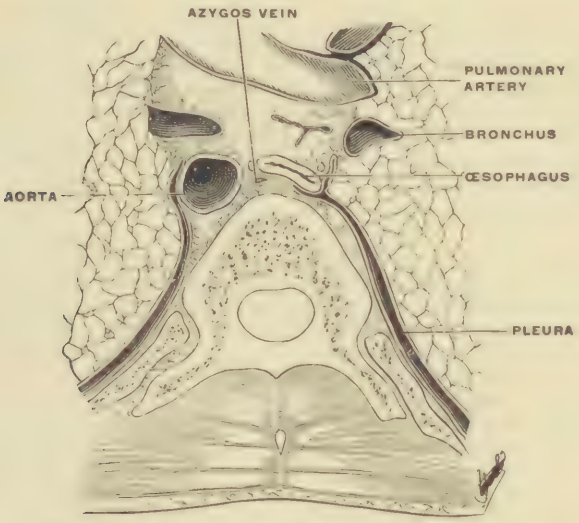

FIG. 826.—Pleural cul-de-sac of the posterior mediastinum.

incisor teeth to the beginning of the gullet is about six inches; the average distance from the incisor teeth to the cardiac opening of the stomach is fifteen or sixteen inches. The portion of the oesophagus which is in the neck is called the **cervical portion** (*pars cervicalis*); the portion in the thorax, the **thoracic portion** (*pars thoracalis*), and the portion which lies in the oesophageal opening of the Diaphragm, the **diaphragmatic portion.** The margin of the oesophageal orifice is narrow in front, thicker behind and to the sides. Behind and to the sides the diaphragmatic portion of the oesophagus is about half an inch in length. In front there is only a thin edge of Diaphragm in contact with the gullet. The oesophagus is connected to the margins of the diaphragmatic orifice by connective tissue. The so-called **abdominal portion of the oesophagus** (*pars abdominalis*) is not over half an inch in length, and is limited to the small portion of the anterior and left lateral surface observed when a stomach which is completely empty is drawn downward with considerable force. The abdominal portion of the oesophagus is covered with peritoneum; the corresponding portions of the right lateral and posterior walls are not covered by peritoneum. This uncovered portion of the oesophagus runs downward and to the left and lies directly

behind the **oesophageal groove** on the posterior surface of the left lobe of the liver, but does not actually touch the *groove*, which in reality holds the thick, right edge of the oesophageal opening of the Diaphragm. When the stomach is distended the abdominal portion of the gullet ceases to exist and becomes part of the stomach wall.

Relations.—In the **neck** the oesophagus is in relation, *in front*, with the trachea, and it is connected to the posterior wall of the trachea by areolar tissue. At the lower part of the neck, where it projects to the left side, it is in relation in front with the thyroid gland and thoracic duct; *behind*, it rests upon the vertebral column and Longi colli muscles; *on each side*, it is in relation with the common carotid artery (especially the left, as the gullet inclines to that side) and part of the lateral lobes of the thyroid gland; the recurrent laryngeal nerves ascend between it and the trachea.

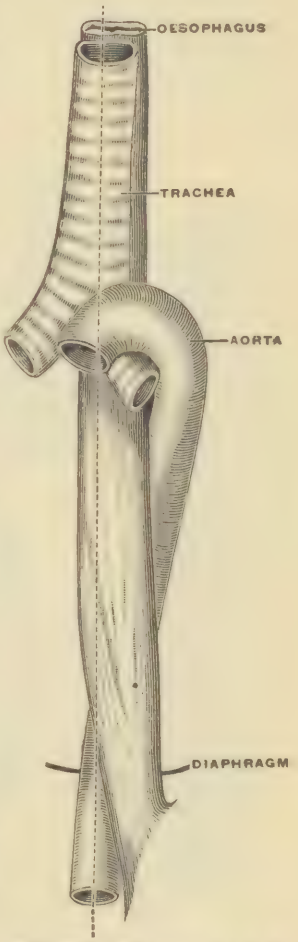

FIG. 827. - The supports of the oesophagus at the aorta in an infant. (Poirier and Charpy.)

In the thorax, it is at first situated a little to the left of the median line; it then passes behind the aortic arch, being separated from it by the trachea, and descends in the posterior mediastinum, along the right side of the aorta, nearly to the Diaphragm, where it passes in front and a little to the left of the artery, previous to entering the abdomen. It is in relation, *in front*, with the trachea, the arch of the aorta, the left common carotid and left subclavian arteries, which incline toward its left side, the left bronchus, the pericardium, and the Diaphragm; *behind*, it rests upon the vertebral column, the Longi colli muscles, the right intercostal arteries, and the vena azygos minor; and *below*, near the Diaphragm, upon the front of the aorta; *laterally*, it comes in contact with both pleurae, especially with the left pleura above and the right pleura below; it overlaps the vena azygos major, which lies on its right side, while the descending aorta is placed on its left side. The pneumogastric nerves descend in close contact with it, the right nerve passing down behind, and the left nerve in front of it, each nerve spreading out into a plexus, the **oesophageal plexus**, around the tube. The two plexuses are joined to each other. The right nerve forms the **posterior oesophageal plexus** (*plexus oesophageus posterior*); the left nerve the **anterior oesophageal plexus** (*plexus oesophageus anterior*).

In the lower part of the posterior mediastinum the thoracic duct lies to the right side of the oesophagus; higher up, it is placed behind it, and, crossing about the level of the fourth dorsal vertebra, is continued upward on its left side.

Above the aortic arch and the arch of the great azygos vein above the root of the right lung, the pleurae are close to but not in actual contact with the oesophagus.

Below the arch of the great azygos vein the right side of the oesophagus is covered with pleura nearly to the diaphragmatic opening. The posterior surface of the gullet also may be covered with pleura. Below the arch of the aorta on the left side the pleura covers only a small portion of the oesophagus, that is, a portion of the left wall, a little above the diaphragmatic opening.

Anomalies.—There may be openings of the oesophagus into the trachea. A **diverticulum** or **pressure pouch** may exist. Such a pouch is usually placed upon the posterior wall near the pharynx. There may be congenital constriction, tubular or annular.

Structure.—The oesophagus is fastened to adjacent structures by connective tissue called the **tunica adventitia**. The tube has three coats—an **external** or **muscular**, a **middle** or **areolar**, and an **internal** or **mucous coat**.

The Muscular Coat (*tunica muscularis*).—The muscular coat is composed of two planes of fibres of considerable thickness, an **external plane of longitudinal** and an **internal plane of circular fibres**.

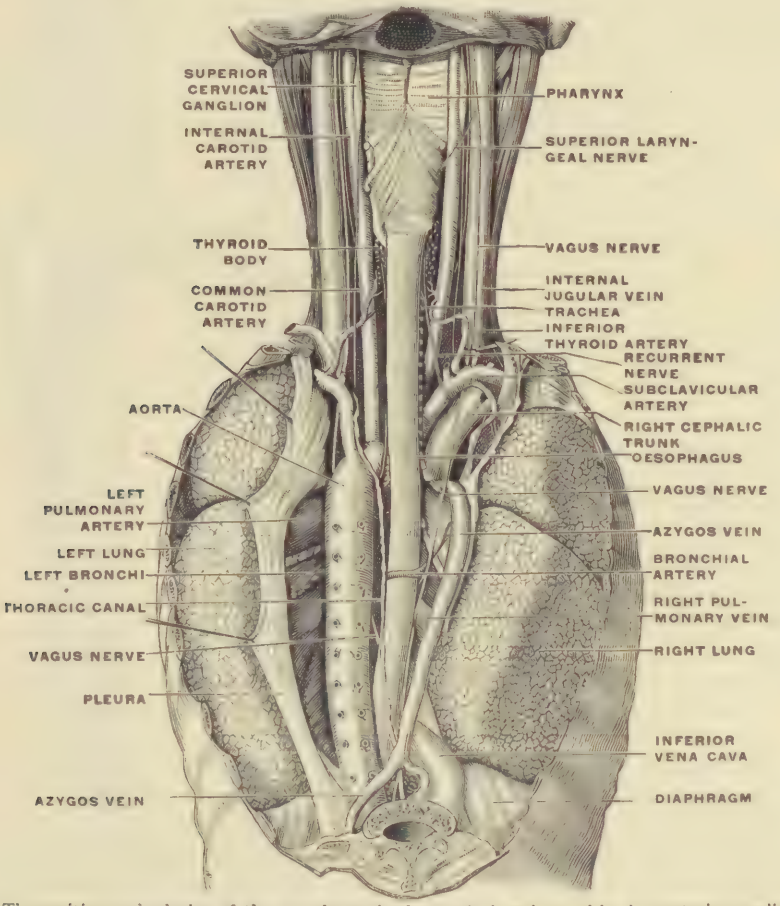

FIG. 828.—The position and relation of the oesophagus in the cervical region and in the posterior mediastinum. Seen from behind. (Poirier and Charpy.)

The **Longitudinal Fibres** are arranged, at the commencement of the tube, in three fasciculi: one in front, which is attached to the vertical ridge on the posterior surface of the cricoid cartilage; and one at each side, which is continuous with the fibres of the Inferior constrictor of the pharynx; as they descend they blend together and form a uniform layer, which covers the outer surface of the tube.

Accessory slips of muscular fibres are described by Cunningham as passing between the oesophagus and the left pleura (*m. pleurooesophageus*), where it covers the thoracic aorta, or between the oesophagus and the root of the left bronchus (*m. bronchooesophageus*), or the back of the pericardium, as well as other still more

rare accessory fibres. In Fig. 829, taken from a dissection in the Museum of the Royal College of Surgeons of England, several of these accessory slips may be seen passing from the oesophagus to the pleura, and two slips passing to the back of the trachea just above its bifurcation. These slips of muscular fibres which pass to adjacent structures give support to the oesophagus. Below, the longitudinal fibres of the oesophagus are continued into the longitudinal fibres of the stomach.

The **Circular Fibres** are continuous above with the Inferior constrictor of the pharynx; their direction is transverse at the upper and lower parts of the tube, but oblique in the central part. Below, the circular fibres pass into the circular and oblique fibres of the stomach.

The muscular fibres in the upper part of the oesophagus are of a red color, and consist chiefly of the striped variety, but below they consist for the most part of involuntary muscular fibre. At the cardia they act as a sphincter to solid food. Some maintain that this sphincter is closed *tonically*, others that it opens and closes rhythmically during gastric digestion.

The Submucous or Areolar Coat (*tela submucosa*).—The submucous or areolar coat connects loosely the mucous and muscular coats. It consists of dense connective tissue and contains blood-vessels, nerves, and **oesophageal glands** (*glandulae oesophageae*). The glands are mucous glands and are found throughout the length of the gullet. The ducts of the glands pass through the muscularis mucosae. These ducts are surrounded by adenoid tissue.

The Mucous Coat (*tunica mucosa*).—The mucous coat is thick, of a reddish color above and pale below. It is disposed in longitudinal folds, which disappear on distention of the tube. Its surface is studded with minute papillae, and is covered throughout with a thick layer of stratified pavement epithelium. The mucous coat contains glands which differ from the mucous glands of the submucous tissue. They are branched and tubular (Hewlett) and are called the **superficial glands**. There are two chief groups of superficial glands; one near the beginning, and the other near the termination of the oesophagus. The ducts of the superficial glands are not surrounded by lymphoid tissue (Hewlett). Beneath the mucous membrane, between it and the submucous coat, is a layer of longitudinally arranged non-striped muscular fibres. This is the **muscularis mucosae** (*lamina muscularis mucosae*). At the commencement it is absent, or only represented by a few scattered bundles; lower down it forms a considerable stratum.

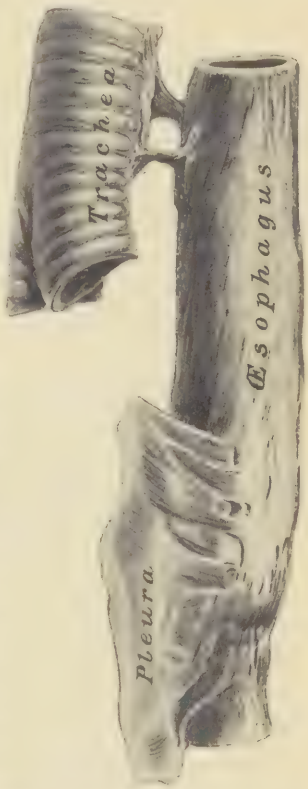

FIG. 829. - Accessory muscular fibres between the oesophagus and pleura, and oesophagus and trachea. (From a preparation in the Museum of the Royal College of Surgeons of England.)

Vessels of the Oesophagus.—The larger vessels are in the submucosa and send branches to the mucosa and muscularis. The **arteries** supplying the oesophagus are derived from the **inferior thyroid branch of the thyroid axis of the subclavian**, from the **descending thoracic aorta** and the **bronchial arteries**, and from the **gastric branch of the cœliac axis**, and from the **left inferior phrenic of the abdominal aorta**. They have for the most part a longitudinal direction. The **veins** are gathered into a plexus on the outer surface of the oesophagus. This plexus receives the venous blood from the walls of the tube. From the lower portion of the plexus branches go to the **coronary vein of the stomach**. Higher up branches go to the **azygos veins**

and **thyroid veins**. In this manner a communication is opened between the portal veins and the systemic veins.

Lymphatics of the Oesophagus.—The lymphatics drain into the inferior deep cervical glands and the glands of the posterior mediastinum.

Nerves of the Oesophagus.—The nerves are derived from the **pneumogastric** and from the **sympathetic**; they form a plexus in which are groups of ganglion-cells between the two layers of the muscular coats. From this fibres pass to supply the muscle, and others go to the submucous tissue to form a secondary plexus. It is usual to regard the plexus as consisting of two parts, an **anterior oesophageal plexus,** derived from the left pneumogastric, and a **posterior oesophageal plexus,** derived from the right pneumogastric. These two plexuses are in the posterior mediastinum; they communicate with each other and contain sympathetic fibres.

Movements and Innervation of the Oesophagus.

Movements. -When liquid is swallowed it is, as pointed out by Kronecker and Meltzer, suddenly forced into the gullet by the contraction of the Mylo-hyoid muscle, the tube playing a practically passive part.[1] In the passage of solid and semisolid food the oesophagus contracts. It does not contract, as was once thought, in sections, but there is a peristaltic wave. "The wave at a given point lasts in the neck region about 3.5 seconds, and from five to nine seconds in the thoracic region.[2] The lower end of the oesophagus or cardia has a sphincter, the cardiac sphincter. It is usually taught that this sphincter is tonically contracted. When a mouthful of food is swallowed it rests above the sphincter for a moment and is then forced through by muscular contractions (Kronecker and Meltzer). If several acts of swallowing follow each other rapidly the sphincter relaxes so that there is no resistance to the passage of food. In cats Dr. Walter B. Cannon[3] has demonstrated "rhythmical relaxations of the cardia, so that fluid food streams from the stomach into the oesophagus even above the level of the heart, then is pressed into the stomach again by a peristaltic wave, only to be released a moment later to pour into the oesophagus anew."

Innervation. -There is in the oesophagus a local reflex, but peristalsis is dominated by the central nervous system. "It seems probable that the peristaltic contractions of the oesophagus, to be efficient, must be supported by nervous influences from outside. In this respect the oesophagus is different from the remainder of the alimentary canal."[4]

Surgical Anatomy. -The relations of the oesophagus are of considerable practical interest to the surgeon, as he is frequently required, in cases of *stricture* of this tube, to dilate the canal by a bougie, when it is of importance that the direction of the oesophagus and its relations to surrounding parts should be remembered. In cases of *malignant disease* of the oesophagus, where its tissues have become softened from infiltration of the morbid deposit, the greatest care is requisite in directing the bougie through the strictured part, as a false passage may easily be made, and the instrument may pass into the mediastinum, or into one or the other pleural cavity, or even into the pericardium.

The student should also remember that obstruction of the oesophagus, and consequent symptoms of stricture, are occasionally produced by *aneurism* of some part of the aorta pressing upon the tube. In such a case the passage of a bougie could only hasten the fatal issue.

In passing a bougie the left forefinger should be introduced into the mouth and the epiglottis felt for, care being taken not to throw the head too far backward. The bougie is then to be passed beyond the finger until it touches the posterior wall of the pharynx. The patient is now asked to swallow, and at the moment of swallowing the bougie is passed gently downward, all violence being carefully avoided.

It occasionally happens that a *foreign body* becomes impacted in the oesophagus and can neither be brought upward nor moved downward. When all ordinary means for its removal have failed, and the body is lodged above the lower one-third of the gullet, external *oesophagotomy* is performed. If the foreign body is lodged in the lower one-third of the gullet the stomach is opened (*gastrotomy*) and the foreign body is extracted. If the foreign body is allowed to remain lodged in the oesophagus, extensive inflammation and ulceration may ensue. In one case the foreign body ultimately penetrated the intervertebral substance, and destroyed life by inflammation of the membranes and substance of the cord.

The operation of *oesophagotomy* is thus performed: The patient being placed upon his back, with the head and shoulders slightly elevated, an incision, about four inches in length,

[1] Recent Advances in the Knowledge of the Movements and Innervation of the Alimentary Canal. By Walter B. Cannon, M.D., in Medical News, May 20, 1905.
[2] Ibid. [3] Ibid. [4] Ibid.

should be made on the left side of the trachea, from the thyroid cartilage downward, dividing the skin, Platysma, and deep fascia. The edges of the wound being separated, the Omo-hyoid muscle should, if necessary, be divided, and the fibres of the Sterno-hyoid and Sterno-thyroid muscles drawn inward; the sheath of the carotid vessels, being exposed, must be drawn outward, and retained in that position by retractors: the oesophagus will now be exposed, and should be divided over the foreign body, which can then be removed. Great care is necessary to avoid wounding the thyroid vessels, the thyroid gland, and the laryngeal nerves.

The oesophagus may be obstructed not only by foreign bodies, but also by changes in its coats, producing *stricture*, or by pressure on it from without of *new-growths* or *aneurism*, etc.

The different forms of *stricture* are: (1) the *spasmodic*, occurring in neurotic individuals, and intermittent in character, so that the dysphagia is not constant. Spasmodic stricture of the oesophagus sometimes occurs in cases of cancer of the stomach and cancer of the liver; (2) *fibrous*, due to cicatrization after injuries, such as swallowing corrosive fluids or boiling water; and (3) *malignant*, usually epitheliomatous, in its nature. Cancer is most common either at the upper end of the tube, opposite to the cricoid cartilage, or at its lower end at the cardiac orifice. Cicatricial stricture may be treated by gradual dilatation. If a stricture is impassible from above, the stomach may be opened, an instrument passed from below, and a string used to divide the stricture.

The operation of *oesophagostomy* has occasionally been performed in cases where the stricture in the oesophagus is at the upper part, with a view to making a permanent opening below the stricture through which to feed the patient, but the operation has been far from a successful one, and the risk of setting up diffuse inflammation in the loose planes of connective tissue deep in the neck is so great that it would appear to be better, if any operative interference is undertaken, with the idea of forming a mouth to introduce food, to perform *gastrostomy*. The operation of *oesophagostomy* is performed in the same manner as oesophagotomy, but the edges of the opening in the oesophagus are stitched to the skin incision. Gastrostomy is the only operation to be thought of in malignant stricture.

THE ABDOMEN.

The abdomen (from *abdo*, I put away or hide, or possibly from *adeps*, fat) is the largest cavity in the body. It is of an oval form, the extremities of the oval being directed upward and downward; the upper one being formed by the under surface of the Diaphragm, the lower by the upper concave surface of the Levator ani muscles. In order to facilitate description, it is artificially divided into two parts: an upper and larger part, the **abdomen proper**; and a lower and smaller part, the **pelvis.** These two cavities are not separated from each other, but the limit between them is marked by the brim of the true pelvis. The space is wider above than below, and measures more in the vertical than in the transverse diameter.

The abdomen proper differs from the other great cavities of the body in being bounded for the most part by muscles and fasciae, so that it can vary in capacity and shape according to the condition of the viscera which it contains; but, in addition to this, the abdomen varies in form and extent with age and sex (Fig. 831). In the adult male, with moderate distention of the viscera, it is oval or barrel-shaped, but at the same time flattened from before backward. In the adult female, with a fully developed pelvis, it is conical with the apex above, and in young children it is conical with the apex below.

Boundaries.—The boundary between the thorax and abdomen is the Diaphragm. This muscle forms a dome over the abdomen, and the cavity extends high into the bony thorax, reaching to the level of the junction of the fourth costal cartilages with the sternum. The lower end of the abdomen is limited by the structures which clothe the inner surface of the bony pelvis, principally the Levatores ani and Coccygei muscles on either side. These muscles are sometimes termed the **Diaphragm of the pelvis.** The abdomen proper is bounded *in front* and *at the sides* by the lower ribs, the abdominal muscles, and the venter ilii; *behind*, by the vertebral column and the Psoas and Quadratus lumborum muscles; *above*, by the Diaphragm; *below*, by the brim of the pelvis. The muscles forming the

boundaries of the cavity are lined upon their inner surface by a layer of fascia, differently named, according to the part which it covers.

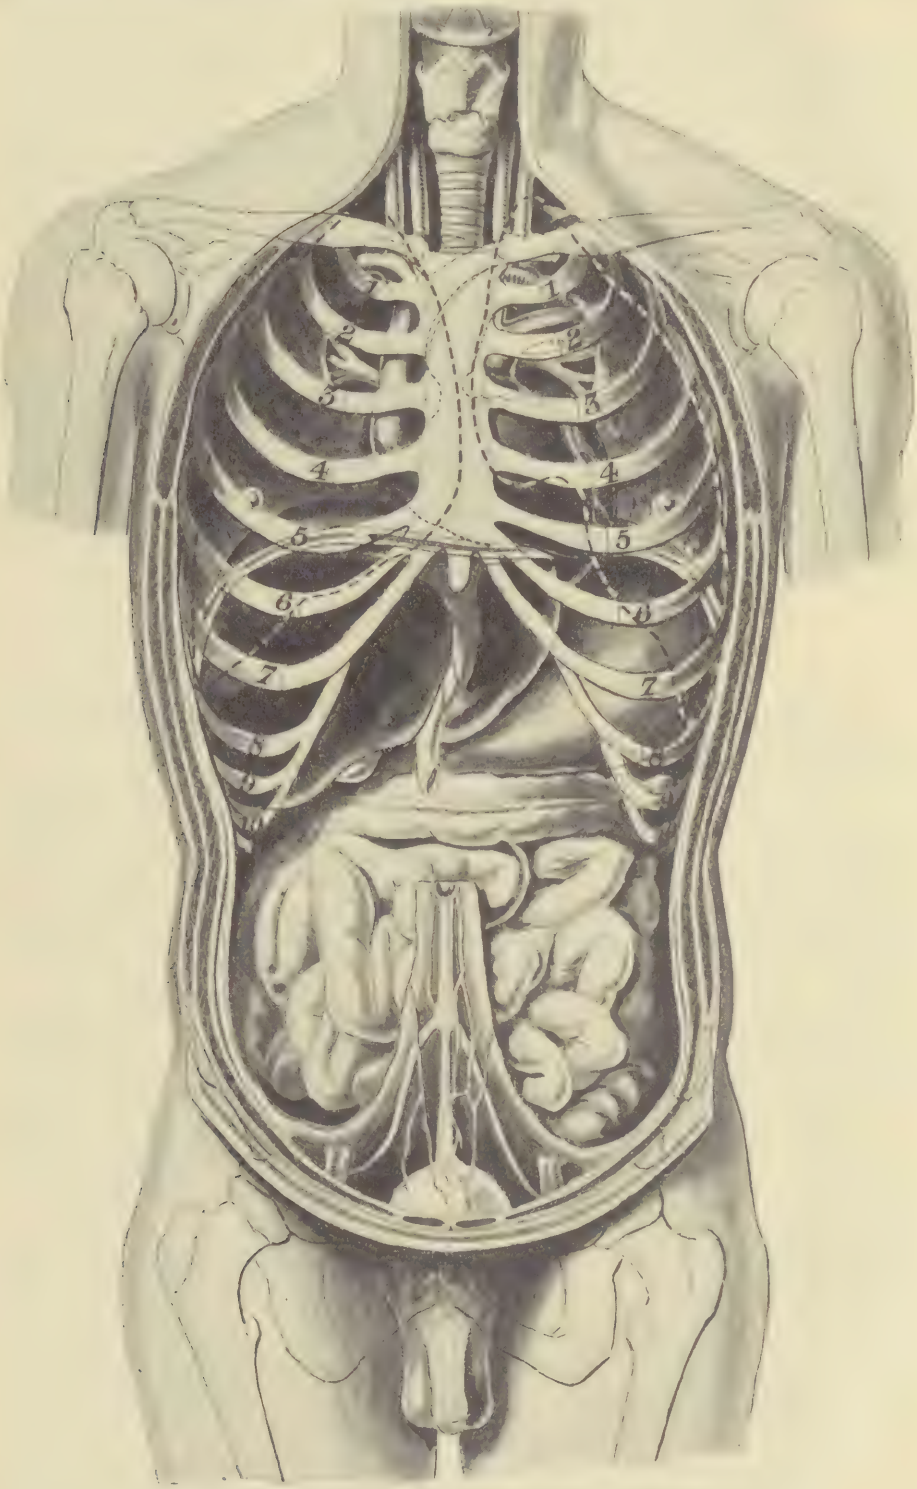

FIG. 830.—Topography of thoracic and abdominal viscera.

The abdomen contains (Fig. 830) the greater part of the alimentary canal; some of the accessory organs to digestion—viz., the liver and pancreas, the spleen, the kidneys, and suprarenal capsules. Most of these structures, as well as the wall of the cavity in which they are contained, are covered by an extensive and complicated serous membrane, the **peritoneum** (Fig. 853.)

The Apertures in the Walls of the Abdomen.—The apertures found in the walls of the abdomen, for the transmission of structures to or from it, are the **umbilicus**, for the transmission (in the fœtus) of the umbilical vessels; the **caval opening** in the Diaphragm, for the transmission of the inferior vena cava; the **aortic opening**, for the passage of the aorta, vena azygos major, and thoracic duct; and the **oesophageal opening**, for the oesophagus and pneumogastric nerves. *Below*, there are two apertures on each side: one for the passage of the femoral vessels, and the other for the transmission of the spermatic cord in the male, and the round ligament in the female.

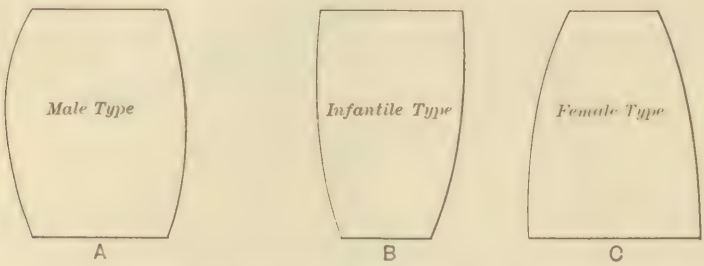

FIG. 831.—Schematic outlines of the abdomen.

Regions (Fig. 832).—For convenience of description of the viscera, as well as of reference to the morbid conditions of the contained parts, the abdomen is artificially divided into nine regions. Thus, if two circular lines are drawn around the body, the one through the extremities of the ninth ribs where they join their costal cartilages, and the other through the highest points of the crests of the ilia, the abdominal cavity is divided into three zones—an upper, a middle, and a lower. If two parallel lines are drawn perpendicularly upward from the centre of Poupart's ligament, each of these zones is subdivided into three parts—a middle and two lateral.[1]

The middle region of the upper zone is called the **epigastric** (*ἐπί, over; γαστήρ, the stomach*); and the two lateral regions, the **right** and **left hypochondriac** (*ὑπο, under; χονδροι, the cartilages*). The central region of the middle zone is the **mesogastric** or **umbilical**; and the two lateral regions, the **right** and **left lumbar**. The middle region of the lower zone is the **hypogastric** or **pubic region**; and the lateral regions are the **right** and **left inguinal** or **iliac**. The viscera contained in these different regions are the following (Fig. 832):

[1] Anatomists are far from agreed as to the best method of subdividing the abdominal cavity. Cunningham suggests that the lower line should encircle the body on a level with the highest point of the iliac crest, as seen from the front—a point corresponding with a prominent tubercle on the outer lip of the iliac crest about two inches behind the anterior superior spine. Addison (Journal of Anatomy and Physiology, vols. xxxiv. and xxxv.), in a careful analysis of the abdominal viscera in forty subjects, adopts the following lines: (1) a median, from the symphysis pubis to the ensiform cartilage; (2) two lateral lines drawn vertically through a point midway between the anterior superior iliac spine and the symphysis pubis; (3) an upper transverse line half-way between the symphysis pubis and the suprasternal notch; and (4) a lower transverse line midway between the last and the upper border of the symphysis pubis.—ED. of 15th English edition.

Joessel draws a line through the cartilaginous ends of the tenth ribs: a line through the two anterior superior spines of the ilia. On each side he carries a perpendicular line from the iliopectineal eminence to the horizontal line connecting the tenth ribs. By this plan the highest plane is subcostal.

Right Hypochondriac.	*Epigastric Region.*	*Left Hypochondriac.*
The greater part of the right lobe of the liver, the hepatic flexure of the colon, and part of the right kidney.	The greater part of the stomach, including both cardiac and pyloric orifices, the left lobe and part of the right lobe of the liver and the gall-bladder, the pancreas, the duodenum, the suprarenal capsules, and parts of the kidneys.	The fundus of the stomach, the spleen, the extremity of the pancreas, the splenic flexure of the colon, and part of the left kidney.
Right Lumbar.	*Umbilical Region.*	*Left Lumbar.*
Ascending colon, part of the right kidney, and some convolutions of the small intestines.	The transverse colon, part of the great omentum and mesentery, transverse part of the duodenum, and some convolutions of the jejunum and ileum, and part of both kidneys.	Descending colon, part of the omentum, part of the left kidney, and some convolutions of the small intestines.
Right Inguinal or Iliac.	*Hypogastric Region.*	*Left Inguinal or Iliac.*
The caecum and vermiform appendix and a portion of the ascending colon.	Convolutions of the small intestines, the bladder in children, and in adults if distended, and the uterus during pregnancy.	Sigmoid flexure of the colon and a portion of the descending colon.

If the anterior abdominal wall is reflected in the form of four triangular flaps by means of vertical and transverse incisions—the former from the ensiform cartilage to the symphysis pubis, the latter from flank to flank at the level of the umbilicus—the abdominal or peritoneal cavity is freely opened into and the contained viscera are in part exposed.[1]

Above and to the right side is the **liver,** situated chiefly under the shelter of the right ribs and their cartilages, but extending across the middle line, and reaching for some distance below the level of the ensiform cartilage. Below and to the left of the liver is the **stomach,** from the lower border of which an apron-like fold of peritoneum, the **great omentum,** descends for a varying distance, and obscures, to a greater or lesser extent, the other viscera (Fig. 861). Below it, however, some of the coils of the **small intestine** can generally be seen, while in the right and left iliac regions respectively the **caecum** and the **sigmoid flexure** of the colon are exposed. The **bladder** occupies the anterior part of the pelvis, and, if distended, will project above the symphysis pubis; the **rectum** lies in the concavity of the sacrum, but is usually obscured by the coils of the small intestine.

If the stomach is followed from left to right it will be found to be continuous with the first part of the small intestine, or **duodenum,** the point of continuity being marked by a thickened ring which indicates the position of the **pyloric valve.** The duodenum passes toward the under surface of the liver, and then, curving downward, is lost to sight. If, however, the great omentum be thrown upward

[1] It must be borne in mind that, although the term abdominal cavity is used, there is, under normal conditions, only a potential cavity or lymph-space, since the viscera are everywhere in contact with the parietes.—Ed. of 15th English edition.

over the chest, the terminal part of the duodenum will be observed passing across the spine toward the left side, where it becomes continuous with the **coils of the small intestine.** These measure some twenty feet in length, and if followed downward will be seen to end in the right iliac fossa by opening into the **caecum,** the commencement of the **large intestine.** From the caecum the large intestine takes an arched course, passing at first upward on the right side, then across the middle line and downward on the left side, and forming respectively the **ascending, transverse,** and **descending parts of the colon.** In the left iliac region it makes still another bend, the **sigmoid flexure,** and then follows the curve of the sacrum as far as the **rectum.**

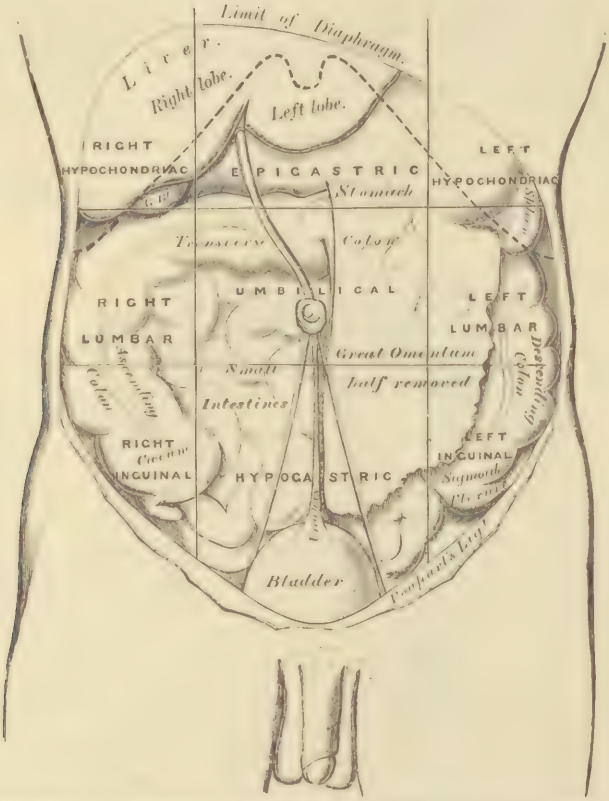

FIG. 832.—The regions of the abdomen and their contents. Edge of costal cartilages in dotted outline.

The **spleen** lies behind the stomach in the left hypochondriac region, and may be in part exposed by pulling the stomach over toward the right side.

The glistening appearance of the deep surface of the abdominal wall and of the exposed viscera is due to the fact that the former is lined and the latter more or less completely covered by a serous membrane, the **peritoneum.**

Development of the Alimentary Canal, Viscera and Peritoneum.—When the paraxial mesoblast of the embryo has developed a series of transverse segmentations it becomes converted into a row of dark, square segments known as the **protovertebrae** or the **mesoblastic somites,** which are separated by clear, transverse intervals. They appear first in the region that is to become the neck, and from there extend back along the entire length of the trunk. These bodies are not solely the representatives of the future permanent vertebrae, but differentiate partly into muscles and true skin.

On each side of the protovertebrae the lateral mesoblast splits into two layers.

The upper layer is applied to the epiblast, and forms with it the **somatopleure** or body-wall. The lower layer becomes adherent to the hypoblast, and forms the **splanchnopleure** or wall of the alimentary canal. The space between these two layers is the **caelom** or the **pleuroperitoneal cavity**. This body-cavity is of large size in the early stages of the development of the embryo.

Anteriorly—or, if the body is in the erect posture, superiorly—there is developed a comparatively large space called the **pericardiothoracic cavity**; and a transverse fold develops, which marks off this cavity from the future abdominal cavity. This fold, with many veins of large size, develops into the primary Diaphragm, although its dorsal part remains incomplete. The dorsal part is completed at a later period, constituting the Diaphragm as we see it in the adult. As Dr. Frederick J. Brockway expresses it: "The Diaphragm is thus made up of a ventral, younger part, and a dorsal, older part. When this posterior part fails to develop, there is opportunity for a congenital diaphragmatic hernia to be present."

The pericardiothoracic cavity becomes divided into three cavities, and the two lateral ones are for a time continuous with the abdominal cavity. This continuation is, however, but temporary, and they are afterward separated. In this manner, four large serous sacs are formed. The two **lateral thoracic sacs** are known as

FIG. 833. (From Quain's Anatomy, Allen Thomson.)

the **pleural sacs**, and are lined with the pleura; the **median thoracic sac** is the **pericardial sac**, and is lined with the pericardium; and the **abdominal sac** forms the abdominal cavity, and is lined with the peritoneum.

The primitive alimentary canal, which was formed early by the closure within the embryo of a portion of the blastodermic vesicle, consists of three parts: first, the **fore-gut**, within the cephalic flexure, dorsal to the heart; second, the **mid-gut**, opening freely into the yolk-sac; and third, the **hind-gut**, within the caudal flexure. In the fore-gut are developed the back portion of the mouth, the tongue, the pharynx, the oesophagus, the stomach, the larger part of the duodenum, and the organs that have grown out from these structures. The hind-gut forms a portion of the colon and the rectum, with the exception of the latter's anal end; and the mid-gut gives rise to the remainder of the digestive tube.

Development of the Alimentary Canal.—The fore-gut and hind-gut end blindly, there being at first neither mouth nor anus (Figs. 833 and 834). The upper part of the fore-gut becomes dilated to form the pharynx, in relation to which the branchial arches are developed (Fig. 836); the succeeding part remains tubular, and with the descent of the stomach is elongated to form the oesophagus. Soon a fusiform dilatation, the future stomach, makes its appearance, and beyond this the mid-gut opens freely into the yolk-sac (Figs. 836 and 837).

This opening is at first wide, but, as the body-walls close in around the umbilicus, it is gradually narrowed into a tubular stalk, the **yolk-stalk** or **vitello-intestinal duct**.

At this stage, therefore, the alimentary canal forms a nearly straight tube in front of the notochord and primitive aorta (Fig. 834). From the stomach to the rectum

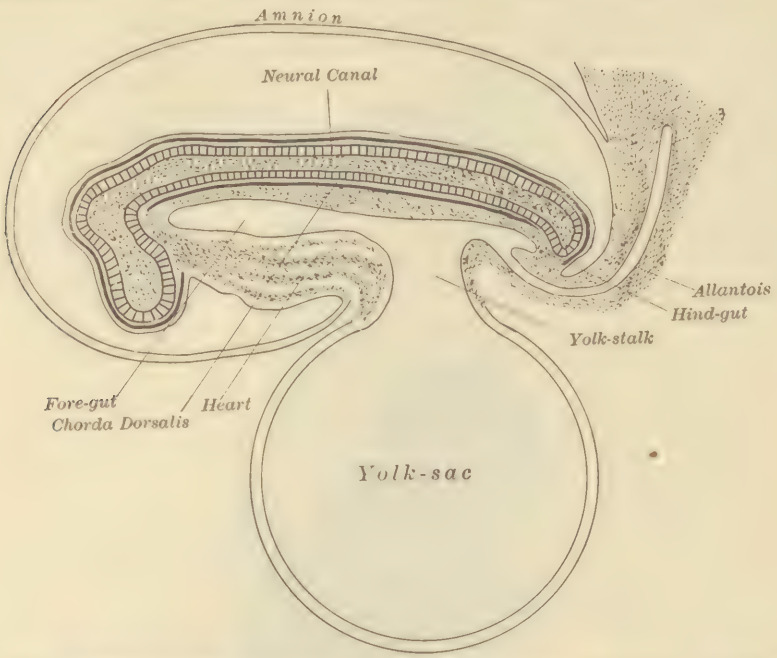

FIG. 834.—Diagram of a longitudinal section of a mammalian embryo. Very early. (After Quain.)

it is attached to the notochord by a band of mesoblast, from which the common mesentery of the gut is subsequently developed. The stomach undergoes a further dilatation, and its two curvatures can be recognized (Figs. 838 and 841), the greater directed toward the vertebral column and the lesser toward the anterior wall of the abdomen, while of its two surfaces one looks to the right and the other to the left. The mid-gut also undergoes great elongation, and forms a V-shaped loop which projects downward and forward; from the bend or angle of the loop the vitello-intestinal duct passes to the umbilicus (Fig. 841). For a time a part of the loop extends beyond the abdominal cavity into the umbilical cord, but by the end of the third month this is withdrawn. With the lengthening of the tube, the mesoblast, which attaches it to the future vertebral column and which carries the blood-vessels for the supply of the gut, is thinned and drawn out to form the **primitive** or **common mesentery**. The portion of this mesentery which is attached to the greater curvature of the stomach is named the **mesogastrium**, and the parts which suspend

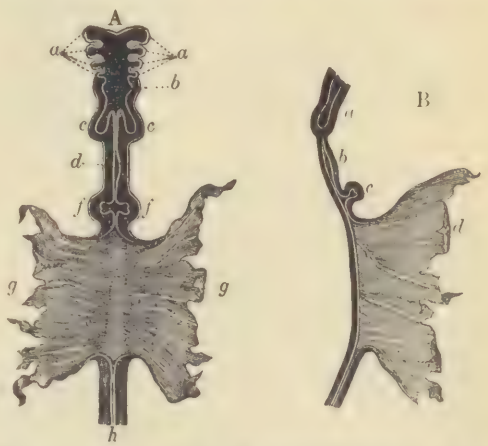

FIG. 835. Early form of the alimentary canal. In *A* a front view and in *B* an antero-posterior section are represented. *a*. Four pharyngeal or visceral plates. *b*. The pharynx. *c, c*. the colon and rectum are respectively termed the **mesocolon** and **mesorectum** (Fig. 841). About the sixth week a lateral diverticulum makes its appearance a short distance beyond the vitello-intestinal duct, and indicates the future cæcum or boundary between the small and the large intestine. This cæcal diverticulum has at first a uniform calibre, but its blind extremity remains rudimentary and forms the vermiform appendix (Figs. 841 and 842). Changes also take place in the position and direction of the stomach. It falls over on to its right surface, which henceforth is directed backward, while its original left surface looks forward; further, its greater curvature is drawn downward and to the left, away from the vertebral column, while its lesser curvature is directed upward, and the commencement of the duodenum is pushed over to the right side of the middle line. The mesogastrium, being attached to the greater curvature, must necessarily follow its movements, and hence it becomes greatly elongated and drawn outward

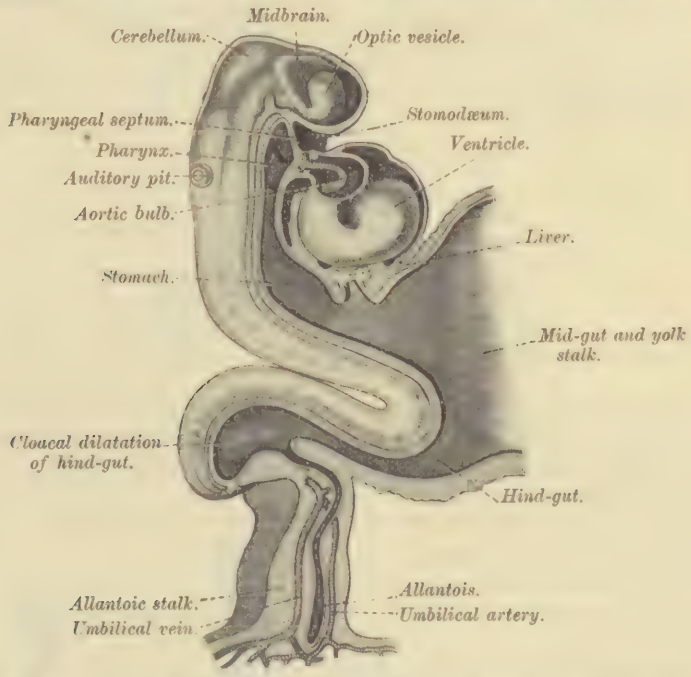

FIG. 836.—Human embryo, about fifteen days old. Brain and heart represented from right side; alimentary canal and yolk-sac in mesial section. (After His.)

from the vertebral column, and, like the stomach, what was originally its right surface is now directed backward and its left forward. In this way a pouch, the **bursa omentalis**, is formed behind the stomach; this pouch is the future lesser sac of the peritoneum, and it increases in size as the alimentary tube undergoes further development; the entrance to the pouch constitutes the future **foramen of Winslow** (Figs. 838, 842, and 845). The remainder of the mid-gut becomes greatly increased in length, so that the tube is coiled on itself, and this increase in length demands a corresponding increase in the width of the intestinal attachment of the mesentery, so that it becomes plaited or folded.

At this stage the small and the large intestines are attached to the vertebral column by a common mesentery, the coils of the small intestine falling to the right of the middle line, while the large intestine lies on the left side.[1]

[1] Sometimes this condition persists throughout life, and it is then found that the duodenum does not cross from the right to the left side of the vertebral column, but lies entirely on the right side of the mesial plane, where it is continued into the jejunum; the arteries to the small intestine (rami intestini tenuis) also arise from the right instead of the left side of the superior mesenteric artery.

The gut now becomes rotated upon itself, so that the large intestine is carried over in front of the small intestine, and the caecum is placed immediately below

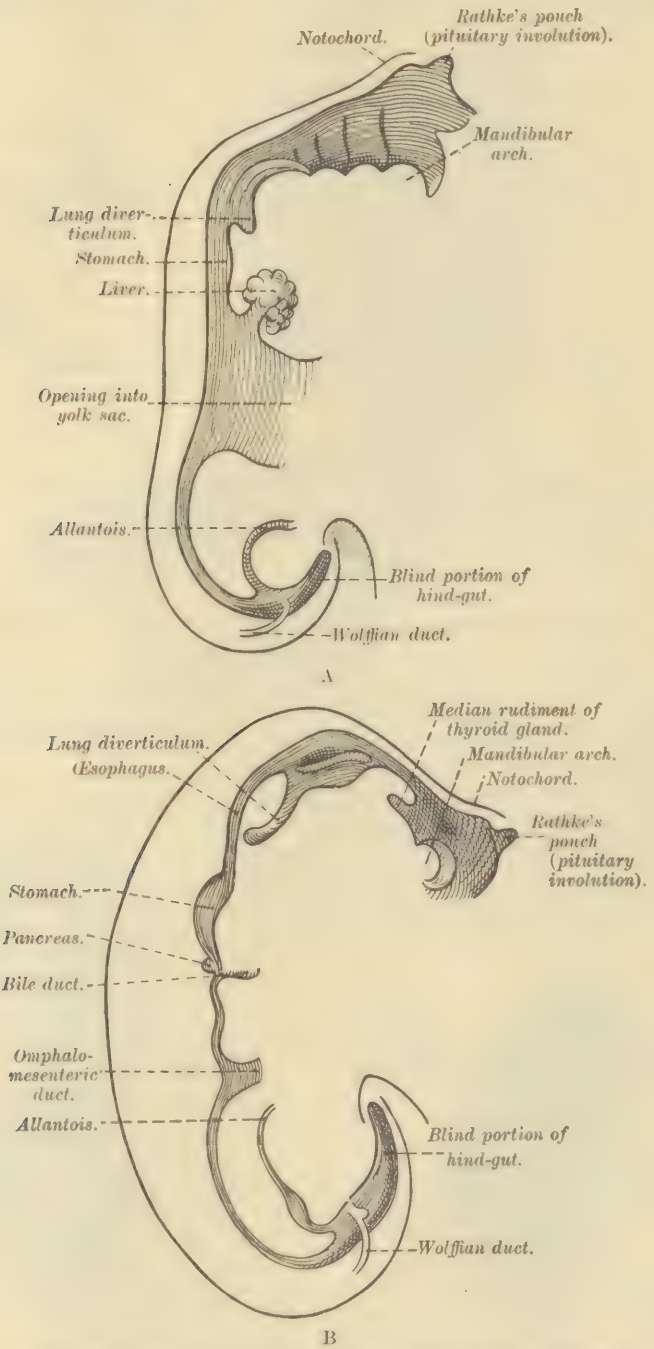

Fig. 837.—Sketches in profile of two stages in the development of the human alimentary canal. Fig. A × 30. Fig. B × 20. (His.)

the liver; about the sixth month the caecum descends into the right iliac fossa, and the large intestine now forms an arch consisting of the ascending, transverse, and descending portions of the colon—the transverse portion crossing in front

of the duodenum and lying just below the greater curvature of the stomach; within this arch the coils of the small intestine are disposed (Fig. 842). Sometimes the downward progress of the caecum is arrested, so that in the adult it may be found lying immediately below the liver instead of in the right iliac region.

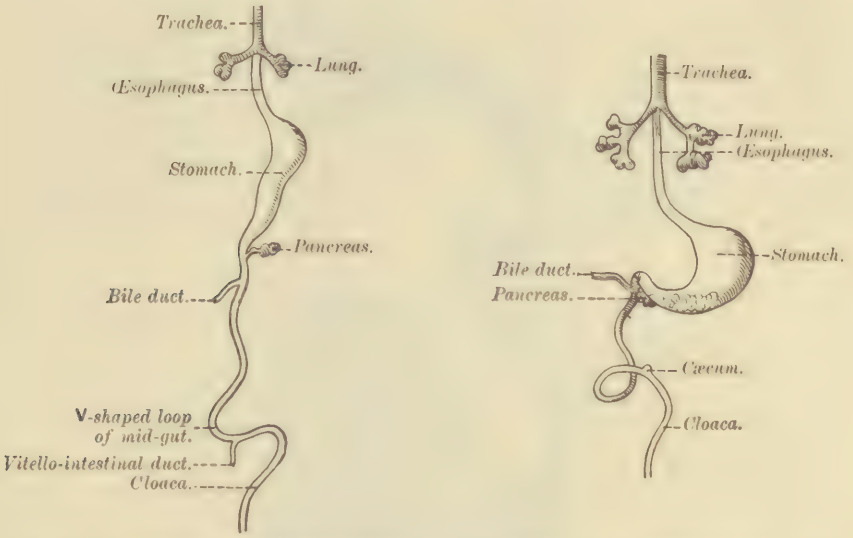

Fig. 838.—Front view of two successive stages in the development of the alimentary canal. (His.)

Further changes take place in the bursa omentalis and in the common mesentery, and give rise to the peritoneal relations seen in the adult. The bursa omentalis, which at first reaches only as far as the greater curvature of the stomach, grows downward to form the great omentum, and this downward extension lies in front of the transverse colon and the coils of the small intestine. The anterior layer of the transverse mesocolon is at first quite distinct from the posterior wall of the bursa omentalis, but ultimately

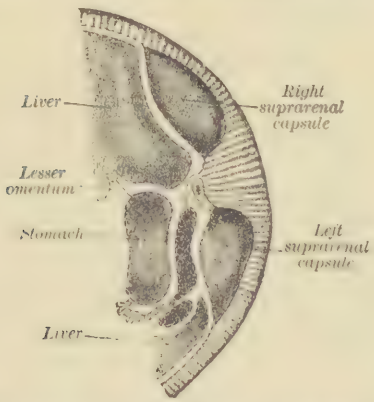

Fig. 839.—Schematic and enlarged cross-section through the body of a human embryo in the region of the mesogastrium. Beginning of third month. (Toldt.)

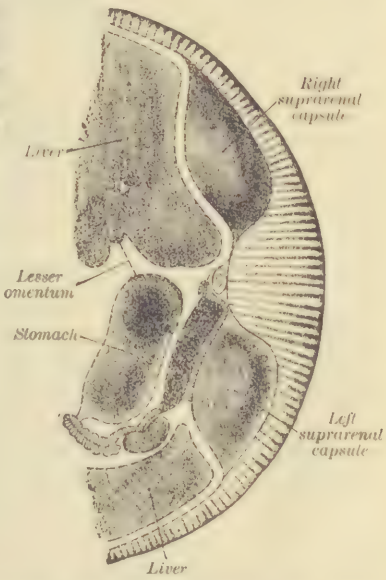

Fig. 840.—Same section as in Fig. 661 at end of third month. (Toldt.)

the two blend, and hence the great omentum appears as if attached to the transverse colon (Figs. 845, 846, and 847). The mesentery of the duodenum, in which

the rudiment of the pancreas is enclosed, disappears, and so this part of the gut becomes fixed to the posterior abdominal wall, and the pancreas lies entirely behind the peritoneal membrane. The mesenteries of the ascending and descend-

ing parts of the colon disappear in the majority of cases, while that of the small intestine assumes the oblique attachment characteristic of its adult condition.

The small omentum is formed by a thinning of the mesoblast or **anterior primitive mesentery**, which attaches the lesser curvature of the stomach to the anterior abdominal wall. By the subsequent growth of the liver this leaf of mesoblast is

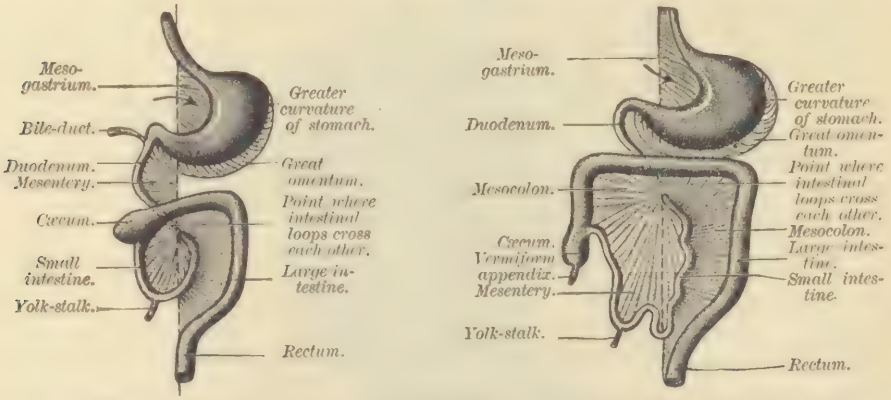

FIG. 842.—Illustrating two stages in the development of the human alimentary canal and its mesentery. The arrow indicates the entrance to the bursa omentalis.

divided into two parts—viz., the **small omentum** between the stomach and liver, and the **falciform ligament** between the liver and the abdominal wall and Diaphragm (Fig. 844).

The anus is developed as a slight invagination of the epiblast a short distance in front of the posterior end of the hind-gut. This invagination is termed the **proctodaeum**, the mesoblast between it and the hypoblastic lining of the hind-gut is thinned, and ultimately the septum breaks down and disappears, and the hind-gut opens on the surface; into this part of the hind-gut the urinary and generative organs open for a time, and so constitutes a **common cloaca**. The small portion of the hind-gut behind the orifice of the anus is named the **caudal** or **post-anal gut**; it communicates with the neural tube by means of a canal, the **neurenteric canal**, already referred to. Ultimately the post-anal gut becomes obliterated, and it, together with the neurenteric canal, finally disappears.

The **peritoneal cavity** is the space left between the visceral and parietal layers of the mesoblast, and the serous membrane is develped from these layers.

The **tongue** originates from the floor of the pharynx. The anterior or papillary portion first appears as a rounded elevation, the **tuberculum impar**, between the ventral ends of the mandibular and hyoid arches (Fig. 848). Between the third and fourth arches a second larger elevation arises, in the centre of which is a median groove or furrow. This second elevation is termed the **furcula**, and from it the epiglottis is developed, while the median furrow becomes the entrance to the larynx (Fig. 849). The tuberculum impar and the furcula are at first in apposition, but are soon separated by a ridge produced by the forward growth of the second and third arches. This ridge gives rise to the posterior part of the tongue and extends forward in the form of a V, so as to embrace between its two limbs the tuberculum impar. At the apex of the V there is a pit-like invagination to form the middle thyroid rudiment, and this depression persists as the foramen caecum of the adult. The union of the two parts of the tongue is indicated even in the adult by a V-shaped depression, the apex of which is at the

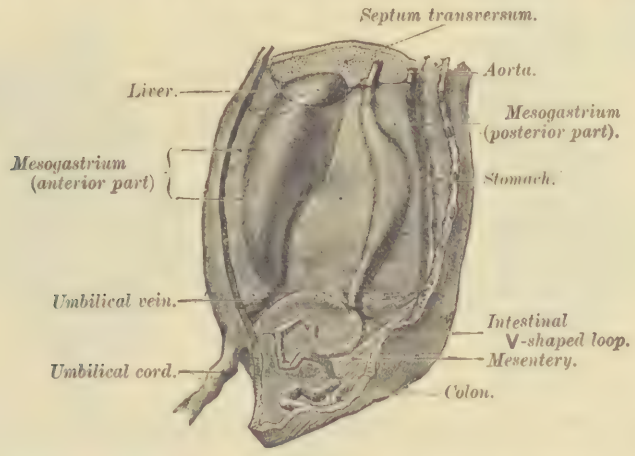

Fig. 844.—The primitive mesentery of a six weeks' human embryo, half schematic. (Kollmann.)

foramen caecum, while the two limbs run outward and forward parallel to but a little behind the circumvallate papillae, which are therefore developed from

the tuberculum impar (Figs. 848, 849, and 850). The **tonsils** are developed from the second branchial cleft, and make their appearance between the fourth and fifth months.

The **liver** arises in the form of two diverticula or hollow outgrowths from the ventral surface of that portion of the fore-gut which afterward becomes the

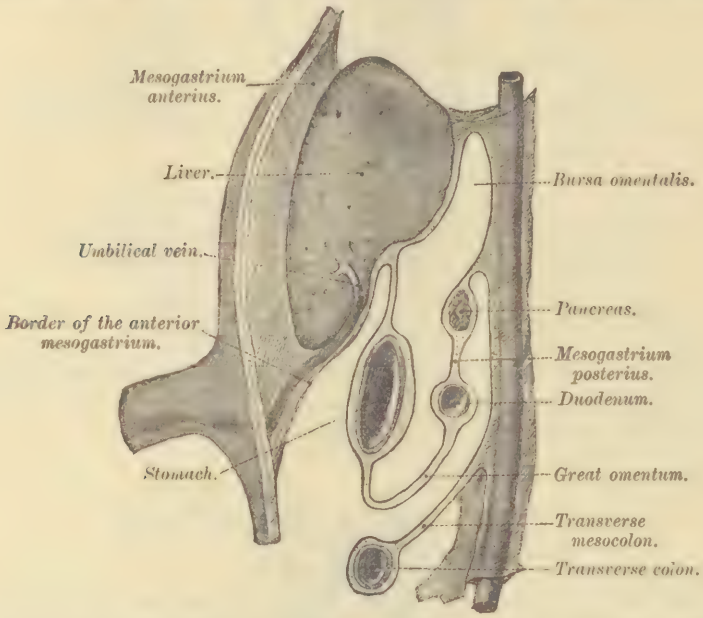

FIG. 845.—Schematic figure of the bursa omentalis etc Human embryo of eight weeks. (Kollmann.)

duodenum (Figs. 836 and 837). The outgrowths, which represent the right and the left lobes, respectively, of the adult liver, give off solid buds of cells, which grow into columns or cylinders; these unite with one another in every direction to form a close network, in the meshes of which are contained the capillary blood-vessels.

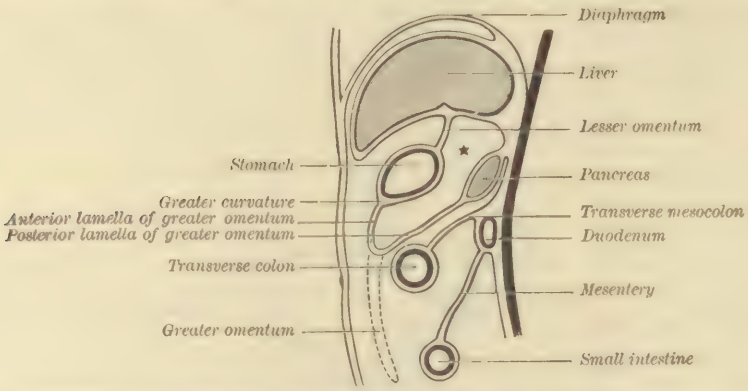

FIG. 846.—Illustrating the development of the bursa omentalis, cavity of the great omentum or lesser sac. Fœtal stage. * Lesser sac. (Hertwig.)

Some of these columns become hollowed out and form the bile-ducts, while the remainder constitute the secreting structure. The minute ducts thus produced unite to form the right and left hepatic ducts; while the common bile-duct is developed as a protrusion from the duodenal wall, and as it grows the liver becomes shifted away from the duodenum. The gall-bladder and cystic duct are formed by

a hollow evagination from the wall of the common bile-duct. About the third month the liver almost fills the abdominal cavity. From this period the relative

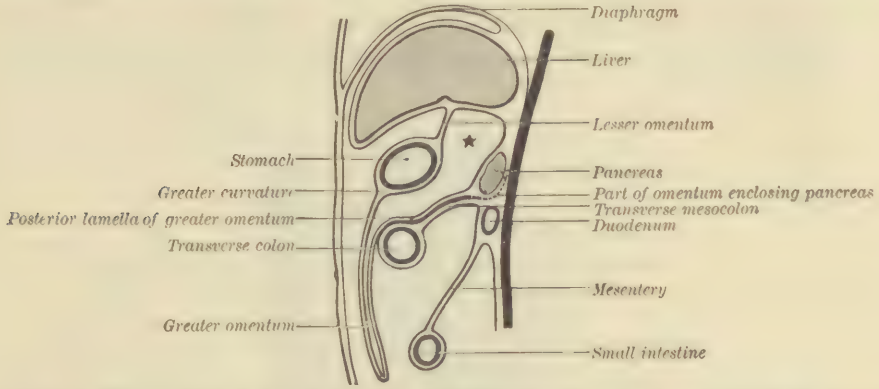

FIG. 847.—Development of bursa omentalis. Infantile stage. Great omentum covers the intestines and has fused with the transverse mesocolon. Pancreas is free from peritoneum posteriorly. (Hertwig.)

development of the liver is less active, more especially that of the left lobe, which now becomes smaller than the right; but up to the end of fœtal life the liver remains relatively larger than in the adult.

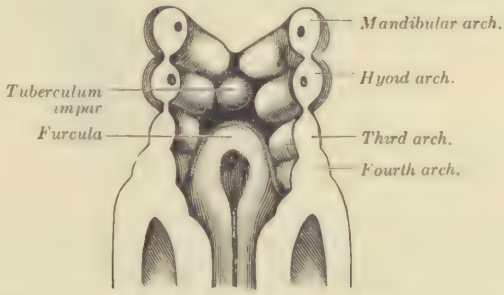

FIG. 848.—The floor of the pharynx of a human embryo about fifteen days old. × 50. (From His.)

The **pancreas** is also an early formation, being far advanced in the second month. It originates as a hollow projection from the hypoblast of the dorsal wall of the duodenum (Figs. 837 and 838), opposite the hepatic diverticula, which, as

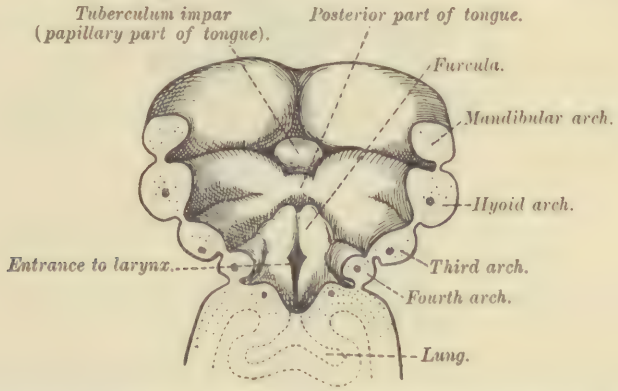

FIG. 849.—The floor of the pharynx of a human embryo about twenty-three days old. × 30. (From His.)

we have already seen, spring from its ventral wall. This hollow process grows between the two layers of the dorsal mesentery and sends out offshoots, which

branch abundantly and form a complicated tubular gland. As torsion of the stomach takes place, the pancreas assumes a transverse position and becomes fixed across the dorsal wall of the abdomen, the posterior layer of its mesentery undergoing absorption. Its duct ultimately opens into the duodenum together with the common bile-duct.

The **spleen**, on the other hand, is of mesoblastic origin, for there is never any connection between the intestinal cavity and the substance of this organ. It originates in the mesenteric fold which connects the stomach to the vertebral column (mesogastrium) (Fig. 841).

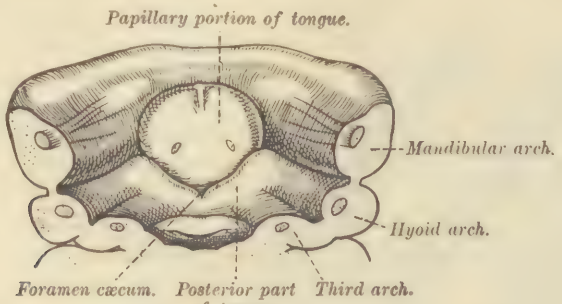

FIG. 850.—Floor of mouth of an embryo slightly older than that shown in Fig. 849. × 16. (From His.)

THE PERITONEUM (TUNICA SEROSA).

During life and in the uncut corpse the peritoneal cavity (*cavum peritonaei*) is air-tight. It is not a real cavity, as muscular tension and atmospheric pressure permit no vacant space to form. When the surgeon or anatomist opens the abdomen, the peritoneal cavity is at that moment produced.

The peritoneum (from *περι*, *about*, and *τειφω*, *I stretch*) is the largest serous membrane in the body, and consists, in the male, of a closed sac, a part of which is applied against the abdominal parietes, while the remainder is reflected over the contained viscera. In the female the peritoneum is not a closed sac, since the free extremities of the Fallopian tubes open directly into the peritoneal cavity. The portion of the peritoneum applied against the abdominal parietes constitutes the **parietal peritoneum**; the portion reflected over the viscera, the **visceral peritoneum**. The *free surface* of the membrane is smooth, covered by a layer of flattened endothelium, and lubricated by a small cavity of serous fluid. Hence the viscera can glide freely against the wall of the cavity or upon one another with the least possible amount of friction. Its *attached surface* is rough, being connected to the viscera and inner surface of the parietes by means of areolar tissue termed the **subserous areolar tissue** (*tela subserosa*). The parietal portion is loosely connected with the fascia lining the abdomen and pelvis, but more closely to the under surface of the Diaphragm and also in the middle line of the abdomen.

The peritoneum differs from the other serous membranes of the body in presenting a much more complex arrangement—an arrangement which can only be clearly understood by following the changes which take place in the alimentary canal during its development; and therefore the student is advised to preface his study of the peritoneum by reviewing the remarks on Embryology.

Structure of the Peritoneum.—It is a thin, glistening serous membrane and consists of a connective-tissue layer and one layer of flat endothelial cells upon the free surface of the membrane. The connective-tissue layer consists of bundles of connective tissue which contain many connective-tissue cells and elastic fibres. It contains a multitude of lymph-spaces, lymph-vessels, and lymph-capillaries.

Beneath the peritoneum is a layer of lax and spongy connective tissue which serves to bind the serous membrane to parts beneath. This layer is called the **subserous connective tissue.** In some regions it is plentiful; in others, as over the liver and intestine, it is very scantily developed. The endothelial cells are flat and polygonal. Some hold that they are joined together by cement-substance. Byron Robinson asserts that there is no cement-substance, but rather an organized connection between the protoplasmic processes of adjacent cells.

On the surface of the endothelium between the cells numerous apertures or interruptions are to be seen. Some of these, the **stomata,** are surrounded by a ring of cubical endothelium (Fig. 851), and communicate with lymphatic capillaries; others, the **stigmata** or **pseudostomata,** are mere interruptions in the endothelial layer, and are occupied by processes of the branched connective-tissue corpuscle of the subjacent tissue. Stomata are particularly numerous in the region of the Diaphragm and are relatively scanty in the region of the pelvis.

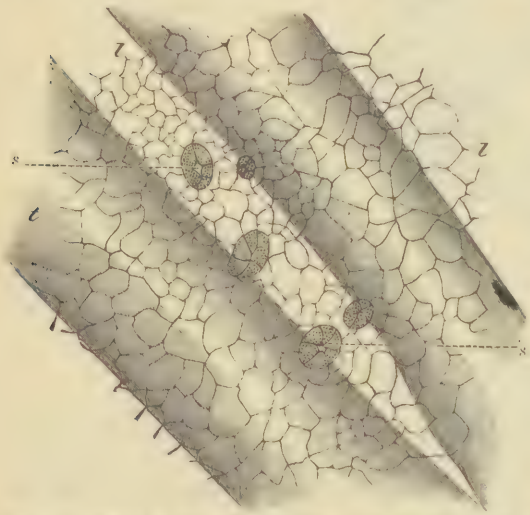

FIG. 851.—Part of peritoneal surface of the central tendon of Diaphragm of rabbit, prepared with nitrate of silver. *s.* Stomata. *l.* Lymph-channels. *t.* Tendon-bundles. The stomata are surrounded by germinating endothelial cells. (From Handbook for the Physiological Laboratory, Klein.)

The amount of fluid contained in the closed sac is, in most cases, only sufficient to moisten the surface, but not to furnish any appreciable quantity of liquid. When a small quantity can be collected, it is found to resemble lymph, and, like that fluid, coagulates spontaneously; but when secreted in large quantities, as in dropsy, it is a more watery fluid, but still contains a considerable amount of proteid which is coagulated on boiling.

The peritoneum is a **lymph-sac** and its walls contain a great quantity of lymphatic structures. In the subserous tissue the numerous lymph-spaces obtain fluid from the peritoneal cavity by way of the stomata of the endothelial coat, and from these lymph-spaces lymph-vessels take origin. Byron Robinson points out that the lymphatic system of the peritoneum consists of: 1. Interstitial lymph-spaces. 2. Non-valved capillaries. 3. Valved lymphatic channels. The subendothelial interstitial lymph-spaces intercommunicate and can take up an immense quantity of fluid from the peritoneal cavity. Normally the spaces contain both nutrient material and waste products. Through these spaces blood capillaries pass, and from these spaces lymph-capillaries come. Lymphatics are particularly plentiful in—1, the tendinous portion of the Diaphragm; 2, the ligamenta lata; 3, the omentum; 4, the ventral surface of the small intestine; 5, the liver and spleen.[1]

The lymph from this region reaches the mediastinal or diaphragmatic glands. The serous surface of the Diaphragm is the region chiefly efficient in absorption from the peritoneum, and there is a current in the peritoneal cavity directed toward the Diaphragm.[2] Absorption is very rapid from the peritoneal cavity. Fluid equalling from 3 to 8 per cent. of the body-weight can be absorbed in one hour. There are a multitude of nerves in the peritoneum, and it seems probable that each endothelial

[1] The Peritoneum. By Byron Robinson. [2] Ibid.

cell receives a nerve ending. The minute arteries of the peritoneum are surrounded by nerve-plexuses. According to Byron Robinson,[1] the nerves of the peritoneum are: 1. Medullated. 2. Non-medullated. 3. Fibres of Remak. 4. The Vater-Pacinian corpuscles and other varieties of nerve endings. 5. Nerve-cells. The visceral peritoneum contains many more nerves than the parietal peritoneum.

The **parietal peritoneum** (*peritonæum parietale*) lines the wall of the abdominal cavity. The **visceral peritoneum** (*peritonæum viscerale*) covers the viscera. Back of the parietal peritoneum is a space, the **retro-peritoneal space** (*spatium retro-peritonæale*), which contains the great vessels and nerves, the suprarenal capsules, the kidney, and ureters (Figs. 853, 854, 855, 856, and 857).

We describe the peritoneum as consisting of two sacs, a **greater sac** and a **lesser sac** (Fig. 853). The larger part of the abdominal cavity is lined by the greater sac, as most of the viscera are covered by it. The lesser sac is placed largely behind the stomach. These two sacs are not two distinct cavities which communicate. They constitute one cavity, a portion of which has been formed into a diverticulum or recess by a process of constriction, the result of changes produced in the position of adjacent viscera by development. Prof. Birmingham says: "If the great sac be compared to a bag, the lesser sac might be represented as a pocket lying behind, and opening into it by a narrow orifice, the **foramen of Winslow**, on its posterior wall."[2] The greater sac lines the walls of the abdominal cavity and covers the viscera which are invested by peritoneum, except the posterior portion of the stomach, the suprarenal capsule of the left side, the superior surface of the pancreas, the Spigelian lobe and the caudate lobes of the liver, and portions of the spleen, left kidney, and transverse colon, which are covered by peritoneum of the lesser sac.[3]

To trace the continuity of the membrane from one viscus to another, and from the viscera to the parietes, it is necessary to follow its reflections in the vertical and horizontal directions, and in doing so it matters little where a start is made.

If the stomach is drawn downward, a fold of peritoneum will be seen stretching from its lesser curvature to the transverse fissure of the liver (Figs. 853 and 859). This is the **gastro-hepatic** or **lesser omentum** (*omentum minus*), and consists of two layers; these, on being traced downward, split to envelop the stomach, covering respectively its anterior and posterior surfaces. At the greater curvature of the stomach they again come into contact and are continued downward in front of the transverse colon, forming the anterior two layers of the **great** or **gastro-colic omentum** (*omentum majus*) (Figs. 853 and 861). Reaching the free edge of this fold they are reflected upward as its two posterior layers, and thus the great omentum consists of four layers of peritoneum. Followed upward the two posterior layers separate so as to enclose the transverse colon, above which they once more come into contact and pass backward to the abdominal wall as the **transverse mesocolon** (*mesocolon transversum*) (Fig. 853). Reaching the abdominal wall about the level of the transverse part of the duodenum, the two layers of the transverse mesocolon become separated from each other and take different directions; the upper or anterior layer, known as the **ascending layer of the transverse mesocolon**, ascends in front of the pancreas, and its further course will be followed presently (Fig. 853). The lower or posterior layer is carried downward, as the anterior layer of the mesentery, by the superior mesenteric vessels to the small intestine, around which it may be followed and subsequently traced upward as the posterior layer of the mesentery to the abdominal wall. From the posterior abdominal wall it sweeps downward over the aorta into the pelvis, where it invests the first part of the rectum and attaches it to the front of the sacrum by a fold termed the **mesorectum** (Fig. 863, p. 1259). Leaving first the sides and then the front of the second part of the rectum it is reflected on to the back of the bladder, and, after covering the posterior and

[1] The Peritoneum. By Byron Robinson. [2] Prof. Cunningham's Text-book of Human Anatomy.
[3] Ibid.

upper aspects of this viscus, is carried by the **urachus** and **obliterated hypogastric arteries** as folds, on to the posterior surface of the anterior abdominal wall (Fig. 852). The fold upon the urachus is the **plica urachi** (*plica umbilicalis media*); the fold on each obliterated hypogastric artery is the **plica hypogastrica** (*plica umbilicalis lateralis*). Between the rectum and bladder it forms a pouch, the **recto-vesical pouch** (*excavatio rectovesicalis*), bounded on the sides by two crescentic or semilunar folds (*plicae rectovesicales*), which pass from the posterior surface of the bladder to the sides of the rectum; the bottom of this pouch is about on a level with the middle of the vesiculae seminales—*i. e.*, three inches or so from the orifice of the anus. When the bladder is distended the peritoneum is carried up with the expanded viscus, so that a considerable part of the anterior surface of the latter lies directly against the abdominal wall without the intervention of the peritoneal membrane. When the bladder is empty the peritoneum forms a transverse fold over its upper surface (*plica vesicalis transversa*).

In the female the peritoneum is reflected from the rectum on to the upper part of the posterior vaginal wall, forming the **recto-vaginal pouch** or **pouch of Douglas** (*excavatio rectouterina*) (Fig. 853). In the pouch of Douglas are two folds of peritoneum (*plica rectouterinae*), which begin at the posterior surface of the cervix, extend back to the sides of the rectum, and bound above the deepest portion of the pouch. The pouch is then carried over the posterior aspect and fundus of the uterus on to its anterior surface, which it covers as far as the junction of the body and cervix uteri, forming here a second but shallower depression, the **utero-vesical pouch** (*excavatio vesicouterina*). It is also reflected from the sides of the uterus to the lateral wall of the pelvis on each side as an expanded fold, the **broad ligament of the uterus** (*ligamenum latum uteri*), in the free margin of each broad ligament can be felt a thickened cord-like structure, the **Fallopian tube** (*tuba uterina* [*Fallopii*]).

When the peritoneum lining the anterior abdominal wall is examined from behind, it is noticed that certain structures which lie in front of it form five peritoneal ridges (Fig. 852). The structure in the middle line is the **urachus,** which is the remains of the fœtal allantois. In the adult it is a fibrous cord which passes from the umbilicus to the summit of the bladder. This cord is slender above, but broader below. External to the urachus are the fibrous cords which resulted from obliteration of the **hypogastric arteries** (*arteriae umbilicales*). These cords become more slender as they ascend toward the sides of the urachus and pass to the umbilicus. More external still are the folds formed by the *deep epigastric arteries*. The fold over each epigastric artery is the **plica epigastrica**; the fold over each obliterated hypogastric artery is the **plica umbilicalis lateralis**; the fold over the obliterated urachus is the **plica umbilicalis media.**

The five peritoneal ridges formed by the above-named structures create three peritoneal fossae on each side, called the **inguinal fossae** or **pouches** (*fovea inguinales*). The **external inguinal fossa** (*fovea inguinalis lateralis*) is external to the deep epigastric artery and corresponds to the internal abdominal ring. There is a funnel-shaped depression in its floor marking the point at which the inguinal process passed down. This depression, if marked, predisposes to oblique inguinal hernia. The **middle inguinal fossa** (*fovea inguinalis medialis*) is placed between the deep epigastric arteries and the obliterated hypogastric vessels. The **internal inguinal fossa** or the **supravesical fossa** (*fovea supravesicalis*) is between the obliterated hypogastric artery and the urachus. Just beneath the inner termination of Poupart's ligament there is another fossa, the **femoral** or **crural fossa** (*fovea femoralis*), which corresponds to the situation of the femoral ring. The obliterated hypogastric artery is to the inner side of this fossa.

On following the parietal peritoneum upward on the back of the anterior abdominal wall it is seen to be reflected around a fibrous band, the **ligamentum teres** or **obliterated umbilical vein** (Figs. 855, 856, and 857), which reaches from the

umbilicus to the under surface of the liver. Here the membrane forms a somewhat triangular fold, the **falciform** or **suspensory ligament of the liver** (*ligamentum falciforme hepatis*), which attaches the upper and anterior surfaces of that organ to the Diaphragm and abdominal wall. With the exception of the line of attachment of this ligament the peritoneum covers the under surface of the anterior part of the Diaphragm and is reflected from it on to the upper surface of the liver as the **anterior** or **superior layer of the coronary ligament** (*ligamentum coronarium hepatis anterior*). Covering the upper and anterior surfaces of the liver it is reflected around its sharp margin on to its under surface as far as the **transverse fissure**, where it is continuous

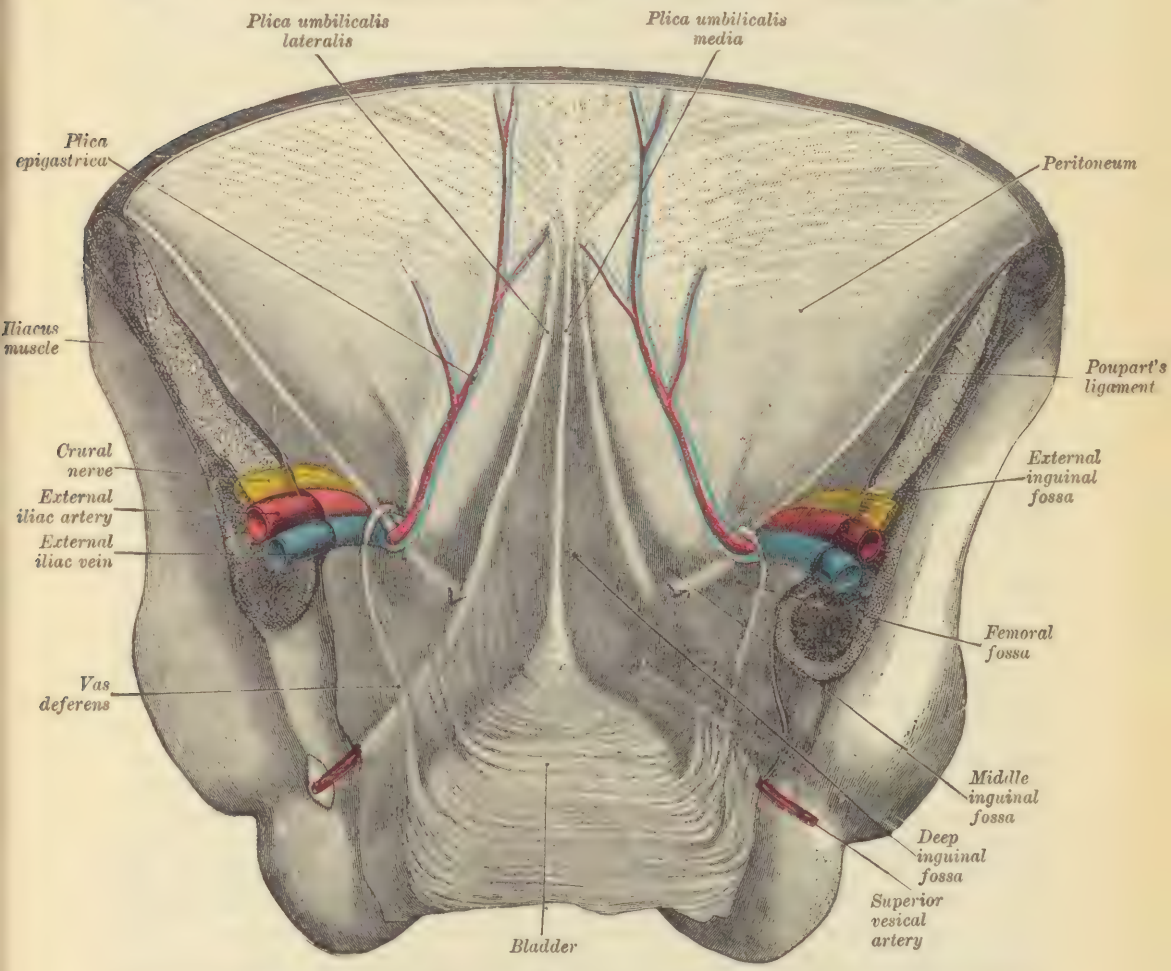

FIG. 852.—Posterior view of the abdominal wall in its lower half. The peritoneum is in place and the various cords are shining through. (Joessel.)

with the anterior layer of the small omentum from which a start was made (Fig. 853). The posterior layer of this omentum is carried backward from the transverse fissure over the under surface and Spigelian lobe of the liver, and is then reflected, as the **posterior** or **inferior layer of the coronary ligament** (*ligamentum coronarium hepatis posterior*), on to the Diaphragm and is prolonged downward over the pancreas to become continuous with the ascending layer of the transverse mesocolon (Fig. 853). Between the two layers of the coronary ligament there is a triangular surface of the liver which is devoid of peritoneum; it is named the **bare area of the liver**, and is attached to the Diaphragm by connective tissue. If, however, the two layers of the

coronary ligaments are traced toward the right and left margins of the liver, they approach each other, and, ultimately fusing, they form the **right** and **left lateral ligaments of the liver** and attach its right and left lobes respectively to the Diaphragm.

If the small omentum is followed toward the right side it is seen to form a distinct free edge around which its anterior and posterior layers are continuous with each other and between which are situated the portal vein, hepatic artery, and bile-duct. If the finger is introduced behind this free edge, it passes through a somewhat constricted ring, the **foramen of Winslow** (*foramen epiploicum* [*Winslowi*]) (Figs. 853, 855, and 858). This is the communication between what are termed the **greater** and **lesser sacs** of the peritoneum and has the following boundaries: in *front*, the free edge of the gastro-hepatic omentum. This free edge is called the **ligamentum hepatoduodenale**. The gastro-hepatic omentum has the portal vein, hepatic artery, and bile-duct between its two layers (Fig. 859); *behind* the foramen of Winslow is the vena cava inferior; *above*, are the Spigelian and caudate lobes of the liver; *below*, the duodenum and the hepatic artery, as the latter passes forward and upward from the cœliac axis.

The **lesser peritoneal cavity** or the **lesser sac of the peritoneum** (*bursa omentalis*) (Figs. 853, 855, and 858), therefore, lies behind the small omentum and has the following dimensions: *above*, it is limited by the portion of the liver which lies behind the transverse fissure; *below*, it extends downward into the great omentum, reaching, in the fœtus, as far as its free edge (Fig. 846); in the adult, however, its vertical extent is limited by adhesions between the layers of the omentum. In *front*, it is bounded by the small omentum, stomach, and anterior two layers of the great omentum; *behind*, by the two posterior layers of the great omentum, the transverse colon, and ascending layer of the transverse mesocolon which passes upward in front of the pancreas as far as the posterior surface of the liver. Laterally the lesser sac reaches from the foramen of Winslow on the right side as far as the spleen on the left (*recessus lienalis*) (Fig. 860), where it is limited by the **lieno-renal ligament**. The extent of the lesser sac and its relations to surrounding parts can be definitely made out by tearing through the small omentum and inserting the hand through the opening thus made. A passage (*vestibulum bursae omentalis*) leads out from the foramen of Winslow over the head of the pancreas to the left as far as the **median vascular gastro-pancreatic fold** (*plica gastropancreatica*) (Fig. 858). This fold carries the gastric artery and the coronary vein. From the vestibule there is a narrow and upward prolongation behind the lesser omentum and caudate lobe of the liver and in front of the lumbar portion of the Diaphragm. This prolongation is the **superior omental recess** (*recessus superior omentalis*). The chief part of the lesser peritoneal cavity extends downward from the gastro-pancreatic fold and is called the **inferior omental recess** (*recessus omentalis inferior*). The constriction which separates the two recesses is due to the passage around the lesser sac and to the front of the gastric and hepatic arteries. "The former winds around its left side, the latter around its right, and each raises up a fold of peritoneum which projects strongly into the sac and partially divides it into two."[1] A small projection of the lesser sac passes to the right side behind the beginning of the duodenum. The splenic artery in its course to the spleen lies back of the posterior layer of the lesser sac.

It should be stated that during a considerable part of fœtal life the transverse colon is suspended from the posterior abdominal wall by a mesentery of its own—the two posterior layers of the great omentum passing, at this stage, in front of and above the colon (Fig. 846). This condition sometimes persists throughout adult life, but as a rule adhesion occurs between the mesentery of the transverse colon

[1] Prof. Cunningham's Text-book of Human Anatomy.

and the posterior layer of the great omentum, with the result that the colon appears to receive its peritoneal covering by the splitting of the two posterior layers of the latter fold.

In addition to tracing the peritoneum vertically, it is necessary to trace it **horizontally** (Figs. 854, 855, 856, and 857). If this is done below the transverse colon, the circle is extremely simple, as it includes only the greater sac of the peritoneum (Fig. 854). Above the level of the transverse colon the arrangement is more complicated, on account of the existence of the two sacs.

Starting from the linea alba, below the level of the transverse colon, and tracing the continuity in a horizontal direction to the right, the peritoneum covers the internal surface of the abdominal wall almost as far as the anterior border of the Quadratus lumborum muscle; it encloses the caecum, and is reflected over the

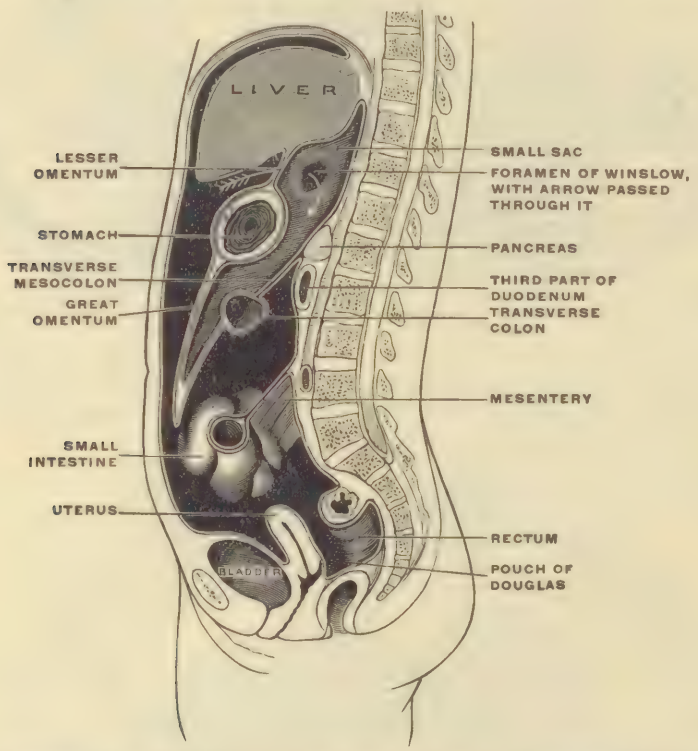

FIG. 853.—Diagrammatic mesial section of the female body, to show the peritoneum on vertical tracing. The great sac of the peritoneum is black and is represented as being much larger than in nature; the small sac is very darkly shaded; the peritoneum on section is shown as a white line, and a white arrow is passed through the foramen of Winslow from the great into the small sac. (Cunningham.)

sides and anterior surface of the ascending colon, fixing it to the abdominal wall, from which it can be traced over the kidney to the front of the bodies of the vertebrae. It then passes along the mesenteric vessels to invest the small intestine, and back again to the spine, forming the **mesentery**, between the layers of which are contained the mesenteric blood-vessels, nerves, lacteals, and glands. Lastly, it passes over the left kidney to the sides and anterior surface of the descending colon, and, reaching the abdominal wall, is continued along it to the middle line of the abdomen.

Above the transverse colon (Fig. 855) the peritoneum can be traced, forming the greater and lesser cavities, and their communication through the foramen of Winslow can be demonstrated. Commencing in the middle line of the abdomen, the membrane may be traced lining its anterior wall, and sending a process back-

ward to encircle the obliterated umbilical vein (the round ligament of the liver), forming the falciform or longitudinal ligament of the liver. Continuing its course

to the right, it is reflected over the front of the upper part of the right kidney, across the vena cava inferior and aorta, and over the left kidney to the hilum of

the spleen, forming the anterior layer of the **lieno-renal ligament,** the posterior layer being formed by the termination of the *cul-de-sac* of the greater cavity

between the kidney and spleen. From the hilum of the spleen it is reflected to the stomach, forming the posterior layer of the **gastro-splenic omentum** (*ligamentum*
